by louse-infection. If such an occurrence takes place in connection with fevers of the typhus group, it must be rare, as it is extremely unusual for two cases of sporadic typhus-like fever to occur in persons who have been in contact with each other; the rare occurrences of this kind may usually be explained by coincidence or by the existence of specially intense endemic conditions.

SUMMARY AND CONCLUSIONS.

There are certain fevers whose clinical manifestations and pathology point to their belonging to the same group, the "typhus group of fevers."

One of these which is called typhus or typhus exanthematicus is known to be conveyed by lice, and therefore it may be called louse-typhus. Another—the Rocky Mountain fever—may be called tick-typhus, and the third—tsutsugamushi disease—can appropriately be called mite-typhus. There are other examples of tick-borne and mite-borne typhus to which the names Rocky Mountain fever and Japanese river fever are obviously inapplicable, hence the necessity for devising names of universal applicability.

There are many places in which sporadic typhus-like fever of unknown vector occurs: in the present state of our knowledge it is most suitable to designate these as "typhus-group fevers."

Most of these cases occur under conditions which suggest that an arthropod of the wilds conveys the infection from a rodent reservoir, and therefore it is desirable that they should be investigated with special reference to ticks, mites and other possible arthropods.

So far as India is concerned all the available evidence points rather strongly to a tick as the vector, but it is desirable that further study of all the available evidence should be made and that medical men should investigate all cases of typhus-like fever with special reference to the vector concerned. When a tick is found in situ in a patient suffering from fever it ought to be sent to the Calcutta School of Tropical Medicine, alive if possible, otherwise preserved in 70 per cent. alcohol. It is desirable that all ticks which are found biting human beings should be preserved and identified.

The possibility of a typhus virus being conveyed by two alternative arthropods, especially the louse and the tick ought to be further investigated.

SEVENTEEN CASES OF SCARLET FEVER.*

By P. SAVAGE,

MAJOR, I.M.S.,

Resident Medical Officer, The Lawrence Royal Military School, Sanawar.

IN marked contrast to measles, "which is common all over the tropical East and especially in India" (Rogers), the occurrence of scarlet fever in India should excite some clinical interest.

This is the necessity for recording these notes of seventeen cases occurring in a large boarding school.

A limited epidemic of scarlet fever occurred in this School in the months of October, November and December of 1927.

The total number of cases observed during this period was seventeen, all from the Boys' School, the ages ranging from 7½ years to 17½. The disease was ushered in with the usual clinical symptoms of vomiting, sore throat and fever, followed by a rash in 24 hours. Only one case, the first to occur, gave a definite history of vomiting, indeed it was for this symptom alone that he was sent to hospital. (It is interesting to note here that vomiting in children should always excite a suspicion of the possibility of one of the exanthemata. This boy, for this symptom alone, was isolated and was found next morning to have a rash.)

All the patients complained of sore throat and examination revealed either patches on the tonsils or a dusky redness of the tonsils and pharynx.

* This article is published by the kind permission of the Director of Medical Services in India.

Every case had pyrexia of varying intensity.

The mildest case was 100° and a few reached 104°.

The distribution of the rash was chiefly on the trunk, at first being confined to the chest.

In mild cases the rash was extremely faint but gave a definite punctate sense to the touch.

Filatow's sign of circumoral pallor was typically seen in two cases. In one case the distribution of the rash was peculiar, being only visible and very intense in the axilla, subcostal area and the abdomino-femoral triangle on both sides of the body.

As commonly described, the duration of the rash in different cases varied, from a fleeting rash lasting only a few hours, to one lasting a week.

Palpable occipital glands and submaxillary glands were felt in all, except two cases who were not detected in the early stages and were admitted to hospital later on account of scaling of the trunk of hands.

The typical scarletinal tongue resembling "strawberries and cream" was satisfactorily observed in only one case, while another in the second week showed a typical "raspberry" tongue.

A degree of desquamation ranging from a fine powdering to large flakes of epidermis was constantly found in every case.

Under a hand lens, this scaling differed from the scaly appearance often found on the skin of children, (not naturally addicted to the excessive use of soap and water) in that it was in the form of small rings and was present even after a thorough wash.

In two boys the rash and sore throat were so transient as to have escaped notice entirely, and they were admitted to hospital later for desquamation and a temperature.

All these seventeen cases were classified as simple scarlet fever (*scarletina simplex*) as in none of them were the symptoms unduly aggravated.

Indeed, the epidemic was of a mild nature, and only one case presented the typical textbook appearance and course of scarlet fever.

Four of the seventeen boys developed *nephritis*. They were all four mild cases who had not been detected in the early stage and had escaped hospital treatment.

The first of these boys was admitted with desquamation on the trunk.

Two days later he developed mild uræmic symptoms, viz., headache, vomiting and twitching of the muscles of the face and limbs.

The urine was reduced in quantity, of high specific gravity (1020), with a pink tinge and contained albumen.

The second boy had a mild form of the disease, but a puffy appearance under the

eyes during convalescence directed attention to the urine which was found to be acid, specific gravity 1028, and to contain albumen.

The third boy presented signs similar to the second boy. The fourth boy had only a trace of albumen for three days. This was discovered during the daily urine tests.

In none of these cases did the albuminometer register more than one part of albumen in a thousand.

In testing the urine for albumen, attention to one point is essential. The urine must be filtered to render it quite clear. The cloudy ring with cold nitric acid is then very distinct. In scarlet fever (as in all pyrexial states) the urine is invariably turbid, and the turbidity must be got rid of by filtering or some other method.

Otherwise, a hazy appearance on boiling or on the addition of the urine to cold nitric acid is apt to lead to the erroneous conclusion that a trace of albumen is present.

The patient may, consequently, be confined to bed and a restricted diet, longer than is necessary.

(Testing for albumen with a solution of salicyl-sulphonic acid is said to be a more delicate test. It did not appear to be so with the cases in which it was used.)

Three boys developed a *secondary adenitis of the submaxillary glands* during the third week. This did not go on to suppuration. No case of *otitis* occurred.

One boy, at the end of the first week had *herpes on the lips* and a *small patch of solid lung* at the right base which very rapidly resolved.

The diagnosis of mild and atypical cases of the exanthemata can be extraordinarily difficult, especially the first few cases met with, and the only way to avoid the pitfalls is to bear them all in mind.

Toxic erythema due to intestinal absorption, common in children, is not accompanied by fever or pharyngeal congestion.

In erythema scarlatiniforme there is little or no constitutional disturbance, and sore throat and enlarged submaxillary glands are not found. There is also an absence of eosinophilia.

The catarrhal signs in measles and rubella are usually distinct, and Koplik's spots may be present in the former disease.

A scarlatiniform rash occasionally occurs with acute tonsillitis, but does not go on to desquamation.

Confusion with diphtheria should be avoided, as in all severe tonsillar inflammations one is usually tempted to examine or send to a laboratory a swab from the throat.

The "fourth disease," described by Filatow and Dukes, and said to resemble a mild course of scarlet fever, probably does not exist.

(In looking up previous records of the occurrence of scarlet fever or any of the

exanthemata resembling scarlet fever in this School, I find that several cases have been recorded during a short period in 1919 as the "fourth disease.")

In doubtful epidemics the later occurrence of nephritis in some of the cases of course confirms any pre-existing suspicions.

The Dick test for scarlet fever can always be done, as it is as well established as the Schick test in diphtheria.

These series of seventeen cases confirms several known facts regarding scarlet fever in India.

Its rare occurrence in epidemic form has been noted, although I believe that sporadic cases do occur.

It would be interesting to know if nephritis in children in India, in the large cities, is uncommon, and whether it is traceable to mild scarlet fever.

In this series only three of the boys of the seventeen affected were of mixed parentage and all three were missed in the stage when the rash, however slight, must have been present.

Has scarlet fever any selective action on race?

In South Africa the natives practically never get it.

The disease amongst the Europeans is milder and invariably occurs in the cold weather. This statement might equally well apply to this country.

Scarlet fever when it occurs in this country is usually of a mild nature and shows no tendency to spread rapidly.

In this epidemic only seventeen cases occurred in a school of over five hundred children.

Of course, precautions to control the spread of the disease to the Girls' School and Preparatory School were in force, but I have never met with other outbreaks of infectious disease in this School, which in spite of similar rigid precautions were so easily controlled. One of the methods of control employed was a subcutaneous injection of Concentrated Scarlet Fever Antitoxin (B. W. & Co.) to contacts. Thirty-seven were thus inoculated, including members of the hospital staff attending the isolation ward. Doses of 3 c.c. to 5 c.c., depending on the age, were given.

The passive immunity conferred is not very long, perhaps up to a fortnight. None of those inoculated developed scarlet fever, but this does not prove that any real immunity was conferred.

Swabs from the throat of several of the cases were examined and a non-hæmolytic streptococcus was isolated.

Dick 'positive and negative reactors' were not sought for amongst the children, as the Dick reagents, owing to climatic reasons, are not available in India.

In the four cases in which albumen occurred the onset was preceded by a day or two of fever. Since the re-opening of School thirteen of these boys have returned after two months' holiday and tests have shown them all to be free from albuminuria.

The treatment in scarlet fever does not call for any special remarks. In septic cases or where there is an anginoid condition of the throat the specific antitoxin should be given. In this series the antitoxin was available but its use was never indicated. Scarlet fever in this country then is seemingly so mild, that, even in the event of albuminuria supervening, there should be little hesitation in giving a good prognosis.

The laity are inclined to regard scarlet fever occurring in India as a grave disease, and its appearance in a school is likely to cause great apprehension to both parents and teachers.

School medical officers should be quick, therefore, to allay this anxiety, as in view of present knowledge, they can safely predict the mild course of the outbreak and in the event of unusually severe clinical symptoms have recourse to the specific antitoxin. The source of the infection could not be determined.

The possibility of the infection by milk was excluded, as no cases occurred in the Girls' School or the Preparatory School and all three schools have a common milk supply from the School Dairy.

THE WIDAL AGGLUTINATION REACTION IN HEALTHY PERSONS.

By A. N. BOSE,

MAJOR, I.M.S.,

Professor of Pathology,

and

S. K. GHOSH DASTIDAR, M.B., D.T.M. (Bengal).

(From the Department of Pathology, Prince of Wales Medical College, Patna.)

VARIOUS authors have referred to the relative immunity of the inhabitants of the tropics to the typho-coli group of organisms. This immunity, it has been argued, is due to infection in childhood or to repeated small inoculations with infected food and drinks at an early period of life. Many observations have been made on the persistence of agglutinins that develop in the blood after protective inoculations. According to Wade McDaniel 11.7 per cent. of cases give a positive Widal reaction after one year from the inoculation. But no Indian data are available regarding the presence of agglutinins in healthy individuals, or regarding the persistence of the agglutinins in the blood after an attack of enteric fever or dysentery.

Infections from the organisms of this group are quite common in Bihar. Both sexes and all ages are affected. It was of interest, therefore, to study the agglutinating property of the blood in apparently healthy Indians who had not been protected previously, especially in an area where the infections from the typho-coli group of organisms are so prevalent.

We selected 100 apparently healthy individuals from different classes, viz., 12 of them from the medical students who live in the college hostel in A, 42 from the professional class of people who live under ordinary sanitary conditions in B, and 46 from the poorer classes who usually work as servants and day labourers and live under questionable hygienic surroundings in C.

Dreyer's technique with Oxford standard agglutinable culture was employed for these tests. The standard technique does not give the serum reaction in dilutions 1:12.5 and 1:83, and for these titres we improvised a simple method; for the former the serum was diluted to 1:5 instead of 1:10 and 10 drops of it were put up with 15 drops of standard agglutinable culture; for the latter 3 drops of serum diluted to 1:10 were put up with 7 drops of saline and 15 drops of the standard culture added.

three between 2 and 3 units; of 3 cases with *Paratyphosus B* agglutinins one had between 4 and 5 and two between 2 and 3 units.

Reference to Table II shows that all cases with positive agglutinins, except one belonging to group B, occurred in the individuals of group C who usually live under unsatisfactory hygienic conditions.

We shall take up in our next paper the subject of the persistence of agglutinins in persons after a definite previous infection from one of the organisms of the typho-coli group.

CONCLUSIONS.

1. Healthy individuals belonging to the middle class in Bihar do not as a rule show any agglutinins of the typho-coli group.

2. The few individuals who do show their presence belong to the poorer classes who live under unsatisfactory hygienic conditions.

3. There is a remarkable absence of *B. dysenteriae* (Shiga and Flexner) agglutinins in all.

4. The comparative immunity to typho-coli organisms in persons living in tropical countries, referred to by so many observers, does not appear to be due to the presence of

TABLE I.
Agglutination Reaction expressed in Serum Dilutions.

Organism.	Negative.	+ $\frac{1}{12.5}$	+ $\frac{1}{25}$	+ $\frac{1}{50}$	+ $\frac{1}{83}$	+ $\frac{1}{125}$	Total.
<i>B. typhosus</i>	94	2	3	0	0	1	100
<i>B. paratyphosus A</i>	96	3	1	0	0	0	100
<i>B. Paratyphosus B</i>	97	2	1	0	0	0	100
<i>B. dysenteriae</i> , Shiga	100	0	0	0	0	0	100
<i>B. dysenteriae</i> , Flexner	100	0	0	0	0	0	100

Reference to Table I shows that 6 per cent. of apparently healthy individuals had *B. typhosus* agglutinins, 4 per cent. had *B. paratyphosus A* agglutinins, and 3 per cent. had *B. paratyphosus B* agglutinins; whereas none had *B. dysenteriae* agglutinins (Shiga and Flexner). It is remarkable to note that 35 per cent. of Col. Megaw's control cases gave a positive reaction to Flexner organisms in dilutions of 1:40 and over, and 5 per cent. to Shiga organisms in dilution of 1:40.

Of 6 cases with typhoid agglutinins only 1 case, who gave a history of continuous fever for 30 days three months before, had 23 units, three cases between 4 and 5, and two between 2 and 3 units; of 4 cases with *Paratyphosus A* agglutinins one had between 4 and 5 and

specific agglutinins in large numbers of individuals and may perhaps be due to some non-demonstrable protective factors in the serum other than agglutinins.

THE TREATMENT OF PSORIASIS BY INTRAMUSCULAR INJECTIONS OF MILK.

By SHAPURJI ARDESHIR BANKER, M.D. (Bom.),
Nawab Building, Hornby Road, Bombay.

THE treatment of psoriasis hitherto has been by internal medication and application of remedies externally.

Long continued internal and external medical treatment, with remissions and exacerbations of the lesions worries the patient to a very great extent, and if the eruptions appear on the face, especially of women, their company is avoided by others, though the disease appears not to be contagious.

In the two cases described below there was no history of rheumatism, osteo-arthritis or direct infection, though they were distantly related, yet lived in distant parts of the country.

Case 1.—The first case was a female, Mrs. F. E., aged about 32. She had extensive lesions on the trunk and extremities and even the face was not spared, the papules extending on to the head to the margin of the hair.

The lesions were so extensive that very little healthy space was left between the scaly patches to give intramuscular injections in the gluteal regions.

She had had both internal and external medical treatment for about four years with partial benefit at times, but with rapid reappearance of the lesions. Application of chrysarobin ointment had also no effect. Later on she was given neosalvarsan injections by a physician with exacerbations of symptoms. She was tired of life, and threatened to take her own life if she was not cured of the complaint.

At this stage she came under my treatment, when I thought of giving her intramuscular injections of milk before trying auto-hæmotherapy.

I gave her in all nine intramuscular injections of sterilised milk (autoclaved) at intervals of about five days.

The first injection was of 5 c.c., the subsequent injections were of 8 to 10 c.c.

There was very little fever; in fact a rise of temperature is not necessary for the disappearance of the lesions. Within the first three injections the lesions appeared to fade and by the time the ninth injection was given all the lesions had disappeared, leaving only pigmented spots; a few papules that remained disappeared under local application of an ointment containing hydrargyri ammoniata and acid salicylici which I had prescribed for her from the beginning of the treatment.

The disappearance and fading away of the lesions under the effect of the injections was very rapid, and could almost be compared with the disappearance of secondary syphilitic eruptions under neosalvarsan injections.

It is now nearly a year and a half since the injections of milk were given, yet there has been no return of the lesions except the appearance of one or two small papules which disappear as soon as she applies the acid salicylici and ammoniated mercury ointment. There has been no necessity to repeat the injections.

Case 2.—The second case was a girl, Miss L., aged 13 years, healthy in every respect excepting the eruptions on the body which were annular and resembled the photograph in Plate 21 of Sir Malcom Morris's book on *Diseases of the Skin*; the duration of the lesions was nine months.

Being related to the first case she at once came under my treatment. I put her on the same line of treatment

as in the first case, the eruptions beginning to fade rapidly after the third injection and disappearing entirely after the ninth.

Nearly six months have passed without any reappearance of the lesions. For the spots left behind after the disappearance of the lesions hazeline snow was applied, and caused them to disappear.

Both these patients were in good health; there was no history of rheumatism or osteoarthritis, nor was there any endocrine deficiency; there was rapid disappearance of the lesions under injections of sterilised milk.

As to diet, as soon as they came under my treatment I put them on ordinary diet, although before that meat, fish and eggs were prohibited.

A third case of psoriasis of both palms of the hands and soles of the feet in an old man aged 65 is under treatment and shows the same tendency to rapid benefit under local applications and intramuscular injections of milk.

How these injections of milk act one can only guess, and one can only suggest that there is bacterial infection which is terminated by the leucocytosis set up by the injections, which, attacking and killing the bacteria, stimulate the formation of immune bodies in the plasma causing the disappearance of the lesions.

The close analogy of the marked subsidence of psoriasis lesions under injections of milk with the termination of influenzal bronchopneumonia and encephalitis lethargica under the same milk injections as reported by others, and perhaps acting in the same way with the rapid subsidence of secondary syphilitic lesions under arsenical injection, is marked.

A CATARACT EXPRESSION OPERATION.

By MANO MOHUN ROY,

Chief Medical Officer, Raj Darbhanga.

THE best operation for cataract has ever been a controversial question. Surgeons who are well versed in operations for cataract are few, but it is a hopeful fact that those who are interested in the operation are always trying to effect improvement in their methods. The older operation by capsulotomy does not find favour with the majority of present-day surgeons. It often gives rise to after-trouble for the patient, and may be attended with indifferent results on account of the formation of secondary cataract. I have seen several such cases, with the operated-on eye practically without any vision and gradually closing to blindness, yet the operations had been performed by distinguished surgeons who had made their name as eye specialists.

Smith's expression operation is usually attended with uniformly good results, but

unless one is fully conversant with the technique, and one's assistant fully educated to help, the operation often results in failure. In this operation the duty of the assistant is difficult. If he is unable to overcome the action of the orbicularis, the patient will either squeeze out the lens, or the lens capsule will burst in the progress of the lens, and in that case Smith's operation in the end practically turns into a capsulotomy one.

A surgeon can only ascertain by continuous practice how any method can be conveniently improved on in the interest of his patients. I have been practising a modified Smith's operation for the past twenty years, and have found that the operation described below is most convenient and is uniformly successful.

After the usual preparation of the patient and cocainisation of the eye which is to be operated on, the knife should be introduced into the anterior chamber to its full length—or almost so, taking great care that the point of the knife does not touch the inner canthus or the side of the nose and thus cause pain to the patient, in which case he may give a start and disturb the operation. It should be noted that the knife must be extremely sharp and with the finest point, for both are essential to the success of the operation.

Next, the knife should be drawn slightly backwards, and at the same time its sharp edge tilted slightly backwards, so that the iris will lie over the cutting edge of the knife. In this way the surgeon can at once fix as much of the iris as he likes between the edge of the knife and the cornea, and, in completing the incision of the cornea can remove as much of the iris as he desires. The surgeon can easily settle the size of the coloboma which he desires to produce. The advantage of the method is that the patient is not put to the discomfort of a separate iridectomy. I have often known patients of a sensitive nature to squeeze out the lens and with it some of the vitreous, just after the completion of the (separate) iridectomy; this does not occur with the method advocated.

As soon as the incision is completed, my assistant holds up the Smith's speculum (which is always used) so as just to relieve the pressure on the eyeball, and presses back the orbicularis as much as possible. I supplement the strength of the upper blade of the speculum by a hook, and by this device it is possible to make the muscle entirely powerless.

It is now easy enough to apply gentle pressure by a hook to the lower edge of the cornea, or adjacent part of the ocular conjunctiva, and the lens presents itself in the wound of the cornea. If necessary, a little counter-pressure may be made by the hook, pressing up the upper lid, and the lens is then

delivered very easily. There is practically no escape of vitreous or prolapse of the iris. A very small loss of vitreous, however, does not injure the eye, whilst if a slight prolapse of the iris occurs, it can be rectified with the small spoon. The eye is now dressed with sterile unguent, hydrarg. oxidi flava on sterile gauze, and covered with a woollen pad, and both eyes bandaged for four days.

On the fifth day the dressings are taken off, and the operated-on eye cleansed with sterile lotion, all accumulated tears and discharge being removed. The operated-on eye is then re-dressed, and it only is bandaged this time. The eye is again examined on the eighth day, and, as a rule, is now found to have healed soundly. A green shade should now be worn for four or five days further, or for a week.

In all I have carried out some 5,000 operations for cataract; of which some 500 were carried out by the above method, with uniformly good results.

THE RATE OF LOSS OF HOOKWORM EGGS FROM FÆCES.

By P. A. MAPLESTONE, D.S.O., M.B., B.S. (Melb),
D.T.M. (Liverpool).

(Hookworm Research Laboratory, Calcutta School of Tropical Medicine. Supported by the Indian Jute Mills Association.)

WHEN one reflects on the enormous amount of work and the great volume of statistical information that has been compiled of late years regarding the question of hookworm infection, it is surprising that the rate of loss of hookworm eggs from fæces seems to have been very largely ignored. This was a matter of little importance in the days when the number of persons infected, and not the degree of individual infection, was the basis on which the importance of hookworm infection in a community was assessed, for the partial loss of eggs from fæces would only mean the possible missing of some of the lighter infections. But since it has been recognised that the true index of severity of infection in a community is the severity of individual infections, and not the total number infected, and since this is estimated by counting the eggs passed in the fæces, it becomes of great practical importance to know at what rate hookworm eggs disappear, if stools have to be kept some days before examination.

The possibility of such loss of eggs occurring is more or less generally recognized, for references to placing the stools on ice pending examination are fairly common in the literature, but precise information as to the fate of the eggs prior to reaching the ice-chest seems to be lacking, and in a large

country this period is probably often a matter of days.

Lane (1924, 1925) when testing his "D.C.F." method, gives some information on the effect of the immersion of fæces in either water or thymolised water for varying numbers of days before examination, and he shows the importance of keeping the specimens at a fairly low temperature during this storage. The same author also quotes Lambert, whose paper is not available to the writer, in which he says:—

"In the South Seas specimens have to be examined in twenty-four hours, or flotation methods are useless. Refrigeration is out of the question and no proper method of keeping specimens for a period that lends itself to ready examination has yet been devised."

This clearly shows that the rapid deleterious effect of fairly high temperatures on hookworm eggs is recognized, but it gives no information as to what this effect is, nor how it bears upon egg counting results.

In describing his method of conducting a survey of the whole of India, Chandler (1928) discusses the possibility of loss of eggs during transit of fæces to the central laboratory in Calcutta, but he dismisses it as improbable, because he only found normal-looking eggs when subsequently making his counts, and he ascribes this to the fact that the fæces containers were completely filled at the time of collection, thus excluding air and preventing development of eggs.

The writer, in the course of the present investigation, has made use of the same tins as those referred to by Chandler, and was surprised to find that there was no difference in his results whether the tins were completely or partially filled. Examination of the tins revealed the fact that the tin itself has an expanded ridge encircling it to check the descent of the lid, and that the flange on the lid is nearly 2 mm. deeper than the portion of the tin which projects above the encircling ridge. Therefore, even if the tin is completely filled and the lid tightly pressed down, there is a layer of air nearly 2 mm. in thickness above the fæces.

It was next tried if complete exclusion of air in the relatively high temperature of Calcutta would have the effect attributed to it by Chandler. This was done by carefully filling tins to the brim, and covering them with glass slides, through which it could be seen that all air was excluded. The subsequent counts of these specimens proved no better than those from partially filled tins, using the same fæces, and in some instances they were distinctly worse, for it was found that the gases generated by fermentation forced out some of the fæces from

the tin and allowed air to enter, and it also seemed that fermentation in those tins from which air was completely excluded was considerably more active than in partially filled ones; this in itself would probably lead to a greater destruction of hookworm eggs.

It might be thought that the process of fermentation easily forced off the glass slides lying loosely on the surfaces of the tins and that the same thing would not occur

their contents had escaped into the packet. This experience clearly indicates that transmission of faeces by post in a hot country is not a method that should be employed, if accurate egg counts are to be anticipated.

The faeces examined during the course of this investigation were placed in tins such as are described above, and put in a cupboard in the laboratory for varying numbers of days, as indicated in the table. All types of stool from quite liquid faeces following a

NOTE:—The figures in this table are the actual counts made, therefore they should be multiplied by 100 to get the eggs per gram of faeces, and they are the average of two counts made by the same two observers on each occasion.

in a tin with a tightly fitting lid. Such is not the case, however, for the writer, as an independent check to his results, had a number of stool samples posted from the Hookworm Campaign Office at Madras. These were in well made tin containers with tightly fitting lids, and on opening the packet in Calcutta three days after it was posted in Madras, it was found that fermentation had occurred in thirteen of the sixteen samples sent, with the result that the lids were partly forced off, and a considerable portion of

purge, to the typical soft pasty stool usually seen in India were used. The observations extended from October until the following March, i.e., the weather was hot at the beginning, fairly cool in January and February, and hot again in March, and as far as this enquiry goes there is no indication that there is any smaller loss of eggs in the cooler months, nor does the loss seem to vary with the different types of stools used. Therefore, it may be concluded that the loss of hookworm eggs in stored faeces of any type

is fairly rapid, and the rate of such loss is uniform in the normal range of temperature experienced in Calcutta.

There are, of course, unavoidable variations in the regularly progressive loss of eggs from day to day in a single specimen; this is due to the unequal distribution of eggs in the fæces, and to the error that is always present in the egg-counting method of Stoll. To reduce the daily variation in results as far as possible, the writer has added the total number of eggs of all the specimens counted on any given day, and the loss is expressed as the percentage loss on the total counts of the same fæces on the day the stools were passed. The graph has been included as it gives a clearer idea of the regular drop in the number of eggs from day to day; the only exception will be noted in the second day, which shows a smaller loss than the first day. This is almost certainly due to the fact that the number of counts done is

due to development of those lying near the surface of the specimen, and that the hatched larvæ rapidly die in the pure fermenting fæces, which is not a favourable medium. The unaltered eggs seen are those from deeper layers of fæces in the tins, where they remain undeveloped in the same way that they do at the bottom of water, and it is many days before these eggs have sufficiently degenerated to become unrecognizable or to disappear altogether.

As it may be thought that the loss of eggs found is greater than actually occurred because only the top layer of the stool in the tins was taken when measuring the portion for counting, it should be noted that the specimens were well stirred before being taken from the tins, the measurement was done by displacement of three c.c. of decinormal sodium hydroxide, and the fæces were measured out by repeatedly dipping a straw deeply into the tin and transferring the

Graph illustrating the progressive loss of eggs during storage of fæces.

too small to entirely eradicate the sources of error referred to above, and if a larger number of counts were done this discrepancy would be rectified.

The figures indicate that there is a fairly rapid and steadily progressive loss of eggs from the first to the sixth day, and that after this the loss is much slower. It is therefore of interest to consider what becomes of the eggs. When examining a series of specimens from the same stool every day for several days, it is found that during the first three or four days it is quite common to encounter eggs containing larvæ, and in a few cases free larvæ were seen in the sample being counted, but the majority of the eggs seen are still normal and undeveloped. From about the fourth day onward, and even earlier in stools that have undergone very active fermentation, definitely degenerating eggs are found. The explanation of these observations put forward by the writer is that the original and relatively rapid loss of eggs is

adherent portion to the liquid until the required amount was obtained. It is thus clear that a sample representative of the whole depth of fæces in a tin was obtained, and it should be added that a new tin of fæces was used on each occasion a count was made, thus obviating the effect of mixing the fæces and bringing some of the deeper lying eggs to the surface, where they would undergo development.

JUNE.

THE VITAMINES.

THE vitamins are becoming more puzzling than ever. No longer can the student rest satisfied with a neat little table showing the characteristics of vitamins A, B and C. Several new letters have to be employed and the old designations have been modified. Funk, who was one of the pioneers in the exploration of vitamins, now divides them into two groups: (i) the vitamins proper, which are nitrogenous and are easily destroyed by alkalies; and (ii) those vitamins which are non-nitrogenous, but are very sensitive to oxidation. In the former group are B, the antineuritic vitamin, C, the antiscorbutic vitamin, D, the stimulant of growth in micro-organisms, and possibly P, the hypothetical anti-pellagra vitamin of Goldberger.

With all due respect to Funk, it is a pity that he has accepted the French terminology by applying the letter D to a vitamin which is not concerned with the life of the higher animals. The letter D has already been applied to the anti-rachitic vitamin, and if we are to have a dispute as to the terminology, it would be far better to drop the use of letters altogether and designate the vitamins in terms of their action. There has lately been a good deal of confusion with regard to vitamin A, and it is likely that the slight saving of time and space which result from the use of artificial symbols will be more than compensated for by the fact that names which indicate the action of the vitamins will be far easier to remember, and will not be liable to alteration at the will of experts.

The second group consists of A, or anti-xerophthalmic vitamin; E, or anti-rachitic vitamin, and F or anti-sterility vitamin. Funk does not include the growth-producing vitamin, but he emphasises the fact that growth depends on the presence of important amino-acids, salts, vitamins, and other factors as well. He raises another important question: vitamins are not only necessary for the healthy growth of animals, they are also necessary for the active growth of certain tumours such as the Rous' chicken sarcoma. Other workers have produced cancerous growths in animals by diets which are devoid of vitamin A; whilst stone in the bladder can be produced in rats by diets devoid of vitamins.

We are at present at an awkward stage of development of our knowledge of the vitamins: a multiplicity of findings is being accumulated, but complicating factors are

present in abundance, and we 'cannot see the wood for the trees.' It is not merely the imperfectly understood vitamins with which we have to deal, but the complicated vitamins which occur between these and the other still more obscure substances which are present in the food. It is easy enough to devise satisfactory diets which will promote growth and maintain health, but when we insist on knowing exactly what part is played by each element of the diet and by all the elements when combined in various proportions, we must expect to embark on a long and toilsome voyage of discovery. Too often our fate will be to see a distant cloud and to cry out that we have sighted land. We owe a great debt to the students of the vitamins, but their services to humanity would be greater if they would content themselves with recording facts, drawing such conclusions as are justified by the facts, and speculating—only—on the bearings or possible bearings of their observations on the problems of disease. Much of the existing confusion has arisen from the tendency to regard isolated observations as complete explanations of problems which are many sided and complicated.

Some idea of the vast amount of work which is being done on the vitamins can be formed from a perusal of the abstracts of papers on the subject in the *Bulletin of Hygiene* for December 1927. Many of these are of a highly technical nature, and their bearing on disease problems is not always easy to determine.

The anti-neuritic vitamin is of special interest to us in India. Jansen and Donath of Weltevereden, Bavaria, claim to have produced this vitamin in the form of a crystallised hydrochloride, and Eijkman has found experimentally that this is a very pure substance. In the abstract of Eijkman's paper polyneuritis gallinarum is used as synonymous with beriberi, but it is possible that the name beriberi has been introduced by the reviewer. It would be somewhat surprising if Eijkman has implied the identity of the two conditions, seeing that he has hitherto been very careful to state that he does not affirm their identity.

Kon and Drummond have shown that many of the symptoms of avian avitaminosis are attributable to partial starvation, and not to vitamin B deficiency, as no differences could be observed in the utilization of food between the controls and the deficiency birds when the amount of food allowed to the controls was exactly the same as that eaten by the birds which were on a diet deficient in vitamin B. The only definite characteristics of vitamin B deficiency in the pigeon are lack of appetite for the deficient food and acute nervous symptoms. The decrease in weight, the green stools, and the fall in temperature are found to be due to partial starvation.

The work of Hasan, Drummond, Chick and Roscoe suggests that vitamine B is made up of two distinct factors, only one of which is concerned in preventing polyneuritis: the other is concerned with growth production and the healthy condition of the skin, and it is probably the same as the 'pellagra-preventing' factor of Goldberger.

Suzuki has tested the vitamine B content of the milk of women whose infants were suffering from infantile beriberi. His method was to observe the effect of the milk in stimulating the growth of yeast in cultures, and he found that fourteen specimens of beriberi milk contained about the same amount of the substance which promotes the growth of yeast as did the milk of control female patients who were suffering from influenza, whooping cough, malnutrition, etc. These results appear to suggest that infantile beriberi is not due to the absence of the yeast growth-promoting substance, which is presumably vitamine B.

The anti-scorbutic vitamine is believed by Rardoin and Lecoq to consist of two factors, one of which influences the health of the capillaries, while the other affects metabolism in general. These workers were the first to demonstrate the presence of two factors in vitamine B.

Evans and Burr find that the anti-sterility vitamine, E, which is contained in the wheat germ, loses its potency when mixed with lard, while it remains active when mixed with butter.

Shiga reports the production of beriberi in human beings when fed on a good and adequate diet, including parboiled rice but deficient in vitamine B. Three such persons developed acute symptoms of beriberi on the 45th and 47th days, respectively; two had lesser degrees of the same symptoms; one had acute cardiac failure, and one a dropsical form of beriberi.

It will be seen that we are still largely at the experimental stage in this matter, and in spite of the enormous volume of literature now extant on it, the chief need is for a clear understand of the bearing of the facts elicited with regard to disease.

J. W. D. M.

THE POPULATION PROBLEM IN INDIA.

IN a report on the epidemiology of typhus fever in Ireland, published by the United States' Public Health Service in October 1927, there is startling evidence of the evil consequences which are likely to follow from an excessive increase of population. This report is one which ought to be read by every educated person in India, as it appears to contain a lesson for this country. Here are some of the facts. Within forty years

(1800 to 1840) the population of Ireland more than doubled itself, and became more than eight millions. At least half the people depended on the potato for subsistence. Stephen Gwynn thus describes the state of affairs which existed about 1840 in his book *Ireland*.

"In a parish with a population of 9,000 the only wheeled vehicle was one cart, there was one plough, sixteen harrows, twenty shovels, no pigs, no clock, three watches, no fruit trees; people slept naked on straw and rushes, men and cattle were housed together. The school teacher, a man of distinction, had a salary of £8 a year. The people had one meal a day, sometimes only one meal in two days. The poor became a teeming multitude, living on potatoes with a little milk. Over two million persons were in distress for more than half of every year. At least a quarter of a million were driven to beg on the roads before the potato harvest."

This is a startling picture of the state of a country which permitted the population to outrun the available food supply, and it is difficult to conceive that it is not a picture of what is happening in many parts of India to-day.

Dr. R. K. Das is reported as estimating that India can support adequately, with moderate opportunity for moral and material development, only one half of its present population. This pessimistic estimate does not take into account the possibilities which exist for increasing the food supply by improved methods of agriculture, and by industrial development. On the other hand, even if the most optimistic view is taken, we must admit that if every increase in the food supply is followed by an increase in the population we can only expect that a larger number of people will eke out a miserable existence without hope of betterment of their condition. It is true that India for many years has been protected from such a catastrophe as that which befell Ireland in 1846 and the following years, but in this country the process of restriction of the population is being pursued by Nature in a relentless manner. Insufficient food lowers the resistance to disease; malaria, respiratory diseases, tuberculosis, dysentery, and other diseases all co-operate to maintain the balance between population and food supply.

At first sight it would appear that the war against disease must inevitably be a hopeless struggle; but there is another side to the picture. Other countries have succeeded in establishing a balance of population without the help of disease and famine: India can do the same, but only on condition that she desists from the process of increasing the population by the marriage of immature boys and girls, who are compelled to become fathers and mothers of weakly children before they are able to maintain themselves in reasonable comfort. The pathetic contentment with their lot which characterised the people of Ireland in 1845 was rudely assailed by the potato famine of 1846-47: a similar fatalism exists in

India, and it will have to be removed by education if this country is to get rid of the evils with which she is beset on every side.

It is interesting to recall the words used by Lord Palmerston, Home Secretary for the United Kingdom, in 1853. He had been asked to appoint a national day of prayer and humiliation to avert the cholera which threatened the country. His reply was as follows: "The Maker of the Universe has established certain laws of Nature for the planet in which we live, and the weal or woe of mankind depends upon the observation of these laws. One of the laws connects health with the absence of the gaseous exhalations which proceed from over-crowded human beings, or from decomposing substances Lord Palmerston would therefore suggest that the best course which the people of this country can pursue to deserve that the further progress of cholera should be stayed will be to employ the interval..... in executing measures by which those portions of their towns and cities which are affected.... may be freed from the causes and sources of contagion, which, if allowed to remain, will infallibly breed pestilence, and be fruitful in death in spite of all the prayers and fastings of a united but inactive nation."

These words are applicable to all countries and to all times. There are two great laws of Nature which must be learned and obeyed. One is that diseases can only be prevented by removing their causes; the other is that the available food supply can maintain in health and comfort only a certain number of human beings. If the population outgrows the food supply, Nature will restore the balance by disease or famine, or both. We have the power of controlling our environment and of securing healthy and satisfactory existences, but only on one condition, that we do not expect the Maker of the Universe to abrogate the laws which He has established for all the creatures of the earth. Ireland has succeeded in maintaining a population of about four millions of people in reasonable comfort for the past thirty years; if the population were restored to its former figure of eight millions, all the resources of preventive medicine would fail to prevent famine and disease.

India may be able to maintain her present population in comfort by improvements in agriculture and industries, by preventing the drain which results from maintaining millions of useless cattle and the wasteful social customs which exist, but there is no hope of prosperity so long as every increase in the food supply is accompanied by a corresponding increase in the number of mouths which have to be fed. Our educationalists ought to study economics, and having done so they ought to teach the rising generation the principles which must be followed if human beings are to enjoy a reasonable degree of health and comfort.

A Mirror of Hospital Practice.

A CASE OF MYCETOMA OF THE HAND AND FOOT.

By M. G. RAMACHANDRA RAO, M.B. & C.M.,
Chief Medical and Sanitary Officer, Maharaja's Hospital,
Pudukotah (Trichy.).

NAME:—Ponnan, Age:—30, Residence:—
Valavampatti (Pudukotah State).

Admitted into hospital on October 29th, 1927.

Condition on admission:—Much emaciated, anæmic, sometimes with a low temperature in the evenings. There was pain in the affected limbs, more severe in the hand. He was

unable to lift the hand and leg. There was a discharge of sanious pus from the sinuses. Pulse:—Weak, small, 92 per minute. Respirations:—20 per minute. Urine:—Specific

gravity, 1,008; reaction, acid; no albumen, or sugar.

Appearances of the affected limbs:—

Right hand:—Swollen in a very characteristic manner with multiple sinuses exuding pus, swelling extended up to elbow with enlarged veins. Glands in the axilla were enlarged.

Left foot:—Swollen in the same manner with multiple sinuses and nodules. On pressure there was a discharge of pus with granules; the limb above was atrophied.

History:—Two years ago he felt a sort of numbness near the web of the index and middle finger. Some days after a bleb formed on the surface which burst and left a small opening discharging pus. Native medicines were applied with no effect. The whole hand began to swell slowly. Induration and nodules appeared in the palmar surface first. Then several new openings formed with discharge of pus and granules.

Six months before admission he felt pain in the big toe which began to swell some days after. Then the swelling extended to the sole; this became studded with nodules and openings with characteristic discharge of pus from sinuses. The limb above atrophied; no glands were affected. Since he was very weak and unwilling for amputation of the limbs, operation was postponed; meanwhile he was fed with nourishing food, and strychnine and iron injections given.

Antiseptic baths were given to the affected limbs. While he was improving a bit he developed diarrhoea which was not amenable to any treatment, as a result of which he became exhausted. He was discharged at his own request on 13th December, 1927.

ASCARIS INFECTION SIMULATING BRIGHT'S DISEASE.

By JAGADISH CHANDRA DUTTA, L.M.P.,

Raja Alli Tea Estate, Assam.

AN Ooria woman, Sita, aged 35 years was admitted into this hospital with general anasarca, dyspnoea, no appetite and a continuous feeling of heaviness in the abdomen. The liver and spleen were normal and there was no heart trouble. I examined her urine and found nothing except a quantity of albumin. I tried purgatives, diaphoretics, pilocarpine nitras, etc., and dietetic treatment, but the dropsy subsided only for a short period. She was treated as a case of Bright's disease. This was the third time she had been admitted into this hospital with the same complaint. There were no symptoms of worms at all. She was not anæmic; her hæmoglobin was 75 per cent. I tried oil of chenopodium and

carbon-tetrachloride mixture followed by salt. After the first dose she passed 200 round-worms, on the second day 150, on the third day 90, on the fourth day nothing, and on the fifth day 60, a total of 500 round-worms. Her heaviness of the abdomen, dyspnoea and dropsy all cleared up and her appetite became normal. I again tried the same medicine twice at weekly intervals, but no more worms were passed. The urine was again examined and no albumin was found. She is now quite fit and left the hospital fit and well.

A CASE OF LIPOMATOSIS.

By DAYA RAM KUMAR,

Assistant Surgeon, Muzaffargarh, Punjab.

THE photograph indicates a condition which needs no description; a few points in connection with this case are given below:—

He was a Mohamedan aged about 19 years—male. No family history. Duration 12 years, but he could not describe how it began.

His speech was thick but he talked well and could reply to questions. He was blind. He could take his food well. His memory was fair as he was learning the Koran by heart. Only the head and face were affected. He refused all treatment.

AN UNUSUAL CASE OF LOBAR PNEUMONIA.

By V. SIVAMANI,

Medical Officer, Sahmaw Sugar Estate and Factory,
Sahmaw (Myitkyina District).

A EUROPEAN officer in the estate, aged 52, was attacked with fever on the night of the 14th January, 1928.

From the very outset almost all the signs of pneumonia were present, though not quite so evident for the first two days. The right lung was more affected than the left.

locally an Antiphlogistine poultice. From the 3rd day onward he was given an expectorant mixture with potassium iodide and creosote. On the 5th day he was given a hypodermic injection of nuclein, 1 c.c.

The collapse was combated by brandy internally and camphor in oil subcutaneously. Besides he had rectal administration of potassium permanganas, 8 oz., twice daily during the period of the crisis.

After a convalescence of about another week the patient made an uneventful recovery.

Except for the temperature chart all the clinical signs, consolidation, tubular breathing and rusty sputum, were in favour of the disease, but throughout the period of illness his temperature was peculiarly intermittent.

The possibility of malaria was not overlooked and repeated blood examinations proved "negative," except for leucocytosis which one would normally expect in a case of pneumonia.

Microscopical examination of the sputum showed only pneumococci and not tubercle bacilli, and hence acute pneumonic tuberculosis was ruled out. The daily intermission of temperature was very peculiar and strange, and I really doubted whether a case of pneumonia would ever show a chart like this. The district Civil Surgeon, Captain Davis, with whom I had the benefit of a consultation on this case, agreed with my diagnosis but was also surprised at the unusual type of temperature.

The disease was severe and the patient passed the crisis with great risk. He took nearly three days to recover from the collapse.

By way of treatment he was given a simple diaphoretic mixture for the first two days and

A CASE OF CONGENITAL DILATATION OF THE COLON, (HIRSCHSPRUNG'S DISEASE).

By KIDAR NATH DATT, L.S.M.F. (Punjab),
Canal Dispensary, Khanewal, Multan District.

A MALE child 40 days old was brought to me on the 17th July, 1927, with a history of extreme constipation alternating with periods of diarrhoea, dating from birth. During the periods of constipation the abdomen would become very greatly distended and the child would vomit most of his feeds. Pressure on the abdomen did not seem to be painful as he did not cry when this was applied. Each attack of constipation had been of increasing duration, followed by two days of diarrhoea. The current attack of constipation had lasted for seven days.

On examination I found his abdomen intensely distended and spherical in shape. The abdominal veins were prominent and very marked peristalsis of the gut was visible in the lower part of the abdomen. Resistance was felt on palpating the colon, and the sigmoid flexure was palpable and seemed to be thickened and enlarged. On percussion the abdomen was tympanitic except in the region

of the sigmoid flexure where there was a dull note. On rectal examination no obstruction was detected and a little fluid greenish matter came out. There appeared to be some difficulty in breathing, and the child was dull, quiet, and apathetic. The respiration rate was 60 per minute. The general condition was good and the child appeared to be quite healthy apart from the intestinal condition.

Treatment. A large sized catheter was passed through the rectum into the colon and some 4 ozs. of a foul greenish fluid evacuant was passed. Castor oil was given by the mouth and turpentine stupes applied to the abdomen. The only diet allowed was water. That day the child passed four similar fluid motions and the abdominal distension was reduced to about half its previous amount. On the 18th July there were six fluid, greenish motions, and a little milk was allowed.

On the 19th July the parents did not bring the child to the dispensary, and I learnt that he subsequently had a very severe attack of constipation. He was treated by a *hakim*, who tried a whole series of purgative drugs. This did not relieve the intense constipation, however, and the child died on the 25th of July.

The condition present could not be attributed to tuberculous peritonitis or to chronic indigestion and proved fatal, so a diagnosis of congenital dilatation of the colon appears probable. Death was presumably due either to toxæmia or to peritonitis.

A CASE OF PERSISTENT HICCUGH FOLLOWING STRANGULATED HERNIA.

By A. SATYANARAYANA,

Sub-assistant Surgeon, Jaipatna, Kalahandi.

N., Hindu male, aged about 35 years, was brought to hospital at about 2 p.m. on the 3rd November, 1927, with the complaint that his old standing hernia had become irreducible for the past twenty-four hours, and that severe hiccough had set in. The swelling was very tender, whilst operative facilities at the dispensary were nearly nil. Taxis was tried, and after some half an hour's careful manipulation under chloroform anaesthesia the hernia was reduced. On recovering from the anaesthetic, however, hiccough recurred, was extremely persistent, and very distressing.

Morphia, gr. $\frac{1}{4}$, with gr. $\frac{1}{100}$ th of atropine sulphate was now given hypodermically, but only temporarily relieved the condition for a couple of hours.

4th November.—Condition as before with incessant hiccough, and the patient is much exhausted. Carminatives were given; morphia and atropine again injected; and at night gr. 3. of calomel with sodium bicarbonate. The patient passed four fluid stools during

the night and next morning, but his condition remained as before.

5th November.—A chloral and bromide mixture was given; also inhalation of amyl nitrite, and a blister to the root of the neck just above the clavicle. Morphia and atropine were injected hypodermically at night, but the patient had no sleep.

6th November.—The patient was now in a critical state, although the abdomen was flaccid, with no abdominal pain, tenderness, or vomiting, so peritonitis could be excluded. As a last resort a hypodermic injection of Harmon's solution—morphia and atropine in 4 c.c. of sterile 25 per cent. solution of magnesium sulphate—was given this evening. As the patient was an habitual drunkard, he was also allowed 3 ozs. of country spirits.

7th November.—The patient was hale and hearty, completely cured of his symptoms. Later, he was discharged in good health.

A CASE OF MALARIA SIMULATING CONFUSIONAL INSANITY.

By V. SIVAMANI,

*Medical Officer, Sugar Estate, Finlay Fleming and Co.,
Sahmaw, Upper Burma.*

A KACHIN boy, aged 15, working on this estate, by name La Noe, was brought to hospital on the 14th July, 1927, with a history of three days of fever. On admission he showed extreme prostration, a temperature of only 98.4°F., the pulse 144 per minute and feeble, and respiration rate 50. A certain degree of aphasia was noticed and he could only talk with difficulty. The tongue was thickly coated and moist, the bowels constipated, and the spleen enlarged to two finger-breadths below the costal margin. The liver was not enlarged.

The pupils were somewhat unequal and reacted only sluggishly to light. The muscles were very much wasted, considering the short duration of the illness. The knee jerks were exaggerated and ankle clonus present. Babinski's sign was present.

The diagnosis with such a combination of symptoms was difficult. He was given an enema, and blood films taken and examined for malarial parasites. None were found.

At 2 p.m. the same afternoon the patient passed into a violent and noisy state. At times he would sit in bed in a melancholic state, at others cry out and shout with anger. He made several attempts to escape from hospital, trying to take his bedding and feeding cups with him, and disturbing all the other patients in the ward. I could scarcely drag any answers out of him on questioning him, and finally he had to be tied down and a wardboy placed on duty to keep guard over him. His general mental state appeared in brief to be one of extreme confusion and hesitancy.

At 6 p.m. he was given gr. $\frac{1}{2}$ of morphia subcutaneously and 1 drm. of paraldehyde by the mouth. In spite of this he was noisy all night and did not sleep at all.

15th July.—Temperature 99°F. During the whole day his condition continued as before, being violent, noisy and irrational. He was given saline purgatives, and the same hypnotics as before at night.

16th July.—Condition unchanged. Treatment as before.

17th July.—Condition the same; temperature 102°F. Blood films taken and examined, but again no malarial parasites could be found. I had previously, however, seen proved cases of malaria with such a confusional mental state, and so gave gr. 10 of quinine intramuscularly into the gluteal region.

18th July.—There was a marvellous improvement. The temperature was 97.4°F., he had slept well throughout the night; and the confused mental state had completely cleared. He now had a voracious appetite which was hard to satisfy.

The patient was now put on to quinine by the mouth, followed later by an iron tonic, and in a few days resumed his work. Interesting features of the case are the low degree of pyrexia associated with so disturbed a mental state, the failure to discover malarial parasites in the blood films, and the immediate response of the condition to quinine administration.

A CASE OF PELVIC PERITONITIS FOLLOWING PUERPERAL SEPSIS TREATED BY INTRAVENOUS IODINE.

By S. SEN, M.B., B.Sc.,
Medical Officer, Arakan Hill Tracts,
and

U. AUNG PHAW KHINE, L.M.P.,
Sub-assistant Surgeon, Civil Hospital, Paletwa.

A BENGALI woman, aged 16, a primipara, was admitted to the Civil Hospital, Paletwa, on the 27th January, 1927, suffering from acute abdominal pain, fever, and a foul blood-stained discharge from the vagina.

A month previously she had given birth to a full term child, without complications, her husband stated. The lochia, however, were very scanty and stopped on the second day. There was no tear in the perineum or laceration in the vagina. The child, however, died on the 15th day; soon after she commenced to feel pain in the lower part of the abdomen, and had a discharge from the vagina, with fever.

She came to hospital walking, but in a stooping posture and leaning on her husband's shoulder. On admission her temperature was 101°F., and pulse 110 per minute, and she complained of acute pain in the abdomen. The

bowels were loose and she vomited twice. She lay on her back with the knees well flexed, had great thirst, was restless and distressed, and appeared to be a typical abdominal case with sunken eyes, and furred tongue. The abdominal muscles were tense and the abdomen distended, especially below the umbilicus. The abdomen was tympanitic on percussion and hyperæsthetic above Poupart's ligament. There was a foul, slightly blood stained discharge from the vagina.

On vaginal examination the uterus was found pushed forward and a mass was felt in Douglas' pouch. The cervix was not freely moveable. No vaginal tear or laceration was found.

The diagnosis was obviously pelvic peritonitis following on puerperal sepsis. The patient, however, absolutely refused any sort of operative treatment, even exploration of the uterus. The problem therefore was how to treat her.

Treatment. 27th January.—An alkaline mixture was given together with ergot, and a hot vaginal douche containing tincture of iodine twice in the day. The temperature rose to 103°F. in the evening, pulse 120. She was very restless at night, and $\frac{1}{4}$ gr. of morphia was given. The patient was placed in Fowler's position.

28th January.—Temperature ranged from 102° to 103°F. and pulse accordingly. The patient was in great distress and pain, and the abdominal distension was very marked, even above the umbilicus. The vaginal douches were continued and saline administered per rectum. In the evening an intravenous injection of iodine, gr. $\frac{1}{2}$; potassium iodide, gr. 2; in 10 c.c. of distilled water was given.

29th January.—Patient's condition much the same. Treatment as on the previous day.

30th January.—Patient better. Temperature 99°F.; mental state brighter. The upper half of the abdomen is soft, but a definite mass is palpable below the umbilicus, chiefly on the right side. In the evening the temperature rose to 101°F., and there was again intense pain in the lower half of the abdomen. Morphia had to be given at night.

31st January.—Better. Temperature between 100° and 102.2°F.; pain confined to the pelvic region. Treatment as before, with the usual intravenous injection of iodine.

1st February.—Decided improvement. Fourth intravenous dose of iodine given.

2nd February.—General condition very satisfactory. Temperature between 99° and 101°F. Put on to a tonic containing iron, arsenic, and quinine.

3rd February.—Temperature normal, and abdomen flaccid. Very little pain and only a very scanty discharge from the vagina. On examination, the uterus was found in its normal position and the pouch of Douglas clear.

From this point the patient made a rapid recovery, and was seen by the senior author some time afterwards at her house, when her recovery was complete.

The case is of interest, as in view of the persistent refusal of the patient to permit the necessary operative measures one scarcely knew what line of treatment to adopt. We attribute her recovery to the intravenous injections of iodine.

SOME OBSERVATIONS ON THE VALUE OF NOVASUROL IN CARDIAC DROPSY.

By G. NARAYANASWAMY MUDALIAR, I.M.S.,
Triplicane, Madras.

HAVING read about the efficacy of Novasurol in cases of œdema, I gave it a trial in two cases of dropsy due to cardiac dilatation, and wish to record the clinical results obtained:—

Case No. 1.—The patient is a lady aged 30. She was anæmic during her pregnancy and gave birth to a child in August 1927. A fortnight after delivery œdema started in the feet and gradually increased, affecting the lower and upper limbs. I was called in to see the case on 14th September, when I noticed extensive dropsy of the body, the face, hands and legs being enormously swollen and tense. There was also some quantity of effusion in the peritoneal cavity and she had diffused bronchitis with a slight rise of temperature. The heart was dilated, the apex being displaced downwards and outwards; the cardiac sounds were feeble and there was a systolic hæmic bruit. The pulse rate was frequent, numbering 120 per minute; the patient had hard breathing and could not lie in the recumbent posture; the kidneys were intact. I gave her a mixture containing expectorants with digitalis, diuretin, injections of pituitrin twice daily and opened the bowels freely. Her conditions did not improve. I started injections of Novasurol on the 17th giving her one full bulb (1 c.c.) intramuscularly at intervals of three to four days. By the time the ninth injection was given the output of urine was increased and œdema had completely subsided, the diminution being first noticed in the lower limbs and then gradually in the rest of the body. The patient was able to lie down comfortably. The expectorant mixture with digitalis was continued during the whole course of treatment. The pulse and heart improved and the lungs also cleared up. She was kept on a simple diet with barley water, fruit juice and milk all the time. After the œdema had gone down I prescribed syrup of hæmoglobin. She came to my dispensary ten days ago for the last injection and I found her free from dropsy, though still weak and anæmic.

Case No. 2.—This patient is an elderly lady aged about fifty who has been subject to

chronic bronchial asthma for several years. Consequently her heart became dilated and dropsy set in about a year ago. There was dense œdema all over the body, hard breathing and severe cough. She discontinued my treatment a year ago. I happened to see her about two months ago and found her in a very miserable condition with the face and limbs considerably œdematous. She was scarcely able to lie down and was night and day sitting in a chair. The urine was scanty but free from albumin. I suggested to her the utility of Novasurol in reducing the œdema and on her agreeing to take the injections I gave her every third day one ampoule of Novasurol intramuscularly; by the time the box of ten ampoules was used up the dropsy had disappeared entirely. The patient felt much relieved and could lie down with ease, but the causative factor, viz., the weak dilated heart and underlying chronic bronchial catarrh still remained unimproved.

Conclusion.—First, Novasurol is undoubtedly a powerful diuretic in cases of cardiac dropsy. The drug can be relied upon to reduce the œdema, but has no influence on the ætiological factor. It may be stated, however, that in the above-mentioned cases the one significant fact was that the kidneys were healthy, though the quantity of urine secreted was scanty.

A BAEL FRUIT IN THE VAGINA.

By INDULAL S. DAVE, M.B., B.S.,
*Medical Officer, Civil Hospital, Kadi (North Gujarat),
Baroda State.*

A FEMALE patient aged about 50 years came to my out-patient department a week ago and asked for medicine for *masâ* which generally means, on this side of the country, piles or anything of such a nature at the anal region. Even syphilitic condylomata are spoken of as *masâ*. She would not allow any examination, so I prescribed the routine purgative draught and unguentum galli cum opio for external application for four days. On the fifth day she came and reported that she had been purged heavily but the *masâ* were not at all better. She demanded a personal examination this time by the female nurse. The nurse reported to me that there was something curious about the patient's vagina. She said the patient had been seen by her 2 or 3 months ago and she had felt something in the vagina like the head of a foetus and that it had now become bigger and had come nearer the vaginal opening. The nurse asked me to see it myself as the patient now allowed it, and also said there was some cancerous growth also.

On inspection I found an epitheliomatous growth of the whole of the left labium which bled on a slight touch, but was neither

full nor tender. The inguinal glands were not much enlarged, though distinctly felt as discrete glands on the left side. On my passing the fingers into the vagina, I was amazed to feel a globular mass filling up the whole of the vagina. I put in the index finger and the thumb to gauge its size and consistency. It was hard, globular, smooth though not without some fine roughness about it, but it had not at all the feel of hair on the foetal head. It was about 3 inches in diameter and when grasped between finger and thumb, it could be moved freely in the vagina. It was not like a submucous uterine fibroid become polypoid and hanging loosely in the vagina through the cervix. There was no pedicle. It then at once struck me that a foreign body had been put in by the patient for some sort of treatment. On inquiry I was told that a bael fruit had been inserted. This is the fruit from which Ext. Bael Liq. has been prepared. On being asked the reason for putting in the vagina this particular fruit, the patient said that she had prolapsus uteri and as bleeding occurred from the *masâ* (the epitheliomatous growth) she had put the fruit inside her vagina.

This was a means invented by the patient herself to raise the uterus and keep it up like a pessary, and as bael fruit is used extensively in India for dysentery to stop bleeding, the patient thought it would have the same action in the case of her *masâ*.

NEOSALVARSAN INTRAVENOUS INJECTION: ITS EFFECT ON THE PATIENT AND THE DOCTOR.

By DINSUKHRAI GOVINDRAI,
Medical Officer, Junagada General Hospital, Junagada,
Kathiawar.

ON March 12th, 1928, I was called in to give an intravenous injection of neosalvarsan to a private patient. It is my rule always to give a good purgative on the previous night and to examine the urine just two or three hours prior to actual injection. I also assure myself about the heart. Accordingly, having satisfied myself, I went to inject neosalvarsan. I began to inject and until half of the 10 c.c.s. of solution was injected the patient was quite cheerful, but when I had completed the injection, and began to address a few words to the patient, I failed to get a response from him. Immediately my attention was drawn to the patient, and to my dismay and wonder I found him death-pale, with no conjunctival reflex, no pulse at the wrist and with very shallow respirations numbering four or five per minute. The reader can easily imagine my mental state at that time, because in my 10 or 12 years' experience this was the first instance of such serious magnitude. I hastened to give him artificial respiration with cold

water douching over the face, and stimulants were administered internally. There was nothing at hand ready to give heart stimulants subcutaneously. I had to resort to artificial respiration for about 10 minutes and then only did the patient show any hopeful signs. He could talk after three-quarters of an hour. When he could talk, he complained of heaviness in the chest with giddiness. He remained listless for about three or four hours and towards the evening at about 6 p.m. he was again almost in his normal mood. It should be noted that—

- (1) the patient was perfectly healthy with hemiplegia of the left side;
 - (2) this was the third injection and with previous injections there had been no trouble;
 - (3) the patient is decidedly not of a neurotic temperament;
 - (4) he was not an illiterate villager who might be frightened by an injection; and,
 - (5) last but not the least, there was no mistake in the technique.
- In spite of all this the patient's condition grew alarmingly serious, and had the patient continued in the same condition much longer I think he would have died of coma, but Heaven saved him to save me from perpetual disrepute.

Now the question which arises is this—supposing the patient had died, what would have been the position of the doctor? In big cities, like Bombay and Calcutta, there are coroners, there are medical councils, and there are expert and honest medical opinions to prove that the doctor is not at fault. But what in a small town or village? There are small Native States with full judicial powers. There are many such States where there is only one doctor, with one police officer, one magistrate and only one High Court and this High Court is generally in the person of the ruling prince. If a doctor is placed in such circumstances and if unfortunately the police officer takes an adverse view, how would a doctor save himself?

A CASE OF IMPACTED FOREIGN BODY IN THE ŒSOPHAGUS.

By MOHAMED HUSEIN ABDUR-RAZAK SOUDAGAR,
Medical Officer, Ranabennur Dispensary,
Dharwar District, Bombay Presidency.

A HINDU, 80 years of age, was brought to this dispensary at 1 p.m. on the 5th February, 1928, by the relatives who stated that the man had swallowed a fig (*Ficus glomerata*), known in Hindustani as "Gular" and in Marathi as "Umbar," which had stuck in the gullet preventing him from swallowing anything.

Condition on admission. The patient appeared to be very uneasy, making futile attempts to swallow. On making him drink a

mouthful of water he returned it after two or three vain attempts to swallow it. The breathing had become difficult from pressure of the foreign body on the back of the trachea, which is not cartilaginous posteriorly as it is anteriorly, and laterally.

Treatment. Attempts were made to push the foreign body further down by means of a stomach tube but to no purpose. It was then thought that a force from below, that is vomiting, would expel it. On enquiry it was stated that the man had gone out early in the morning without taking any food. However, a hypodermic injection of apomorphine was given; in about 6 or 7 minutes the very first reverse peristaltic wave of the œsophagus expelled an entire full grown fig measuring 2" long, 1" thick, and 1½" broad (flattened by the gums), to the great joy of the relatives and others who had gathered to watch the patient anxiously.

The noteworthy thing about the case is, that a simple reverse peristaltic action of the œsophagus without any other aid of pushing from below was effective enough to dislodge and expel the foreign body which appeared to have been caught firmly within about 2" of the pharyngeal end of the œsophagus.

AN INTERESTING CASE OF MALARIA.

By S. N. RAGHAVA, M.B., B.S.,
Railway Road, Aligarh.

THE patient was a Mahomedan male, aged 40.

History. He complained that he had been suffering from frequent attacks of high fever for the last five years.

He used to get fever with rigors followed by high fever going up to 104° and 105°F. daily. This kind of fever went on for a week or two when he used to take brisk purgatives in order to get rid of fever. He had recourse to doctors for treatment, but quinine produced symptoms of anaphylaxis and he had to discontinue the treatment. He had no symptoms of chronic malaria and hence I did not believe his history, but he got another attack in my presence with typical symptoms of malaria, 104°F. temperature.

I was very much afraid of giving him quinine but was anxious to give him relief. I gave him Esanofêle tablets which gave him a lot of trouble; he had an urticarial rash all over the body, and a choking sensation in the mouth with hoarseness of voice. These symptoms persisted for some time and disappeared in a day or so.

After enquiry I came to learn that the administration of a bitter medicine by a Vaidya or Hakim produced the same symptoms, though it was "not quinine." I thought over the matter and came to the conclusion that the bitter principle of any drug might produce

these symptoms of anaphylaxis. Working on this hypothesis I decided to give him euquinine which he tolerated without much difficulty up to grs. 20 a day. He got rid of the fever and was all right.

TWO CASES OF CARBON MONOXIDE POISONING.*

By P. V. KARAMCHANDANI,
CAPTAIN, I.M.S.,

Commanding Indian Military Hospital, Pishin.

About midnight 1st-2nd February, 1928, two men went to sleep in a small room (8 × 7 feet) in this cantonment, with the door and the window closed and a pan of steam coal burning inside. As they did not get up by 9 a.m. next day (2nd February, 1928) and noisy breathing was heard from their room, with a smell of poisonous gas emanating from the chinks, the window was broken open. Both men were found unconscious, number one lying stark naked. I was immediately summoned and had them forthwith removed to the hospital. Their condition when I saw them first was as under:—

Case No. I (died). Case No. II (survived).
Private Syce No. 83986
Md. Khan. Dr. Abbas Khan.

General physique	Well built, aged 35 years.	Spare built, aged 25 years.
Coma	.. Deep. Unconsciousness complete.	Do.
Sensory functions	Abolished ..	Do.
Motor functions	Whole body in a state of motor paralysis.	Do.
Skin and tendon reflexes.	Abolished ..	Do.
Organic reflexes	Involuntary passage of feces. Eyelids closed. Conjunctivæ insensitive.	Retention of urine only. Do.
Eyes	.. Pupils moderately dilated; equal on both sides.	Definitely contracted; equal on both sides.
	Reaction to light nil.	Do.
Lungs	.. Both bases congested; crepitations all over.	Slight congestion bases; rest clear.
Breathing	.. 36 p. m. stertorous.	30 p. m. not stertorous.
Pulse	.. 77 p. m. full	.. 64 p. m. weak.
Temperature	.. 97°F.; surface of skin cold.	Do.
Venous blood	.. Scarlet red	.. Scarlet red.

The urine of Case No. 2 was examined by Major C. D. M. Buckley, in-charge District Laboratory, Quetta, and was found to contain large quantities of lactic acid and traces of albumen.

* Published by the kind permission of the Director of Medical Services in India.

Treatment 10 a.m., 2nd February, 1928.
Both cases.

- (1) Oxygen inhalations.
- (2) Potassium permanganate solution 12 c.cm. (1 in 500 solution), intravenously.
- (3) Strychnine 1/30 grain, subcutaneously.
- (4) Hot water bottles.

No. 2 after potassium permanganate injection opened his eyes and showed distinct improvement in that:—

- (i) his eyes looked brighter, having lost their blank look;
- (ii) some response to external stimulation could be obtained;
- (iii) temperature rose to 99°F., pulse to 80 per minute, and respiration came to 24 per minute. He regained consciousness at 8 p.m. on 2nd February, 1928.

Case No. 1.—After the first potassium permanganate injection opened his eyes which appeared brighter, vomited and looked better, the rate of respiration decreased, while stertorous breathing became less noisy. Within half an hour he relapsed into his previous condition. At 11 a.m. he appeared to sink, and respirations became irregular almost gasping like the approach of death. He was immediately given a second injection of potassium permanganate and his condition, like the sudden brightening up of a dying flickering candle when fed with oxygen, improved and respirations, though stertorous, became regular. Strychnine grain 1/30 subcutaneously was repeated and oxygen continued almost continuously. The above condition lasted till 8 a.m. on 3rd February, 1928, when he showed signs of sinking again and a third injection of potassium permanganate was given at 8-30 a.m., but there was no improvement and the patient expired at 9 a.m.

Autopsy of his brain only was obtained. There was a small quantity of fluid between the brain and the dura mater. There was no congestion of the brain or the membranes, while the consistency of the brain was normal.

The most striking thing was the vermilion red colour of the arteries and the veins.

REMARKS.

I. I have no doubt that these were cases of carbon monoxide poisoning. Firstly, the coal used was not charcoal, but steam coal, which when kept burning in a pan in a room has a low rate of combustion. Waddell says that a certain quantity of carbon monoxide is always formed during combustion under ordinary conditions of coal or fuel, but the amount is greatest when combustion is least active. Secondly, the blood was scarlet red

in colour and not darkened as is the case in carbon dioxide poisoning.

II. It is asserted that the compound formed by combination of carbon monoxide and hæmoglobin of the blood (carbonic oxide hæmoglobin) is stable and that it cannot be broken up by simple exposure to air or oxygen. If this be really so, how is it that Case No. 2 recovered although he had been inhaling the narcotic for over nine hours before he was seen and treated?

III. Whether potassium permanganate had any salutary effect? The sudden brightening up of the eyes was striking.

IV. Whether there are any cases of carbon monoxide poisoning on record who had been under the effect of the narcotic for such a long time and had recovered?

V. Had the naked condition of the body of the first on the cold night (temperature 11°F.) and congestion of both lungs anything to do with his demise, as compared to the want of this in the second case?

ATRESIA OF THE VAGINA AND CERVIX UTERI.

By A. F. W. DE COSTA, F.R.C.S., D.T.M.,
CAPTAIN, L.M.S.,
Civil Surgeon, Bilaspur, C. P.

A GIRL aged 14, well developed, well nourished, consulted me for a big tender swelling in the abdomen, felt just below the umbilicus. She had not menstruated. The diagnosis seemed to lie between an ovarian cyst and a subperitoneal myoma. A vaginal examination gave an entirely different aspect to the case. The patient was already prepared for an operation, so an anæsthetic was administered and it was found that there was no vagina—a case of atresia of the vagina. So I decided to cut it open and on doing so found the barrier about half an inch thick. On passing the finger through this the cervix could be felt, but there was no sign of an os—a case of atresia of the cervix uteri. This was opened and a probe passed into the uterus gently from which dark red viscid fluid came out, and on squeezing the abdominal tumour there was a rush of similar fluid until about 14 ozs. were drained, with the consequent disappearance of the abdominal tumour. The cervix, which was adherent all round to the vaginal walls, was dilated and freed, during which there was considerable bleeding. The vagina was packed all round the cervix to prevent further adhesions, and the patient made an uneventful recovery and went home happy. This is a very rare case of congenital atresia of the vagina and of the cervix uteri, while the rest of the internal genitalia were apparently normally developed, the vulva also being normal. I do not think there are many similar cases on record in the literature.

Current Topics.

Willem Einthoven.

By S. L. BHATIA, M.C., M.A., M.D. (Cantab.),
M.R.C.P. (Lond.),

CAPTAIN, I.M.S.,

Professor of Physiology and Dean, Grant Medical
College, Bombay.

"To have striven, to have made an effort, to have been true to certain ideals—this alone is worth the struggle."—*An Alabama Student.*

Willem Einthoven, one of the great leaders in physiology in our day, was an Asiatic by birth. He was born in Samarang, Java (Dutch Indies), on May 21st, 1860. His father was a medical practitioner there. After his father's death in 1870, his mother took her six children to Holland, and settled in Utrecht. Willem became a medical student at Utrecht in 1878. After obtaining his degree in 1885, he became an assistant in the Physiology Department of Utrecht University under Snelling and Donders. From there he went to Leiden. He was appointed Professor of Physiology in Leiden University at the early age of 25, a position which he continued to hold till the time of his death, which occurred at Amsterdam on September 29th, 1927.

His chief work in physiology consisted in inventing and perfecting recording instruments of extraordinary delicacy. This was due to his great knowledge of physics, in which he was unusually well-trained. In the early part of his career, his interest was attracted by optical problems, and he carried out investigations in regard to the effects due to colour differences in monocular and stereoptical vision, the determination of the cardinal points of the eye for different coloured lights with the help of the refractometer, etc. In 1900 he demonstrated that a very high frequency alternating current was capable of stimulating nerves. He also worked out the movements of the soft palate, the action of bronchial muscles, etc.

But the actual work which will make Einthoven's name immortal in the annals of physiology and medicine was in the field of electro-cardiography. He carried out researches in this subject for more than thirty years. Electric currents in an exposed beating heart had been demonstrated by Waller in 1887 by means of Lipmann's capillary electrometer, and he obtained photographic records of the same. He later showed that these currents could be demonstrated in the intact bodies of animals and human beings. Einthoven worked on the principle of the d'Arsenval galvanometer, and devised a special thread galvanometer to record these currents. This was first described by him in 1901. It consisted of a silver-coated quartz thread stretched in a field, strongly magnetic. The movements of the thread resulting from the passage of a current were magnified by means of a microscope and recorded photographically. This instrument was found to possess extraordinary sensitivity, and is now universally used in hospitals and laboratories. He obtained a standardised curve for human beings with this instrument, and described the waves P, Q, R, S, T, their significance and variations in health and disease. The leads I, II & III, now universally employed, were originally described by him. By means of a microphone, he obtained graphic records of cardiac sounds. This is not the place, however, to give a full account of all his researches. Suffice it to say, that electro-cardiography owes a great debt to Einthoven. Its application to medicine has already yielded very useful results, and in physiology this method of investigation has solved many problems regarding the action of the heart.

I have a personal recollection of Einthoven. I had the pleasure of seeing him at Stockholm in August 1926 at the 12th International Physiological Congress. One afternoon he presided over one of the scientific sectional meetings. A man of medium height and moderate build,

very calm, and dignified, wearing glasses, with grey beard and moustache, faultlessly dressed in black is the picture of him that I have in my mind. With his clear-cut features, sharp penetrating eyes, a kind and generous expression of the face, looking remarkably well and active for his age, he reminded me to a certain extent of my Professor the late Sir Clifford Allbutt, Regius Professor, of Physic at Cambridge. *Vultus est index animi.* Einthoven had a charming personality. Sir Thomas Lewis, his great associate in the same field of work, thus speaks of him: "A man of simple, almost of humble habits he (Willem Einthoven) was untiring in his work, in its exposition, and in the study of related problems. He awakened in both friends and associates a profound admiration by his genius, by the charming simplicity of his character, by his touching if not child-like modesty of thought and manner, by his patience, by his natural and profound courtesy, by the warmth of his hospitality to those privileged to enter his home, by his unswerving devotion to truth in the most exacting sense. These noble qualities endeared him to all who knew him at all intimately." He spoke English with perfect fluency. In fact in the particular section of the Physiological Congress already referred to, he contributed his own remarks in the English language. His exposition was clear, brief and to the point. He was a man of profound culture and learning and possessed delightful humour, gentleness and loving kindness. In his work, he exhibited extraordinary diligence, patience and accuracy and by his labours strove persistently to add to the store of human knowledge. Owing largely to his work, the University of Leiden became renowned in the whole of Europe.

For his researches in physiology and medicine Einthoven was awarded the Nobel Prize in 1924. In the same year he was made an Honorary Member of the Physiological Society of England. In 1926, he was elected a foreign member of the Royal Society of London.

He remained in harness till he died in his 67th year. By his death physiology has suffered an irreparable loss. He belonged to that distinguished band of workers, to which men like Gaskell, Langley, Schafer, Sherrington, Gley and others belong, who during the last forty years or so have done so much to make physiology what it is to-day. Although he is no longer with us, Einthoven's work will live, even as the work of Johannes Muller, Carl Ludwig and Claude Bernard does, for all time, and his personality will remain a source of inspiration to all those who came after him.

The Tropical Diseases' Bulletin and a New Departure.

We regret that the pressure on our space has previously prevented our commenting on a new departure by our admirable contemporary, the *Tropical Diseases' Bulletin*. We need not emphasise the fact that the *Bulletin* is absolutely essential to every practitioner of medicine in the tropics: for month by month it summarises the whole of the published literature on tropical medicine, and there is no other journal which can quite take its place.

The new departure consists in a "historical" section dealing with early records of research and discoveries in the domain of tropical medicine. In the first number to contain such a section—that for May 1927—Mr. Clifford Dobell, F.R.S., deals with tropical medicine of the Portuguese of the *renaissance*, with notes in the 16th and 17th centuries on dysentery from Dutch authors; Col. W. P. MacArthur with the history of plague in the Middle Ages—a series of reviews of different papers, all of great interest—Lieut.-Col. A. Alcock, F.R.S., I.M.S. (retd.), with malaria in Les Dombes in the valley of the Rhone in the 18th-19th centuries, and with

old time leprosy in the days of Robert the Bruce. Ancient records with regard to dysentery and scurvy are also dealt with.

In all, a delightful number. There are to-day a few—but only too few—journals dealing with the history of medicine, first among which must be placed the sumptuous *Annals of Medical History*, which deals especially with America. The *Transactions of the Royal Society of Tropical Medicine and Hygiene* have always been remarkable for their reports of Dr. Andrew Balfour's delightful essays on the pioneers of tropical medicine; whilst the *Edinburgh Medical Journal* has always paid attention to the past history of medicine. With regard to India, the subject has been but very partially explored. In the first two editions of Sir Leonard Rogers' *Fevers in the Tropics*, there was an introductory chapter on the historical aspects of the subject, which was of absorbing interest, but it was deleted in the third edition.

The history of medicine, and especially of tropical medicine, is not unimportant. Most diseases of the tropics are of parasitic origin. Now the evolution of our knowledge of such diseases may be said to pass through certain well established phases: there is first the phase before the parasitic cause is discovered. During this, the physician has to depend entirely on his clinical acumen for his success in treatment, and hence this period is characterised by the rise of the great clinicians, from the days of Sydenham to those of Sir William Osler. The second phase opens with the discovery of the parasitic cause of the disease, and attention is now concentrated on laboratory methods of diagnosis. The third phase opens with the recognition of the fact that, if the causative parasite is important, of not less importance is the soil in which the seeds of disease are sown. With this phase is associated the recent rise of biochemistry in medicine. The fourth phase, as Sir Ronald Ross has insisted in his *Prevention of Malaria*, is the recognition that we must have quantitative as well as qualitative measures of disease, that mathematical and statistical methods must be introduced into the study of disease, whether in the individual or in the mass.

And the study of the history of tropical medicine very clearly illustrates the evolution of these four phases. It is not unimportant to get back to those wonderful early clinicians in India, or even further to the famous Indian clinicians of the Vedas; to study the evolution of the science of tropical medicine in this and other tropical countries. Castellani and Chalmers' well known *Manual of Tropical Medicine* is of special value for its wealth of information on the history of the subject, but perhaps textbooks of tropical medicine might well include, for the benefit of future generations, one or two introductory chapters on the subject.

In any case we are delighted to bring to the notice of our readers the new departure on the part of our well known contemporary. The *Tropical Diseases' Bulletin* only costs 21s. a year, and is or should be the vade-mecum of medical practitioners in the tropics. The editorial office of the journal is the Bureau of Hygiene and Tropical Diseases—23, Endsleigh Gardens, London, W. C. 1.

The Cinema in Medical Education.

THAT the world moves too fast has always been the complaint of the middle-aged. But both youth and middle age, as far as the medical profession is concerned, are agreed that the present medical curriculum is too congested, and that something will have to be done to reform it.

Is that "something" the cinema? We are tempted to ask the question on receipt of a copy of a most interesting address on the "possibility of medical movies" by Dr. J. F. Montague, M.D., F.A.C.S., to the American National Board of Review. In olden days the making of a doctor was a simple matter; the would-be candidate apprenticed himself to a local medical celebrity and subsisted on the crumbs which fell from the great man's table, or else after study set up for himself in a less

densely populated part of the countryside. But universities, medical Registration Acts, and legislation in general have revolutionised "the good old times."

In some ways this is a pity, for there is nothing which can replace the intimate touch of personal teaching between master and disciple. It has always been such personal teaching of the essentials of clinical medicine that has distinguished British medicine.

To-day, however, the highways of medical education are over-congested, and Dr. Montague calls in the cinema to re-adjust matters. The medical school books of the future, he claims, will be made of celluloid. In the teaching of anatomy cinema demonstrations can give the student a real and vivid presentation of the subject (but not—we venture to submit—if they go through at the speed at present current in the cinematograph). Every detail of medical and surgical technique can be made visible on the moving film; in fact a cinema film photographed from just above the operation site will give a student a far more vivid and true picture of the steps of the operation than he can obtain by overlooking the operation from a side gallery where he obtains but a partial view. "These films have the advantages of presenting clear and detailed data, and making these data permanently and instantly available; of being readily accessible and capable of countless repetitions. Moreover films are capable of additions, selection, editing and re-arrangement." Experiments in physiology may be demonstrated on the films, and full details of diseased conditions exhibited much more fully than they could be on the actual patients themselves. The film will save the student's time, for it will give him a rapid visualisation of the subject, and leave him time for its more detailed study in textbooks.

In public health propaganda the cinema has come to stay; in fact it is not too much to say that if ever a "public health conscience" is to be awakened in India, the cinema may be the most important factor in its creation. All Directors of Public Health in India have realised this, and the "exhibition trains" which now traverse the rural parts of India on the different railway systems always make a special feature of public health propaganda films.

We are all in favour of the cinema in medical education, for its educational value is enormous. We are accustomed, indeed, to use it very largely ourselves. If one has described the life-cycle of a parasite to a class of students, nothing will impress it more on the class than to see such a life-cycle on the screen. We have "mechanised" the Army—much to the disgust of its cavalry regiments. But, a question lurks behind. Are we going to mechanise the teaching of medicine? We rather fear for the medical student of the future. If his knowledge of anatomy, physiology, surgery, and obstetrics is to be derived from the films, we fear that it will become too superficial. If his knowledge of cardiac sounds is to be derived from the loud speaker, we fear that he may not recognise them through the stethoscope. The cinema has its place—a very important one, we would judge—in the medical education of the future; but neither it, nor anything else, can replace the personal touch of master and pupil. We can imagine the medical student of 1950 instructed in the dissection of the head and neck by a study of a cinema film, but we wonder whether he will derive as much information of real value from it as he would from dissecting out that area for himself. The cinema is an invaluable adjunct to medical education, undoubtedly; but it remains an adjunct, and we would resist to the utmost any tendency to "mechanise" medical education.

Milk Injections in Leprosy.

IN the *Transactions of the Royal Society of Tropical Medicine and Hygiene* for January 1928 (Vol. XXI, No. 4, p. 305), there appears an amazing—not to say amusing—article by Dr. N. A. Dyce Sharp, of the West African Medical Service, Nigeria, on "a new treatment for the leper."

Dr. Dyce Sharp first comments on the fact that what most workers on leprosy appear to aim at is producing severe, but not too severe, reactions in the leprotic tissue by the injection of various products. The efficiency of moogrol intravenously appears to be in proportion to the severity of the initial reaction. Sir Leonard Rogers notes that the cases which reacted most favourably to sodium gynocardate and sodium morrhuate were those which showed most reaction, although he regards such cases as very exceptional. Waldron, in a study of moogrol treatment in West Africa, states that he usually aims at a definite febrile reaction lasting for two to three days.

The rest of the story must be given in Dr. Dyce Sharp's own words, which we quote almost in *extenso* from his article.

The Choice of an Agent.

These observations seem to indicate that the essential feature in the treatment of advanced cases of leprosy is the degree of the initial reaction, and it would, therefore, appear that any substance which will produce a smart reaction in a leprosy individual will, in all probability, achieve a beneficial result quite apart from any specific action. If this is so, the shock which we have learnt to produce by the intravenous of various protein bodies should in such cases have an equally potent action, and it is the purpose of this note to suggest that most of the beneficial results of intravenous medication on the leper are thus produced and to put forward a ready method of achieving this end which is both cheap and easily administered.

Given that the shock is to be produced by a protein body, it remains to decide what form of protein is best suited to the purpose.

T.A.B. vaccine—the protein most popular in England, is not available in the tropics, and is in any case too costly for use on a wide scale. *Egg albumen* is perhaps the next best form in which to administer it, but fresh eggs are desirable, if not imperative, and to spend one's days squeezing premature eggs out of tardy layers is a tedious and tiresome occupation. *Fresh milk* is rarely available in tropical countries, but *tinned milk* prepared under the most hygienic conditions and perfectly free from preservatives of any sort can readily be obtained in any part of the world. "Milkmaid Brand" was chiefly used by the writer for the bulk of the cases, but "Ideal Milk" was also used in some of the cases intramuscularly. The mode of preparation is identical but there is a slightly higher solid content in the latter.

The Procedure.

The procedure was as follows:—

The top of the milk tin was cleaned and a small hole made in it with a sterile nail.

Two or three c.cm. of milk were slowly drawn up into a 10 c.cm. syringe and diluted with distilled water in a test-tube so that the strength of the solution was 1 in 10. The standard dose of 0.5 c.cm. of tinned milk was therefore contained in 5 c.cm. of diluted milk.

The injection was made very slowly into the vein and the patient was immediately placed on a couch with the head as low as possible.

The Results.

With a reaction of average severity there was first of all a feeling of giddiness coming on within half a minute and the patient might fall before reaching the couch. Within three or four minutes there would be marked respiratory distress and often precordial pain of greater or less severity. Commonly a dry irritable cough would occur and might last for ten minutes. Within five minutes of the injection there was always intense pain in all the joints, especially in those already affected, together with a very severe frontal headache, but the most pronounced seat of the pain was usually in the lumbar region. After another five minutes a profuse perspiration would appear on the face, and thereafter there would be a general amelioration of all the symptoms; the pulse, which had become gradually

feeblér until quite imperceptible, would now become bounding and regular; the pains would diminish but not disappear and the respiratory distress would vanish. After half an hour or more the patient was generally able to go home. At night the secondary reaction would set in and the temperature would rise to 103°F. or 104°F. and there might be a nocturnal rise for several nights. No food was allowed on the first night and there was rarely appetite on the second day.

The effect of the first injection was in each and every case to give complete relief from pains in the joints and bones and from formication within twenty-four hours. This was all the more remarkable because as a rule at the end of twenty-four hours the leper was still suffering from fever and anorexia, but his relief from pain was so profound and so rapid as to overshadow the ill-effects of the injection. At the end of forty-eight hours the temperature was usually normal, there was almost complete freedom from pain (the exceptions being septic ulcers which remained painful until clean) freedom from formication at night and marked reduction in hyperæsthesia.

Within a week red maculæ would be appreciably black in the centre and the red margins less pronounced. Perforating ulcers of the soles of the feet may become painless and clear up in three or four days. In three cases nodules on the brows and ears have been absorbed in ten days, and in most of the cases the skin resumed its normal unwrinkled appearance, to the amazement of the leper's friends, in two to three weeks. In one case this change was apparent in the first seventy-two hours.

The improvement and the changes described are not necessarily permanent and relapses are apt to occur. A second injection may then give further beneficial results which, however, are less marked for obvious reasons.

In two cases—an old man of 55 and a frail woman of 50—the injection was given into the buttocks. Given thus it may be almost painless or, more commonly, extremely painful. When given into the muscle there is little if any immediate reaction but, provided there is a smart febrile reaction a few hours later, the end results seem to be the same.

This note refers to twelve cases only. Of these only four have been followed up for as long as five months. The rest drifted away because, it was alleged, they found themselves cured. There was no doubt of the benefit they had received. One boy who had only been able to crawl the few yards to the hospital and back for many months while undergoing treatment with moogrol was later seen carrying an eighty-pound bag of rice on his head from the beach to the town. He had had two milk injections. In another case a former blacksmith was enabled to resume his occupation in Government service after five injections of milk. He had had previously one year's intramuscular moogrol and seven months' intravenous moogrol.

Discussion.

This treatment, which is admittedly drastic and undoubtedly dangerous, seems to be especially applicable to the late and more hopeless forms of the disease. Like so many other remedies it will not replace lost fingers and toes, but it can and does have a profound effect on the torpid indolent ulcers that affect the extremities, and can assist to heal otherwise incurable ulcers. It is possible that this treatment has no effect on Hansen's bacillus, but it has at least enabled the majority of cases treated to earn their own living once more in more or less strenuous employment. And this is what the leper wants. Whether it would be of service in the early cases of childhood has yet to be determined. Probably, it would prove decidedly harmful. The severity of the immediate reaction is at times so extreme as to be positively alarming and it is only the otherwise hopeless prospect of the patient that has made this particular investigation feasible.

Desperate remedies are sanctioned by desperate cases, and the dangers inherent in a line of treatment of which the physiological mechanism is still so obscure are manifestly considerable. But having acknowledged

its disadvantages, its vast possibilities of benefit to the hopeless leper remain, and this paper will have served its purpose if it draws the attention of medical men in charge of leper camps to a line of treatment which demands extensive and careful investigation under all sorts of conditions.

Leptospirosis in Malaya.

AN exceedingly interesting paper on this subject by Dr. William Fletcher, M.D., M.R.C.P.,—formerly Director of the Institute for Medical Research, Kuala Lumpur, and now Secretary to the Medical Research Committee of the Colonial Office under the British Medical Research Council—appears in the *Transactions of the Royal Society of Tropical Medicine and Hygiene* for January 31st, 1928 (Vol. XXI, No. 4, p. 265). As with all Dr. Fletcher's papers, this one is illustrated by most admirable photographs taken at post-mortem examination of patients or inoculated animals. The paper indeed constitutes a standard account of Weil's disease as it is met with in Malaya, and will be of special interest to those who are on the look out for similar cases in India, where the disease almost certainly occurs. Malaya, explains Dr. Fletcher, is not only relatively healthy; it is also relatively wealthy; and "the Government is very ready to help medical research in every way by providing equipment and money."

The first patient observed was diagnosed almost by accident. In trying to obtain the virus of "tropical typhus" the blood of suspected patients was being inoculated into guinea-pigs. This patient—a Punjabi—had been suddenly taken ill five days previously with severe pains in the head, fever, and vomiting. His eyes looked as if someone had thrown pepper in his face, and there was hyper-acute pain in the muscles of the arms, legs, and back. The urine showed a trace of albumin, and there were a few rose spots on the back and in the axillæ. The temperature finally came to normal on the 9th day.

Obviously this was not typhus, and but little further attention was paid to the matter until one guinea-pig died and the other became severely ill 13 days later. Both showed extreme jaundice and hæmorrhage from the nose. On post-mortem examination leptospira were found in the blood and in films from the liver and kidneys. The virus proceed fully virulent on passage. The cardinal lesion in inoculated animals is one which we believe has not been previously described in the textbooks; a condition of "butterfly lung." In this, in addition to jaundice of the lungs, there is hæmorrhagic and circumscribed mottling of the lungs, so that on section the lung resembles a butterfly's wing in appearance. In addition to this, post-mortem examination of the inoculated animals shows an almost universal condition of jaundice and hæmorrhage.

For culture of the leptospira the following simple medium was found to be most satisfactory: it consisted of 5 c.c. to 7 c.c. of sterilised tap water or distilled water, with the addition of 0.5 c.c. of melted 2.5 per cent. nutrient agar and 1 c.c. or a little less of rabbit serum. To inoculate the medium from the patient's blood, 0.5 c.c. of blood is withdrawn from the vein and added to the medium, which is incubated at body temperature and examined under the dark-ground at the end of a week. Leptospira usually appear in the bloodstream about the 5th or 6th day of disease, and usually disappear again about the 7th day of disease. (It is probably precisely this fact which makes it so difficult to establish the existence of Weil's disease in India.) If immune serum be added to the culture tube before it is inoculated the leptospira show agglutination into granular lumps and granules as they grow, and not the diffuse hazy growth in the upper half of the medium that occurs with normal rabbit serum.

The leptospira, Dr. Fletcher notes, are very difficult to see in the patient's blood by examination under the dark-ground microscope. They are so small, so thin, and so very active that their movements do not disturb the red corpuscles, as those of relapsing fever

spirochætes do. "All that one sees is a flash of light, and they are gone." A far better method is to stain blood films by Fontana's method. The leptospira in the blood are always very scanty, however; they were only found in blood films from 3 out of 32 cases investigated. Blood culture is far more satisfactory and almost always yields a positive result, if carried out before the 8th day of illness.

Leptospira appear in the urine, and can be detected in the centrifuged deposit from about the 15th day of disease onwards; the urine has been found positive as late as the 32nd day after onset of the disease, and well into convalescence, but this point could not be properly studied because patients would not stay in hospital after they were convalescent. The leptospira in the urine are not the delicate, beautiful, actively motile forms seen in culture, but sluggishly motile or dead and often loaded with adherent debris which gives them a "mossy" appearance—the so-called Rieckenberg phenomenon. Probably there are immune bodies excreted in the urine, and these tend to paralyse the spirochætes. Again, culture, or inoculation of guinea-pigs is the most certain method of isolating and demonstrating the organism. In general, it may be said that the urine is positive from the 15th to the 25th day of illness.

There then follows an account of an investigation into the serological reactions of the strains of leptospira isolated, both by agglutination methods and by the Pfeiffer reaction. Strains supplied by workers in other parts of the world were also tested. The general result is to classify the leptospira into six main groups; *L. icterohæmorrhagica* and *L. icteroides*, which behave alike; *L. hebdomadis*, type A; *L. hebdomadis*, type B; *L. pyrogenes*; and two other unnamed groups. *L. icteroides* behaved in every way like *L. icterohæmorrhagica*, thus confirming the recent contention of American workers that *L. icteroides* is not the causative micro-organism of yellow fever.

Of the 32 cases only one proved fatal, and this patient appears to have contracted the infection in the hills 40 miles from Kuala Lumpur. The disease in brief is one of the country, and not of towns. Sudden onset is noted as a marked feature—31 cases. Great prostration was present in all; agonizing muscular pain and tenderness in 29; casts and a trace of albumin in the urine in 28; and acute redness of the eyes in 22. Jaundice was absent in 18 of the 32 cases. Epistaxis was present in 4 cases, other hæmorrhages in 2, and a hæmorrhagic rash in another 2. Vomiting was present in 15 cases and intense headache in 8; diarrhœa in 6. Taken together, these symptoms form a very definite clinical picture, with the diagnosis confirmed either by culture or inoculation of guinea-pigs. The duration of the fever varied from 6 to 12 days, but was most commonly about 8 to 9 days; the fever is not a "seven-day fever" in other words.

Possibly associated with these cases was a curious epidemiological phenomenon. What appears to be true Weil's disease has previously been recorded by a few observers in Great Britain as occurring among dogs. Now in the previous Christmas there had been very severe floods in Malaya, and this had been followed by an outbreak of epidemic hæmorrhagic jaundice among dogs in Kuala Lumpur. Post-mortem examination suggested that this was due to leptospirosis, and finally a leptospira strain was isolated by inoculation of guinea-pigs. Puppies proved experimentally susceptible to inoculation with this strain. The dog strain proved serologically identical with *L. hebdomadis*; and the disease was especially associated with hæmorrhages into the mucous membrane of the stomach.

Leptospira were also isolated from the Kuala Lumpur water supply, and from rats in the locality, the rate of infection among the latter being as high as 26 per cent. These strains of rat origin again corresponded serologically to *L. hebdomadis*. The water leptospira proved to be practically non-pathogenic to guinea-pigs.

* * * * *

In the discussion which followed the reading of Dr. Fletcher's paper several well known workers took part. Major H. C. Brown, I.M.S. (ret'd.) commented on

the value of Dr. Fletcher's culture medium, which he had since found to be of great value. Dr. Manson-Bahr commented on the great variability of symptoms and of mortality in leptospiral diseases. Dr. Andrew Balfour discussed the possibility that *L. icteroides* is the same organism as *L. icterohæmorrhagie*; Dr. C. M. Wenyon the possibility that non-pathogenic strains of leptospira might acquire virulence under certain conditions.

The whole paper and discussion are of great importance in tropical medicine, and we would refer laboratory workers and clinicians alike to the original text. It is a paper which marks a very definite step forward in our knowledge of leptospiral diseases in India and the adjacent countries.

Beri-beri in Burma.

IN connection with the beri-beri problem, Burma perhaps presents unusually interesting conditions. True beri-beri is well known in Malaya, whilst epidemic dropsy—if this disease be regarded as a "wet" type of beri-beri—is often epidemically prevalent in Bengal. Geographically, Burma occupies an intermediate position between the two, and if beri-beri is an infectious disease, its relative prevalence in Burma would be of interest. Further, if beri-beri is not an infectious disease, but is a food-intoxication disease due to diseased rice or other food, then, since the population of Burma consists of so many different and mixed races with different dietaries and habits, the study of beri-beri in Burma cannot fail to be of interest.

A report on the results of a preliminary investigation into beri-beri in Burma by Lieut.-Col. J. Taylor, D.S.O., I.M.S., Major C. de C. Martin, I.M.S., and Sub-assistant Surgeon U. Thant, from the Pasteur Institute of Burma, constitutes *Indian Medical Research Memoir No. 8*, March 1928, published as a supplement to the *Indian Journal of Medical Research* (Thacker, Spink and Co., Calcutta; price Rs. 2-12-0).

After presenting a detailed analysis of all the figures and information available, the authors conclude as follows:—

1. (a) Over the greater part of the populous agricultural areas of Burma beri-beri is not endemic or epidemic to any extent, and although cases do occur, their total number is small.

(b) There is a regular annual incidence in the larger coastal towns, notably Rangoon and Bassein, which mainly affects Hindu labourers who are temporary immigrants from India.

(c) Outbreaks of beri-beri frequently occur in certain small communities living under special conditions. These epidemics occur in timber-felling camps in forests, military police posts, schools, lock-ups, light-houses and light-ships, etc.

(d) In one outlying area of the province, viz., the Upper Chindwin district, beri-beri is probably of more frequent occurrence than in the rural areas of the rest of Burma. Other such areas may exist and require further investigation.

2. (a) The diet of the average Burman, both in towns and villages, is generous and varied and comprises a good allowance of other articles in addition to rice. In the villages a good quality of freshly hand-pounded rice is used, and in the towns undermilled rice is usually eaten. Under normal circumstances the rice mills only mill up to immediate requirements, and the rice is not usually stored for long in the milled state.

(b) Mahomedan dietaries, taken from town figures, are somewhat similar to Burmese, but are slightly less in their quantities of food-stuffs other than rice. Special enquiries have not been made into diets of Mahomedan coolie gangs.

(c) The diet of vegetarian Hindus is similar to that of the same class in India, and shows the use of considerable quantities of atta as well as the use of milk and milk products. The use of atta will be of value in replacement of any vitamine deficiency in the rice used.

(d) The meat-eating Hindus form a large class with somewhat varied diet habits. Their dietary is distinctly

inferior to that of Burmans, and in the case of certain groups is extremely badly balanced. Large groups of Indian immigrant coolies, chiefly Hindus from Madras Presidency working in the larger coastal towns, consume large quantities of rice, frequently 2½ lbs. a day, and use extremely small quantities of any supplementary articles of food.

3. The outstanding feature of beri-beri in Burma is its incidence amongst the Hindu labourers in the larger towns, large groups of whom use an almost exclusive rice diet.

4. The outbreaks under the special circumstances mentioned in 1 (c), the records of which have been examined or in which investigations have been made, appear to be associated with two factors which prevail in varying degrees. These are (a) a diet consisting largely of rice, with a minimum amount of other food-stuffs; and (b) conditions favouring the deterioration of rice which occurs readily when rice is stored in the husked state in the damp conditions of the monsoon in Burma.

5. There is a definite seasonal prevalence of beri-beri in Burma, commencing about two months after establishment of the monsoon, reaching its height about October, and diminishing during the cold weather months.

6. The deterioration of rice from damp and moulds appears to be a very important factor in the outbreaks which we have had an opportunity of investigating. It is not possible to form a definite opinion on the evidence obtained as to whether the production of any toxic substance in the rice may influence the occurrence of beri-beri, or whether the necessary washing of the friable mouldy rice to make it fit for consumption results in such loss of the outer layers of the grain as will materially reduce its vitamine content.

7. The varied and generous dietary of the average Burman under normal circumstances would appear to be a very important factor in preventing the occurrence of beri-beri under ordinary town and village conditions.

Monsol.

THERE has been so much discussion in the lay papers recently regarding the newly introduced antiseptic Monsol—(manufactured by the Mond Staffordshire Refining Co., 47, Victoria Street, London, S. W. 1)—that we take the liberty of reproducing the following report on the new preparation from *The Practitioner* of March 1928, p. 207.

Monsol is a germicide derived from the oils produced by the gasification of coal by the Mond Power Gas Process; these oils are fundamentally different from those produced by the ordinary process of coal-gas production. In a series of animal experiments to determine the lethal dose, it was found that while 2.5 c.cm. of lysol was fatal to a rabbit, 15 c.cm. of monsol was not, the assumption being, therefore, that monsol is over six times less poisonous than lysol. Other experiments showed that the tolerance of animals to intravenous injection of monsol was remarkable, no ill-effects following the injection of considerable quantities. As a result of bacteriological experiments, it was found that monsol exerts a selective action on streptococci, an opposite effect to that produced by phenol and by coal-tar antiseptics produced by the ordinary process. As regards irritant properties, that monsol is reasonably non-irritant is shown by the fact that while lysol produces a burning sensation on the delicate skin between the fingers, monsol produces no irritation, and on being applied to the tip of the tongue only a slight stinging sensation is produced. To the practitioner, however, the most important test of every antiseptic is the clinical one, and from this searching test we find that monsol emerges triumphant. We find it to be remarkably penetrating, apparently stimulating phagocytosis, and it promotes the formation of healthy granulation tissue in ulcerative conditions. Upon mucous membrane its action is stimulating yet bland, and it is valuable as a douche, spray or gargle. Internally it appears to be similarly valuable in its antiseptic and non-toxic effects. The mass of

clinical evidence collected from many hundreds of practitioners, which has been submitted to us, agrees with these observations, and speaks volumes for the value of this new germicide. Monsol is obtainable as monsol liquid, which forms an instant bland emulsion on being added to water, as monsol ointment, as monsol capsules, for internal administration including asepsis of the lower alimentary tract and the urinary tract, and as monsol pastilles, which have been especially designed to ensure slow solution in the mouth.

Injection of Cerebro-spinal Fluid in the Treatment of Tetanus.

THE treatment of tetanus is so difficult in India, and the specific antiserum either so difficult to obtain or impossibly expensive, that our readers may be interested in the following note from *The Practitioner* of March 1928, p. 206.

G. Spanyi records his experience of withdrawal of cerebro-spinal fluid in tetanus and its re-injection subcutaneously. He advises this method of treatment as an adjunct to the administration of anti-tetanic serum, basing his opinion on a series of ten cases of tetanus treated in this way. Five to 10 c.cm. of cerebro-spinal fluid were withdrawn in each case and re-injected into the skin of the thigh or the abdominal wall. Of these cases seven, or 70 per cent., recovered, whilst in twenty-seven other cases treated by serum alone the recoveries numbered twelve, or only 44 per cent.—(*Schweizerische Medizinische Wochenschrift*, October 29, 1927, p. 1047.)

The Metadysentery Bacilli.

THE work of a pioneer is always of interest, and in the extremely difficult field of the bacteriological study of those bacillary strains of organisms which are apparently associated with dysentery and possibly pathogenic, but which do not conform to the tests for the true dysentery bacilli, Sir Aldo Castellani has always been a pioneer. In a recent paper in the *Journal of Tropical Medicine and Hygiene* (15th November, 1927, p. 285), he presents what is at least a preliminary proposed classification of this very difficult group of bacteria. The paper contains tables of the sugar and other reactions of the different types which will be of great interest to laboratory workers in general. Dividing the strains isolated into two main sub-tribes, viz., those which do not produce gas in glucose or any other sugar, and those which produce gas in glucose and in most other sugars, he identifies six genera in the first and five genera in the second—and proceeds to give the points of identification of the eleven genera concerned, based upon their reactions in milk, lactose, and glucose media. One important lesson in the paper is that, when such organisms are pathogenic, the patient's serum usually agglutinates to them in a high titre. In such cases treatment with an autogenous vaccine often completely clears up the symptoms present.

In his conclusions, the author writes as follows:—

(1) There are several clinical conditions in which organisms of the *metadysentery group* (*Lankoides-Dysenteroides* group) have been found. These conditions may be acute, subacute, or chronic. There may be dysenteric diarrhoea or there may be simple diarrhoea. In certain cases fever may be present and may be a prominent symptom, so much so that some form of enteric or para-enteric may be suspected.

In this paper I have called attention to a chronic type of colitis characterized by recurrent attacks of diarrhoea, generally simple diarrhoea, but occasionally dysenteric for brief periods of time. Between the attacks the symptoms are somewhat indefinite and obscure. The patient feels tired, disinclined for work, nervy, and often complains of slight abdominal discomfort and

flatulency. The symptoms are so indefinite that very different diagnoses are made: intestinal intoxication, intestinal subinfection, mucous colitis, abdominal neurasthenia; not rarely a typical appendicitis is suspected and an operation is performed.

(2) The metadysentery bacilli are intestinal bacilli similar to the dysentery bacilli Shiga and Flexner with regard to certain characters, viz., they do not produce gas in any sugar; they differ, however, from them as they either clot milk and produce acidity in lactose, or they clot milk without producing distinct acidity in lactose, or they produce acidity in lactose without clotting milk. Some species of the so-called metadysentery bacilli group (*Lankoides-Dysenteroides* group) are pathogenic, others probably are not. The two principal species I found in 1905 and published in 1907 and 1908, viz., *B. ceylonensis* B and *B. ceylonensis* A, are, in all probability, pathogenic, and so is the *Bacillus metadysentericus* described by me. In the chronic conditions I have discussed, the blood of the patient generally contains a large amount of agglutinins for the variety of metadysentery bacillus isolated from the patient's stools, as well as the same variety isolated from other patients with the same symptoms. In one of the recent cases three varieties of *Lankoides* were isolated from the stools—two (*B. ceylonensis* B and *B. ceylonensis* A) were agglutinated equally well by the patient's blood, and the agglutinins were specific; the third variety, a strain of *B. madampensis*, was not agglutinated, and was probably non-pathogenic. This case was probably one of mixed infection caused by a strain of *B. ceylonensis* B + *B. ceylonensis* A of the metadysentery group.

I shall be pleased to supply workers interested in the subject with cultures of *B. ceylonensis* B, *B. ceylonensis* A, and certain strains of *B. metadysentericus*.

ESSAY REVIEW.

MALARIA INVESTIGATIONS BY THE DEPARTMENT OF PUBLIC HEALTH, BENGAL.

(i) Report of the Malaria Survey of the Jalpaiguri Duars (1926). [Official.] By S. N. Sur & M. O. T. Iyengar.

(ii) Report on the Malaria Survey of the Environs of Calcutta (1928). [Re. 1-6-0.] By M. O. T. Iyengar.

(iii) Report of the Field Malaria Observatory at Sonarpur during 1921—1925 (1928). [Official.] By M. O. T. Iyengar & P. Sur.

THE Director of the Central Malaria Organization once told the writer that, in his enquiries into the existing literature on malaria in India, he was extraordinarily impressed with the amount of work which at one time or another had been done, and which was largely buried in official reports in various offices, many of them only in manuscript form, which, if more widely known, would help to remove a somewhat widespread extra-India opinion that in this country comparatively little has been accomplished in connection with the study of the most important disease of the Empire. Though it has not been the fate of the three

reports here dealt with to blush unseen in manuscript, none the less, seeing that two of them are "for official use only," they will probably be far less widely read than they deserve, unless, as is hoped, this article draws the attention of malariologists all over the world to their detailed study. For detailed study they are well worth.

In (i), Dr. Sur and Mr. Iyengar deal with the disease in a group of tea estates in the Himalayan foothills. The paper should be read in juxtaposition to Dr. Strickland's recent report on malaria in Assam, recently reviewed in these columns by the present writer, and bearing in mind descriptions of estate-malaria in somewhat similar terrain in Malaya and in Ceylon by Sir Malcolm Watson and the present writer, respectively. In all cases the same species are incriminated as carriers, namely *A. maculatus* and *A. funestus*, by whatever of its varietal names the latter may be known locally, and the present report emphasises, more clearly than anything we have yet read, the disappointment and waste of money that can result from trifling with the control of these species. At Meenglas Estate, the Public Works Department worked on an *obiter dicta* of Sir Malcolm's, that the abolition of anopheline breeding within a 20-chain radius circle would abolish malaria from a spot in the centre. They would therefore appear to have drawn a mathematical circle round the estate tea-factory as a centre, and only attempted control within its perimeter. Now in such relatively minute distances as 20 chains nothing must be left to chance, and it is obvious to anyone having experience of tea estates that if the centre of the circle was the factory, the coolie lines, the protection of which was the desideratum, would be some distance out along various radii from the factory centre. It does not need the disheartening mathematical theorizing quoted to realize that a failure must be the result. The correct application of Sir Malcolm's thesis would in any case result in the protection of an ellipsoid, whose foci would lie at the two most distant points of the blocks of coolie lines. Again, I think that a moment's consideration would have shown that the Malayan thesis was not strictly applicable. Malaya grows rubber, not tea, and a rubber estate resembles a block of pure forest devoid of undergrowth, with all the flight impediment that forest is known to give. Such is absent from the low growing bushes of a tea estate, even if, as is possibly the case at Meenglas, there is a spare admixture of various shade trees among the tea.

We then learn that on failure of the theoretical scheme to provide protection, the area treated was extended to the whole garden. Unfortunately the sketch-map accompanying the report has no scale attached, but from

the description of Lower Fagoo Estate also appearing in the map, Meenglas only appears to be about half a mile broad in all, by one and a quarter miles long, so it is obvious that, even if the factory lines are situated at about the actual centre of the estate, the extension of control to the whole garden can only afford 20-chain protection in two directions, even though the other quadrants are protected to twice that distance. The reduction of the spleen-rates experienced after the taking in of the increased area is eloquent, not of the original failure to eliminate mosquitoes by the means adopted, but of the results of too rigid application of a Master's theorem under unsuitable conditions. Only a pedant mind would omit to control a breeding-place because it lies a few yards beyond a rigidly drawn line. The original failure, however, reflects in no way on Sir Malcolm Watson, little indeed on those originally responsible for the idea of control, but solely on the Public Works Department for pedantry, unless, indeed, their defence is that they were conducting a strict experiment to test the Watsonian hypothesis!!

The description of uncontrolled conditions, and their results on the neighbouring estates, which follow, are of extreme interest as illustrating once again the ravages of malaria among estate labour forces, and one wonders at the financial perspicuity of the managements that allow such losses to continue. Surely an annual expenditure of Re. 1 per head (which is all that was required at Meenglas) is justified to eliminate malaria.

A final, most interesting point, brought out by examination of the working of the original scheme, is that control cannot be brought about by an automatic flushing arrangement designed to reproduce a rainfall spate. The writer had more than once thought of trying out such an arrangement for himself, but finds here the experiment already done for him.

(ii) Extremely interesting as are the facts elucidated and tabulated in this paper, one is only left in the dark as to any explanation of the reasons underlying these. In respect of its primary object, the discovery of areas suitable from the health viewpoint for extensions of the city of Calcutta, the report is satisfactory, inasmuch as it indicates where such healthy areas are to be found, and as equally unsatisfactory, inasmuch as it shows that such healthy areas are invariably so lowlying as to be entirely unsuitable for residential purposes, and one wonders whether reclamation, to raise levels and provide approach roads, might not easily alter the sanitary status of the selected sites. But, on the scientific side, the mechanism governing the extremely patchy distribution of malaria is barely hinted at. There are

references to "dead rivers," etc., but out of the mass of detail presented we cannot form a clear mental picture of the essential differences in water lay-out (to coin a phrase), with its attendant differences in anopheline species, that distinguish a malarious from a healthy patch in what, at first sight, appears an almost uniform stretch of country. Mr. Iyengar, as all his other work shows, has an excellent eye for mosquito ecology, and from the material at his disposal in drawing up this report, will, we hope, formulate for us parallel pictures of the water and faunistic differences between, for instance, Sinthi and Naparo villages on the Barrackpore Trunk Road, where, in a few furlongs, the spleen-rate rises from six to seventy-three per cent., or between the absolutely healthy Ghariabad and the contiguous Dattabad, with 16 per cent., in Dum Dum Thana, in respect of which last pair we read that the non-carrying *A. rossi* is the only anopheline found in both villages.

Why, in this country, *A. stephensi* does not, as in the Punjab and elsewhere, spread out from its wells into open waters, and why *A. ludlowi*, known from only twenty miles further down the Delta, does not spread into waters which the present report shows to contain *Enteromorpha*, are not only problems of great scientific interest, but of vital importance in their solution to the continued existence of many of the suburbs of the city, for changes which would bring about such invasions would undoubtedly, create a situation of the most extreme gravity. Lest these changes be inadvertently brought about, we must strongly urge the necessity for, in particular, the discovery of the factor which inhibits the nearer approach of *A. ludlowi* to Calcutta.

(iii) It has seldom been our lot to read a paper on malariology of which we so thoroughly approve. Investigations on a group of villages made, not *pari passu* with an attempt to control malaria, as is too frequently the case, but entirely as a detailed study of the factors governing the uncontrolled incidence of the disease over an extended period, have long been wanted in connection with malaria investigations in India, and we most heartily congratulate Dr. Bentley, the Director of Public Health, who conceived them, and the authors, who carried them out so thoroughly. Even so, one can only regret that the exigencies of printing seem to have prevented the reproduction of the breeding-place maps, and of greater details concerning those breeding-places that have shown a specifically fluctuating Anopheline fauna, in comparison with those in which the species complex has remained constant. The authors most rightly in consequence warn against the

carrying out of anti-anopheline measures on the results of a single survey, as is commonly done, in areas such as Deltaic Bengal. The writer, who two years ago carried out detailed surveys of Santragachi, in similar country west of the Hooghly, repeated his January examination in July, and found, at the second examination, specific changes in the Anopheline fauna of various ponds and tanks sufficient to engender doubt as to the probability of effecting the least improvement in health by dealing only with the proved breeding-places of carrier species, and after reading this report, feels confident that anti-anopheline measures in the Delta must be based on very much more extended surveys (in respect of repetitions in time), than are found sufficient in other types of country.

The report brings out many other most interesting points. The meteorological tables, for instance, show that in the Calcutta district the transmission of malaria is possible right through the year, the minimum fortnightly average being for humidity 73 per cent. and for 8 a.m., dry bulb temperature 66.1°F., but for all that we still see, as is general over the plains of India, the maximum fever incidence in September-November, as in districts where there is no pre-monsoon transmission. This season is that of the close of the period of maximum humidity—(there is no noteworthy temperature difference until near the end of the quarter)—which to the writer's mind indicates that for India the original work of Jancso requires repetition and amplification.

The report briefly mentions a point which also struck the writer during his Santragachi survey previously referred to, that there seems to be an association between *Eichornia crassipes*, the water hyacinth, and *Anopheles funestus*. If this point could be definitely proved, the "lilac devil" would be saddled with responsibility for an even more serious crime than any it is yet convicted of, and the railway and road embankments perhaps released from the rather vague charge now advanced against them. It is a pity that Dr. Strickland's recently published Anopheline survey of Bengal did not touch on this point, which only needs extended observation for its elucidation.

The question of responsibility for transmission in this part of Bengal is gone into, but the results seem to the writer to be inconclusive. The report appears to blame *A. fuliginosus* almost equally with *A. funestus*; though on page 28 the importance of the latter is emphasised.

Chart X, the relationship between the fluctuation in the spleen-rate and the prevalence

of the two carrier species is extremely interesting, but against *fuliginosus* being the principal culprit we see the following facts:—

practically closed down as from 1926. There can be no doubt that it was doing work of particular value to the science of malariaology

1922	Spleen-rate max.	5 months after <i>fuliginosus</i> max.	2 months before <i>funestus</i> max.
1923	do.	4	1 do. after do.
1924	do.	9 } 7 } 4 }	2 do. after do.
1925	do.	3 } 1 }	1 do. before do.

Now from charts X and XI it appears that the date of the spleen-rate maximum is identical with or follows by one month the fever maximum. As the anopheline maximum is recorded on larval examinations—this should mean at most a two months' lag between the maximum of the carrier species and that of the spleen-rate—and on the above figures this incriminates *funestus* in two years out of four, and *fuliginosus* in one year only, leaving the responsibility for the events of 1922 obscure.

In favour of *fuliginosus* being responsible for the start of the spleen-rate rise are the years 1922 and 1923; against it the two which follow. In any case we cannot subscribe to the hypothesis that the late spring rise in spleen-rate is due to general relapses due to the heat of this period, for at Delhi, with far higher temperatures at this time, as we shall show in a forthcoming report, there is no rise in the fever curve at this time of year save in those years in which there are meteorological conditions definitely permitting transmission a month or so earlier. The late spring rise in Bengal appears to us to be definitely a transmission and not a relapse phenomenon. Careful study of chart X, however, shows a small *funestus* maximum every February-March, and in the writer's opinion reveals the culprit throughout the year. In any case, this is an equation with two variables, and in attempting elucidation or control efforts should first be concentrated on the widely spread *funestus*, to see what effect its elimination alone will have, before attempting the very much more difficult problem of the control of the ubiquitous *fuliginosus*.

Chart XIII, the variations in the three species of the parasites, is unfortunately reproduced too small for clarity, but it reveals the singular phenomenon of a double maximum for malignant tertian malaria, in July-August and in October-November. Benign tertian malaria, on the other hand, has a maximum which varies widely in time, and the picture presented is in many ways quite foreign to the ideas conceived from Northern-India investigators.

It is with great regret that we learn from the introduction that the observatory was

as a whole and the Province of Bengal in particular. Enough general investigation had been done to make it apparent what particular problems could next be studied with fair hopes of obtaining definite answers to definite questions, and we would press for its re-opening at the first opportunity.

Reviews.

FIGHTERS OF FATE.—By J. A. Myers. Baltimore: The Williams and Wilkins Co. British Agents: Messrs. Baillière, Tindall and Cox, London, 1927. Pp. xix plus 318. Price, 13s. 6d. net.

THAT genius is often allied to tuberculosis, or even possibly inspired by it, is an old time observation, and in this book the author gives brief bibliographies of twenty-four very eminent persons who were all the subjects of pulmonary tuberculosis. His style is easy and pleasant to read, but this chief purpose is propaganda—of the right order. In former times the tuberculous genius had but a short spell of life ahead of him; his days were numbered; and, often as a result of this knowledge, the lamp of genius burned the more brightly before it flickered and went out. In present days pulmonary tuberculosis, when treated under suitable open air and sanatorium conditions, is an eminently curable disease, or at least the patient can be restored to the prospect of a considerable number of years of useful life. Thus Roger W. Babson, attacked with pulmonary tuberculosis at the age of 27, is to-day one of the foremost business men of the United States; Lawrason Brown, also attacked at about the same age, was recently Vice-President of the American National Tuberculosis Association and has made many notable contributions to the literature upon the disease; Will Irwin, one of America's most prolific writers, after suffering from the disease is a vigorous man of fifty-two, and still in the forefront of the literary world. Perhaps the most notable example is that of Eugene O'Neill, the famous American playwright, beachcomber, labourer, sailorman, ship's stoker, then in a sanatorium suffering from a severe type of the disease, and now celebrated in two hemispheres.

The book is an eminently readable one, and includes a preface by Charles H. Mayo of the Mayo Clinic. The brief bibliographies included show how terrible is the toll which tuberculosis levies on genius. Paganini, Schiller, Bichat, Laennec, Leigh Hunt, Keats, Elizabeth Barrett Browning, St. Francis of Assisi, Chopin, Thoreau, Dostoevsky—whose tragic life is here well outlined—Artemus Ward—who preserved his humour on his death bed—Trudeau, Cecil Rhodes (it is amazing to find him in this collection, and it is amazing to think that Rhodes, who accomplished such tremendous things for the Union of South Africa was

a tuberculous subject), Aubrey Beardsley, Eugene O'Neill, who is still happily with us; it is an impressive list.

The book is certainly one for the medical man not only to read but to put into the hands of his tuberculous patients, for its chief lesson is that the enforced leisure which pulmonary tuberculosis brings about may result in the patient's discovering within himself new vistas of literary or artistic genius and a new outlook on life. "All tuberculosis workers, as well as the patients themselves, cannot but be heartened by the facts included in these various lives."

It only remains to add that the volume is very well got up and printed. It is a mine of bibliographical information and contains numerous good stories. One of the best relates that Artemus Ward, when on his death bed, detested the medicine prescribed for him.

"My dear Tom," said Artemus protestingly, "I can't take that dreadful stuff."

"Come, come," said Robertson, "take it, my dear fellow, just for my sake. You know I would do anything for you."

"Would you?" said Artemus, faintly, grasping Tom's hand.

"I would indeed."

"Then you take it."

We must congratulate both the author and the publishers on this most interesting book.

PHYSICAL DIAGNOSIS.—By W. D. Rose, M.D. Fifth Edition. St. Louis: The C. V. Mosby Co., 1927. Pp. 819, with 310 illustrations and 3 plates in colour. Price, \$10.00.

In the preface to the first edition of this book the author stated that he had in mind the medical student and the general practitioner during the composition of the work; his object was to present the main facts of physical diagnosis in a manner at once concise, succinct and comprehensive without straying into the abstruse and the theoretical. In the present (fifth) edition this point of view has been most admirably maintained.

Considerably more than one half of the book is devoted to the physical examination of the broncho-pulmonary and circulatory systems, both in health and in disease. The remainder deals with the abdomen, the head and neck, and the extremities, together with a short description of the examination of the nervous system.

Our attention was particularly held by the sections on the heart and lungs, and the author's treatment of these is among the best we have encountered. The clear and logical style, together with the abundant use of excellent photographs and diagrams gives the reader a firm grasp of the activities of these organs, both physiological and pathological. There is a most happy compromise between the somewhat disjointed style of the average "synopsis" and the laboured gait of certain of the larger "systems."

The work is gratefully free of errors. *Auriculve-tricular* on p. 353 line 18 is obviously a slip in typing. The photographs, printing and illustrations are in keeping with the best traditions of the publishers. We unreservedly recommend this volume to all students of medicine—undergraduates and practitioners alike.

J. M. H.

THE HEART AND ITS DISEASES.—By Charles W. Chapman, M.D. (Durh.), M.R.C.P. (Lond.). Edinburgh: E. & S. Livingstone, 1927. Pp. 216. Price, 8s. 6d. net.

The author has tried to summarise well-established facts and recognised theories in connection with the diseases of heart in the light of an extended experience. Special attention has been given to heart-disease in children regarding education and games. The book will be most useful to general practitioners who have no time to refer to the more complete treatises on the subject.

S. P. B.

THE DISEASES OF INFANTS AND CHILDREN.—By J. P. Grozer Griffith, M.D., Ph.D. and A. Graeme Mitchell, M.D. Second Edition. London and Philadelphia: W. B. Saunders Company, Limited, 1927. Two Volumes. Pp. 1715, with 461 illustrations, including 20 coloured plates. Price per set, 90s. net.

THE authors have described in these two volumes the subject of medical pediatrics as exhaustively as possible, without attempting to make it encyclopædic. The subjects of surgery and other special branches with which physicians should be familiar in treating diseases of children have been included. Very valuable are the footnote references to original literature throughout the book. Temperature charts, photographic and other illustrations have been reproduced freely, accompanied by brief notes of the histories of the cases. We are sorry to note the exclusion of some of the important tropical diseases in children. For instance there is no mention of such an important disease as infantile beri-beri, and there is only a mere reference to infantile cirrhosis of the liver, which is very prevalent in India. There is no description of infantile kala-azar. The book deals very exhaustively with the diseases of children, other than those found in the tropics. The authors are to be congratulated on bringing out such a complete account of the most important diseases of children. The volumes can be recommended as constituting a very good book of reference.

S. P. B.

THE NORMAL CHEST OF THE ADULT AND THE CHILD.—By J. A. Myers, in collaboration with other authors. London: Baillière, Tindall and Cox, 1927. Pp. 419, with 141 plates and figures in the text. Price, 22s. 6d. net.

THIS is a very handy book describing the developmental anatomy, applied physiology, x-ray and physical findings of the normal thorax. The human body operates in health and disease in accord with immutable laws. When these laws are known, when the factors concerned can be measured, then medicine will be a science. The authors believe that, far off as may be the goal, progress toward it to be made along this line. The book is to be highly recommended to students, as well as to practitioners as its aim is to explain the clinical findings in diseases of the chest in accordance with our present knowledge of the anatomy and physiology of the organs concerned. It is admirably illustrated and printed.

S. P. B.

MODERN ASPECTS OF THE DIAGNOSIS, CLASSIFICATION AND TREATMENT OF TUBERCULOSIS.—By J. A. Myers. London: Baillière, Tindall and Cox, 1927. Pp. xii plus 275, with 54 figures in the text. Price, 25s. net.

IN an introduction to this volume which is written by a medical friend of the author the reason for adding yet another book to the literature of tuberculosis is given. The author is pre-eminently a teacher, and he has sought to produce a work which will give the doctor and medical student a clear idea of the diagnosis and treatment of this difficult disease. Too often tuberculosis is left to specialists, but until the ordinary practitioner is familiar with the earliest signs and symptoms these will pass unnoticed and the patient will have reached the more advanced and less remediable stages before effective means are taken. The author was formerly a teacher of anatomy and it is from the teacher's point of view that he approaches the subject, though he is able to draw upon wide personal experience.

Practically no new facts are brought forward and quotations are chiefly from the works of American writers; the merits of the book are chiefly the selection and discussion of information useful for ordin-

ary practitioners, all points which are not of practical importance being discarded.

E. M.

THE CANCER QUESTION: A REPRODUCTION THEORY.—By W. H. Tomlinson, L.M.S., S.A. London: Baillière, Tindall and Cox, 1927. Pp. 20. Price, 2s. 6d.

THERE are about as many theories about the causation of cancer as there are varieties of malignant growths; but we fear that Mr. Tomlinson's theory is one which is foredoomed to die of inanition from want of evidence. In the first place we are not as pessimistic as he is regarding the value of the research work which is going on in well-organised laboratories on the problem; nor do we agree with his dictum that "the labour of bacteriologists and chemists is so much money and time wasted. It appears like looking in a dark room for a black hat which is not there."

Having reviewed the various views current, the author insists upon four points; that cancer in any one species of vertebrate can only be transplanted into animals of the same species; that it is always at first a local growth, surgically removable; that irritation is a prelude to its development; and that its malignancy is due to the uncontrolled reproductive activity of the cancer cells. He then compares the cancer cell with the ovum; points out that in pregnancy abortion may result from chronic lead poisoning, whilst cancer is being successfully treated by lead salts; and on this extremely slender basis of evidence concludes that the cancer cell results from the union of male and female cells of the tissue concerned under the stimulus of irritation.

We fear that no one will ever discover these male and female cells in somatic tissues, whilst the author singularly fails to supply any evidence that somatic cells possess sex. If he could bring forward evidence of reduction of chromosomes in their cell division, or of the actual occurrence of syngamy in somatic cells, his theory might be worth attention. As it is, it seems to be but little more than an inferior variation of Cohnheim's well-known theory associating cancer with embryonic cell rests.

The book is admirably printed and bound, but the author's excessive use of capital letters is rather deplorable.

ON ROUS, LEUCOTIC, AND ALLIED TUMOURS IN THE FOWL: A STUDY IN MALIGNANCY.—By J. P. McGowan, M.A., B.Sc., M.D. London: H. K. Lewis & Co., Ltd., 1928. Pp. vii plus 99, with 21 illustrations. Price, 10s. net.

THIS study in malignancy is interesting, both on account of the records of the author's careful observations and of his guarded conclusions.

The main portion, preceded by a short chapter on blood cell origins and nomenclature, deals with Rous and leucotic tumours in fowls.

This is followed by a record of observations on the occurrence of melanomata in fowls, and from them the conclusions drawn are that two types arise—mesoblastic and epithelial.

He considers that the melanogen which gives rise to the melanin in these cases is derived from a "melanogenic lipo-protein complex" probably produced in the liver, and that in its distribution the sympathetic and the suprarenal play an important rôle. He refrains from applying these conclusions to melanomata as encountered in man. Further discussions are on the rôle of the lymphocyte in avian pathology, and on the ætiology of tumours.

He characterises the agent concerned in the causation of Rous tumours in fowls as a "stimulin" produced by cells in "reticulo-endothelial areas" throughout the body, and agrees with Carrel that it is not a multiplying particulate virus.

This work should be read by those interested in neoplastic diseases from the points of view of diag-

nosis and ætiology, and also by those who have studied wandering cells in general, and their lineages.

G. S.

THE NORMAL DIET.—By W. D. Sansum, M.S., M.D., F.A.C.P. Second Edition. St. Louis: The C. V. Mosby Co., 1927. Pp. 136. Price, \$1.50.

At the first glance one is inclined to regard this little volume as being suitable only for Americans, as the numerous dietaries which are detailed appeal chiefly to our friends on the other side of the Atlantic. There is another aspect of the book however; it gives a brief but exceedingly sound review of the essentials of a good diet. Each constituent is discussed and the reasons for its necessity are clearly stated. Rather unusually, the vitamins are relegated to a place low down on the list: probably this procedure is justified as very few modern European diets are deficient in any of the vitamins and it would indeed be difficult to devise a diet which is satisfactory in other essential respects, but defective in vitamin content only. For those who have occasion to give advice to European patients this little book will be found very useful.

J. W. D. M.

BAILLIÈRE'S SYNTHETIC ANATOMY: A SERIES OF DRAWINGS ON TRANSPARENT SHEETS FOR FACILITATING THE RECONSTRUCTION OF MENTAL PICTURES OF THE HUMAN BODY.—By J. E. Cheesman. Part IX. The Head and Neck. 12 Plates. London: Baillière, Tindall and Cox, 1928. Price, 2s. 6d. net.

WE would like to draw the special attention of those of our readers who do not know of Baillière's Synthetic Anatomy—both medical students and practitioners—to these splendid issues. The idea underlying them is admirable; for they consist of a series of coloured transparencies, beautifully and most faithfully executed, which can be superimposed one above another to give either the full details of any one or two systems concerned, or a complete presentation of the entire anatomy of the part. Short of a cinema film illustrating the entire dissection of the part concerned, it is difficult to imagine any more illustrative and informative way of instruction; it gives the student what amounts to an ideal dissection of the part for detailed study.

Part IX deals with the difficult subject of the head and neck, and both the author and his publishers are to be congratulated on the exceptionally able way in which this difficult part, in which structures are so crowded, has been dealt with. For example when Plates IV, V and VI are superimposed, a very complete and clear picture of the sub-occipital muscles on their different planes results. We understand that enlarged plates of the pterygo-maxillary region will be ready shortly, and that volumes dealing with the thorax, abdomen, the inferior extremity, and the perineum are in preparation. These—and especially the last, on account of its importance in the teaching of obstetrics—will be eagerly awaited.

The index has been well arranged, as in the previously published parts.

This synthetic anatomy constitutes a new adjunct to the study of human anatomy, and will be found invaluable to the medical student, the practising surgeon, and the specialist. It is a very well conceived work, most admirably executed. The price is extremely moderate.

N. P.

GONOCOCCAL INFECTION IN THE MALE.—By A. L. Wolbarst, M.D., with a chapter by J. E. R. McDonogh, F.R.C.S. St. Louis: The C. V. Mosby Co., 1927. Pp. 237, with 89 illustrations, including 7 colour plates. Price, \$5.50.

THIS book is frankly written for the general practitioner to offer him a working familiarity with the present-day methods of diagnosis and treatment, based mainly on the author's personal views. The anatomical

and pathological aspects of the subject receive in consequence only very brief notice. The sections on diagnosis of the sites of chronic infection are the clearest we have seen anywhere and the plates which show the various glass tests are worthy of careful study. For the treatment of acute gonorrhœa the author is opposed to routine irrigation and prefers treatment by a hand syringe and the newer silver salts. This question was supposed to have been settled many years ago, but there has been a tendency lately to reopen it. All who have treated many cases by urethro-vesical irrigations must have now and again encountered a case where an early and severe posterior urethritis left one uneasily wondering whether the patient would not have fared better with less vigorous treatment. On the other hand the number of untreated or almost untreated cases who do not get complications and appear to rid themselves of all but a trifling secondary infection of the prostate must be very great. The question is one that could be best decided by a large scale investigation in army hospitals. The author is hopeful for the future of the new methods of treatment by intravenous therapy which are still on trial; he omits to give the dosage of mercurochrome, a point on which some discussion, has lately centred. The sections on the use of the posterior urethroscope are full and profusely illustrated from original sources, more so than is usual even in works written for specialists. Even if one does not find anything new in the way of treatment, the sections furnish most instructive reading. Diathermy is put in its proper place as a most valuable adjuvant means of treatment in the complications, depending for its good effect on its indirect action rather than on direct lethal action on the organisms. The author is an enthusiastic advocate of Belfield's operation of vasotomy for chronic spermatoecystitis and claims that massage, etc., rarely brings about a cure. It will be evident that the book deals dogmatically with many controversial matters and we doubt whether the methods advocated are always the best, especially for the general practitioner for whom the book is intended. Still it is a good book which we can recommend to all practising in this field of work, its outlook is unconventional, and the treatment of the subject is strictly scientific.

W. L. H.

THE EXTRA-OCULAR MUSCLES: A CLINICAL STUDY OF NORMAL AND ABNORMAL OCULAR MOTILITY.—By Luther C. Peter, A.M., M.D., Sc.D. Philadelphia: Lea and Febiger, 1927. Pp. 294, with 98 illustrations and 5 coloured plates. Price, \$4.

THIS volume is in an amplified form the substance of the lectures delivered by the author to his class in the University of Pennsylvania, and deals in a very readable way with this very troublesome subject. It gives a really good and accurate account of the anatomy and physiology of the muscles and their innervations, the anatomical description being largely based, as the author acknowledges, on Whitnall's well-known book *Anatomy of the Orbit*; and then goes on to the consideration of the heterophorias, squints, conjugate paralyse and nystagmus, all in due course well and clearly put; the diagnosis and treatment of the heterophorias being particularly good and clear.

The really good points of the book in one's opinion are, the clearness and accuracy of its expression, the omission of a considerable amount of more or less irrelevant detail both in anatomy and clinical tests, and its clearness and helpfulness in applying practical methods of treatment to the pathological conditions described, obviously the result of a large experience in teaching and practice on the part of the author. The get up of the book is good, and it can be strongly recommended as a readable and practical guide to the modern theory and practice of this phase of medicine.

W. V. C.

AIDS TO OPHTHALMOLOGY.—By N. Bishop Harman. London: Baillière, Tindall and Cox, 1928. Pp. viii plus 236, with 112 figures. Price, 3s. 6d. net.

THIS well known old "Aid," now in its 7th edition, presents little change from the last though it has been revised, and the chapter on glaucoma much enlarged, and a new chapter on the "Blind" added which contains some very interesting points. The short notes on "Examination of the Eye" and "Refraction" are good, and better put from a practical point of view than in many of the larger textbooks, the examples of refraction cases being especially useful. The treatments suggested differ in many ways from those in use in India for similar conditions, but are useful and sound, and the book is quite a useful one for those for whom it is intended. Students going up for their examinations in this subject will find it useful.

W. V. C.

DICTIONARY OF BACTERIOLOGICAL EQUIVALENTS.—By W. Partridge, F.I.C. London: Baillière, Tindall and Cox, 1927. Pp. xii plus 141. Price, 10s. 6d. net.

THIS little work will be found useful to laboratory workers and librarians. It contains the English equivalents of about 2,400 French words, 2,600 German words, 1,200 Italian words, and 1,600 Spanish words, in connection chiefly with the science of bacteriology; and is intended to supplement general dictionaries. There is a particular need for this class of small technical language dictionaries, for the medical and laboratory worker will frequently fail to find translations of technical and scientific words in general dictionaries. The book is well printed and got up.

FIRST AID FOR INDIA.—By Major Hassan Suhrawardy, O.B.E., M.D., F.R.C.S.I., I.T.F., Med. Corps. Second Edition, 1927. Pp. 339, with 89 figures. Price, Rs. 1.

WE have previously had the pleasure of reviewing the first edition of this excellent little book. It is well, clearly, and simply written, and one cannot but feel that, as it is especially written with reference to Indian conditions, it is rather more suitable as a textbook for first aid classes in this country than the official British Red Cross textbook which is usually used. Major Suhrawardy has included several matters of specially Indian interest, such as the first aid treatment of snake-bite, of bites from rabid or possibly rabid animals, and of how to put out a blazing sari. The book is well printed and well illustrated, of very convenient size, and well indexed. We can cordially recommend it to our readers.

CATECHISM SERIES. HISTOLOGY. Second Edition. Edinburgh: E. & S. Livingstone, 1927. Pp. 80. Price, 1s. 6d. Postage 2d.

THIS is the second edition of one of the small brochures of the well-known "Catechism Series." It is well put together, clearly printed, and contains a surprisingly large amount of information in a small space. A useful book for the student preparing for his examination, or for reference when looking up a forgotten point in histology.

PRINCIPLES AND PRACTICE OF MOSQUITO CONTROL.—By John F. Marshall, M.A., F.L.S., F.E.S. Hampshire: British Mosquito Control Institute, Hayling Island. Price, 2s. 6d.

THIS little book is in the nature of a guide to the activities and resources of the British Mosquito Control Institute, written by the founder of the Hayling Island Mosquito Control and the Director of the Institute which has grown out of it. It may be interesting in the first place to review briefly the history of the Institution, which has many lessons for rural Bengal and its Anti-malaria Co-operative Societies.

Hayling Island is a high class residential district east of Portsmouth, the residents of which suffered intolerably from mosquito nuisance caused by the European salt-water breeder, *Ochlerotatus detritus*, in company with *Culex pipiens* (first cousin to *C. fatigans*, only too well known to dwellers in the East), and *Theobaldia annulata*. Among the local residents was Mr. J. F. Marshall, a qualified engineer and barrister, with entomological training in addition, who organized a local committee, collected funds from residents, and inaugurated the campaign.

Mr. Marshall proceeded on the soundest lines throughout. A room in his own residence was fitted up as a laboratory, from which a thorough survey of the area was made. To those of us who have to work on topographically unsurveyed ground, using sketch maps, and control large and largely inaccessible perimeters, the details of the survey, and the indicating "washers" (showing the state of each breeding-place at the moment, and the control position, which fig. 5 of the first report illustrates), can only bring a sigh of hopeless envy. Never, in the tropics, can one hope to run a control with so much minute attention to detail. It is a great pity that this figure is not reproduced in the handbook now under review, though the method used is fully described.

Unfortunately we do not possess a complete set of the circulars issued by the Control; the first in our possession being No. 4, giving the results of experimental work on the relative cost of creosol and kerosene as larvicides, invaluable work that had not been done elsewhere. This is summarized in the handbook, and all practising malariologists have cause to thank Mr. Marshall for his investigations.

Work of so thorough a nature can have only one result, success, and we learn from the preface to the handbook, that the long-standing mosquito nuisance at Hayling has been entirely abolished. But, as was inevitable with such work and such a Director, lacuna in our knowledge of mosquito biology became painfully apparent, and research has now come largely to the fore in the work of the Control, so much so that out of the single room in the Director's private residence has grown the entirely new Institute described in the handbook. Illustrated by an admirable set of original photos the reader is taken through the general life-history of mosquitoes, after which the formation and growth of the Institute is described, from which it will be seen (*mirabile dictu* in India), that no Government funds have been utilised, save a single small grant for research purposes only, but that, beyond some limited private subscriptions towards the cost of the original control from local residents, the whole financial burden has been on the back of the Director. When, we wonder, will this country be able to show the like, not only the funds, but the capacity to apply them, in the same individual?

The photos and plans reveal a building admirably suited to its purpose, governed by a council of the highest zoological names in Great Britain, and supported entirely by voluntary subscriptions; there, then follow "Some Practical Details of Mosquito Control Organization," which will be invaluable, especially the illustrations, to all malariologists having to deal with tidal areas; finally records are dealt with, and we can only say that "some day" we hope to have our own department as highly organized!

The book is manifestly designed for the layman and as a means of creating interest and attracting subscriptions, but the professional man can study many parts of it with great profit.

R. S. W.

A TEXTBOOK OF PRACTICAL THERAPEUTICS.—By Hobart Amary Hare, M.D., LL.D. Twentieth Edition. London: Henry Kimpton. Pp. x plus 1094, with 158 engravings and 8 plates. Price, 38s. net.

THE 20th edition of this very useful and well-known work is very welcome. This volume like the previous

editions is practical in every detail and the author has taken great pains to make the information he gives ready for bedside use. Part I deals with matter introductory to the study of pharmacology and supplies useful information necessary for the practice of rational therapeutics. Part II discusses the pharmacology, toxicity and therapeutics of remedies and briefly but lucidly gives all the information that a general practitioner wants about the drugs he is going to prescribe. Part III contains articles on remedial measures other than drugs and gives an excellent account of foods for the sick and feeding of the sick. In part IV the symptomatology of important diseases and their therapeutics is discussed with full practical details.

This book is the best of its kind and should form a part of the library of every practitioner.

R. N. C.

Annual Reports.

THE 12TH ANNUAL REPORT OF THE BRITISH SOCIAL HYGIENE COUNCIL, JUNE 1ST, 1926, TO MAY 31ST, 1927.

THE aims and object of the Council are succinctly stated in its opening page.

(i) To preserve and strengthen the family as the basic social unit.

(ii) To promote educative and social measures directed towards the development of control of the racial instinct.

(iii) To emphasise the responsibility of the community and the individual for preserving or improving, by educative and social measures, the quality of future generations.

(iv) To further social customs which promote a high and equal standard of sex conduct in men and women.

(v) To promote the prevention and treatment of venereal diseases by appropriate educative, medical and social measures.

(vi) To promote the elimination of commercialised vice.

(vii) To promote the removal of conditions conducive to promiscuity.

(viii) To co-operate with the various organisations interested in the above subjects with a view to co-ordinating efforts to secure these ends.

In view of the Delegation which the Council sent to India last year, the Annual Report will have a greater interest for our readers than usual. It will be remembered that Dr. Lees and Mrs. Neville Rolfe visited India in the cold weather of 1926-27. Their purpose was to investigate roughly the incidence of venereal diseases in India, to explain the seriousness and the crippling effect of these diseases on men, women and children, to explain what was being done to tackle the problem in England by the State, by local bodies and by voluntary agencies like the British Social Hygiene Council, and to suggest what could be done in India by better education of medical men in the diagnosis and treatment of these diseases, by the provision of better facilities for treatment in hospitals and clinics, and by instruction of the general population—to make a beginning in fact of tackling the problem. It must be admitted that apart from conditions in the Army, venereal diseases in India are not properly understood, diagnosed and treated by the great majority of the practising medical profession. Quack remedies are widely and shamelessly advertised in all but the highest class newspapers.

The Delegation, in a short report on Indian conditions, state that they found evidence of a high incidence of syphilis and gonorrhœa in the Provinces and States of India. Social conditions and customs lead to the dissemination of the diseases among the adolescent as well as the adult population. Out-patient treatment in the

large cities has not proved very successful in army province and there is little systematic complete treatment anywhere. The reasons given for failure are lack of trained staff, of suitable premises, and of equipment. The Delegation made recommendations under medical, social and educational heads. Under "medical" they suggest adequate accommodation in hospitals for diagnosis and treatment, ante-natal beds, treatment for children at clinics, more practical teaching to under-graduates and post-graduates, free bacteriological service for practitioners, free supply of drugs to hospitals, and the appointment of a specialist in each province. Under "social and education" they advocate the study of biology by all teachers, instruction of all students in social hygiene, parent conferences, medical inspection of school children, propaganda work amongst the general public, and public enlightenment as regards the effect on the race of commercialised vice and disease. The British Social Hygiene Council offers co-operation in the fulfilment of these aims.

It will be agreed by all who came in contact with the Delegation that their visit to India was stimulating, though it remains to be seen whether the practical results will ensue immediately or later.

It might be as well to state the present position in England. Under the Venereal Disease Regulations of 1916, Local Bodies in England and Wales (and Scotland) must submit to the Ministry of Health a scheme for providing free diagnosis and free treatment to all who may desire such, whether suffering from disease or not, and for the free supply of drugs to selected practitioners. No public money can be spent on schemes not approved by the Ministry, a provision which ensures that only the best of diagnosis and treatment is utilised. Local Bodies may spend public funds on lectures, demonstrations and such propaganda as they wish.

Under the Venereal Disease Act of 1917, where such a scheme is in operation, no unregistered practitioner or quack is allowed to treat venereal disease nor any person advertise any remedy for such disease.

The British Social Hygiene Council is a voluntary organisation which co-operates with the State and the Local Bodies to the full in helping to reach individuals who would not ordinarily take advantage of the treatment and diagnosis centres provided; and by lectures, cinemas and visiting, by co-operating with "parent societies," scout and guide movements, endeavours to disseminate accurate, sane and healthy knowledge about reproduction, and the difficulties and dangers that beset the human race in the conflict of instincts and ideals that civilisation and intelligence have brought to it in its evolution from the purely animal.

The Council's report bears ample evidence of the careful enthusiasm of its members and of its appreciation of the difficulties and possibly the dangers of its activities. One of its most beneficial activities is in the Seaman's Welfare Societies which are being formed all over the world. Responsible countries too long have accepted light-heartedly that a sailorman could have a wife (of sorts) in every port and shut their eyes to the misery and the many grim tragedies that followed. It is pleasing to note that all over the world attempts are being made to provide decent homes and decent entertainment, recreation and medical facilities ashore for the mercantile marine of all countries.

We commend the report to all interested in a very important, difficult, and often delicate subject.

A. D. S.

ANNUAL REPORT OF THE UNION MISSION TUBERCULOSIS SANATORIUM, AROGYA-VARAM, MADANAPALLE, S. INDIA, FOR 1926-27. BY C. FRIMODT-MÖLLER, M.B., CH.B.,

PERHAPS the brightest feature in the campaign against tuberculosis in India is the wonderful work carried on by the Madanapalle Sanatorium—work with which our readers are already familiar. The Sanatorium is situated in ideal surroundings in a dry and relatively cool climate at an altitude of 2,500 feet above sea-level. It includes more than ninety buildings, and with its

spacious gardens covers more than 100 acres of ground. The atmosphere is entirely free from dust, whilst the surrounding hills protect the site from heavy monsoon storms.

The annual report for 1926-27, as usual, is illustrated with a very fine series of photographs showing the bright, airy and open types of wards, and the new x-ray and laboratory buildings. Dr. Frimodt-Möller has conclusively shown that the results of sanatorium treatment in India are as good as—perhaps even better than—results in Europe. The year opened with 141 patients in residence; 288 were admitted during the year; 278 discharged; leaving 151 patients in residence at the end of the year. The waiting list is a very extensive one, and at one time there were as many as 80 patients on it. The total accommodation, however, has been increased to 176 beds.

Of the patients admitted only 21 per cent. came from the co-operating Missions who are responsible for the upkeep of the Sanatorium; 49.6 per cent. came from districts in the Madras Presidency, and the remainder from other areas all over India; Calcutta, for example, sent 26 patients during the year.

Statistical results are given for 225 patients who were discharged during the year. On admission 23.6 per cent. were in stage I, 32.4 per cent. in stage II, and not less than 44.0 per cent. in stage III—figures which show the general severity of the types of cases admitted. On discharge 74.2 per cent. were discharged with "positive results"—i.e., either arrested, much improved, or improved. Taking stages I and II together, positive results are obtained in some 93 per cent. of cases. "These figures" writes Dr. Frimodt-Möller, "emphasize in the most striking way the very great importance of sending patients for treatment as early as possible." During the last seven years the results of treatment of patients in stage III have improved yearly. This is due chiefly to (i) the introduction of artificial pneumothorax treatment; (ii) the thorough treatment of the different complications due to other diseases; (iii) the longer time the patients are kept under treatment, and (iv) sanocrysin treatment. For 2,027 patients discharged during the twelve years since the Sanatorium opened, the results are as follows:—

	Arrested.	Much Improved.
472 in stage I ..	72 per cent.	18 per cent.
695 in stage II ..	32 per cent.	36 per cent.
860 in stage III ..	1 per cent.	22 per cent.

The bacteriological findings show that tubercle bacilli were detected in 66 per cent. of patients on admission, and had disappeared from the sputum of 40.5 per cent. of patients on discharge. Of stage I cases the bacilli disappeared in 93 per cent. Sixty-three per cent. of patients showed fever on admission, and 59 per cent. of patients discharged were afebrile. The average gain in weight was 11 lbs. Artificial pneumothorax treatment was given in 57 out of the 225 cases; sanocrysin treatment in 49; tuberculin B.E. in 12; and autogenous secondary vaccines in 4 cases. Of important complications *Entamoeba histolytica* infection was present in 35 patients, ankylostomiasis in 45, malarial infection in 69, hæmoptysis in 14, and diabetes in 11. The amount of laboratory work involved during the year was enormous, some 16,000 specimens of different sorts having been examined.

After-histories.—Whilst the immediate benefit gained by sanatorium treatment is very marked in the majority of cases, the after-history is a measure of the patient's final resistance to conditions which are frequently only too bad. Poverty is much more acute in India than in the West, and hygienic conditions very much lower. These facts, as also the much greater severity in the types of cases dealt with, must be remembered when comparing after-results in India with those obtained in Europe. It has been possible to trace 679 out of 1,073 persons discharged more than five years previously from the Sanatorium. Of these 53 per cent. were living, and 48 per cent. doing full work five years after discharge. Of stage I patients 89 per cent., of stage II cases 72

per cent. and of stage III cases 70 per cent. of those traced were doing full work. Discharged patients who subsequently die from the disease usually do so within two years of leaving the Sanatorium, whilst of those who are well five years after discharge very few subsequently die of tuberculosis. "Taking all the information obtained about the after-histories of the patients into consideration, it is found that the Sanatorium treatment in India is apparently of equal value to that in the West, and when Indian conditions are borne in mind probably even of greater value."

Other features of the year's work include the special training of doctors, medical students, and laboratory assistants, the publication of papers—two of which appeared in our columns during the year, and the restoration to use of the x-ray apparatus. The new laboratory building provided for by funds collected by the Lee Memorial Mission was completed during the year, and was in charge of the Rev. R. M. Barton, M.A. Two further semi-general wards and two double special wards were added during the year. A medical retreat was held for fifteen doctors employed in mission hospitals in South India. Lantern lectures, cinema shows, and dramatic performances were held, and the annual fancy fair. Miss M. K. Blair, the Matron, reverted to other work after four years of work at Madanapalle, and Miss L. Stanes was appointed Matron from April 1927.

Dr. Frimodt-Møller is to be congratulated on the lead which he has given to India in the sanatorium treatment of pulmonary tuberculosis under Eastern conditions.

ADMINISTRATION REPORT OF THE KING EDWARD VII MEMORIAL HOSPITAL AND THE SETH GORDHANDAS SUNDERDAS MEDICAL COLLEGE, BOMBAY, FOR 1926-27.

THIS report is by Dr. Jivraj N. Mehta, M.D., M.R.C.P. (Lond.), Dean of the College. The combined institution is a new one and much spade work had to be done during the year in equipping and furnishing, drawing up rules and regulations, and making out syllabuses. Permanent affiliation of the College and Hospital to the University of Bombay for the M.B., B.S. degrees was secured in 1926, whilst recognition for post-graduate medical degrees and diplomas has also been secured, and the hospital is now recognised as a training centre for probationer nurses.

The hospital opened the year with 125 beds available, but this number was increased to 267 by the end of the year. Equipment for all the departments continued to arrive during the year, and the x-ray and electro-therapy department, which was the last to be opened, was opened in May 1926. With the opening in December 1926 of the Nowrosjee Wadia Maternity Hospital (130 beds) in close proximity, the maternity section of the King Edward VII Hospital was gradually closed down, the students attending the Wadia Hospital; this gave extra accommodation for gynaecological cases and increased the accommodation for children. The ophthalmic department was increased, and it is aimed at a final total accommodation in the hospital of 334 beds. The question of erecting special venereal wards is under consideration.

In-patients admitted during the year numbered 4,378, and out-patients seen 79,823. Operations on in-patients numbered 1,687, and on out-patients 1,106. The recurring expenditure of the year was Rs. 3,41,000. The average cost per out-patient attendance is about Re. 0-7-2, including medicine or dressings, and per in-patient Rs. 3-14-1 per day.

Turning to the report on the college, 183 students were under training during the year, whilst 40 medical graduates were also under training for periods varying from 1 to 8 months. The library constitutes a special difficulty, as the grant is inadequate for the proper provision of books and journals. The Bombay Branch of the Royal Asiatic Society lent a collection of 1,345 old medical books to the library, but, however, interesting

such works, we fear that they do not meet the need for up-to-date textbooks and current journals. Good progress was made with the Pathology and Anatomy Museum during the year, and the Materia Medica Museum is practically complete. The anatomy, physiology and pathology and bacteriology departments are now fairly fully equipped; the hygiene department more or less so; whilst the pharmacological and toxicological sections were only slightly equipped by the end of the year. In addition to routine duties, research work has been carried on on indigenous food-stuffs and several indigenous Indian drugs.

The Students' Hostel was completed in May 1926, and can accommodate 100 students. There is no accommodation for lady students, whilst the existing accommodation is likely to prove inadequate very shortly.

A marked feature of the hospital is that a considerable part of its income is derived from voluntary subscribers, from factory owners, and by way of sickness insurance from factory workers in the Bombay mills. Local philanthropists and others in Europe and America have also endowed beds or wards; and in his concluding paragraph Dr. Mehta pleads with the philanthropists of Bombay for further endowments for research and for medical education.

Correspondence.

WHY ARE WE ONE-SIDED?

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—I have to-day read in your current issue the letter of Dr. Janeschi, headed "Why are we one-sided?"

It seems to me that the undoubted fact that most of us use the right side of our bodies more than the left can be traced to force of circumstances. Our aboreal ancestors, for example, were ambidextrous. Anyone who doubts this can resolve his doubts by a visit to the Zoo, or better still to—let us say—the hill station of Matheran.

As man ascended in the evolutionary scale and descended from the comparative security of the trees, he gradually found it necessary to evolve means of protection from his fellows and from other animals, and to invent weapons of an offensive as well as defensive nature. *Si vis pacem, para bellum.*

As man discovered that the dried hides of animals parried the blows of attackers, the shield developed down the centuries from the Stone Age, through the days of "chivalry" to that culminating act of "progress" and "civilization"—the Great War. Meantime, man, the warrior, always on the *qui vive*, carried the shield on his left arm to protect the cardiac area, since instinct and experience, if not post-mortem examinations, had taught him that this was the "vital spot."

The result over centuries of years is the "habit" of one-sidedness. That this habit, even after such long experience, is not congenitally fixed and ingrained can be proved by the most casual observation of a child who uses both hands equally well, or rather equally ill; and who, as he grows older, when—as he does as often as not—he offers his left hand to greet strangers is checked by his nurse or mother. He is taught that it is "wrong"—i.e., impolite—to offer the left hand. Later, he is taught to write, draw, etc., with his right hand only, and the discarded left hand and arm remain clumsy, untrained, undeveloped.

But they can be restored to full utility. The telegraphist, the stenographer suffering from "writer's cramp," can quickly learn to write with the other hand; the man with a whitlow on his right thumb soon realizes that he can button his clothes satisfactorily with the left hand after a few days of awkwardness.

It is too late to cry a halt to this progressive degeneration of an abused—because disabused—extremity, and the corresponding side of the body? Must the left side of

the body go the way of the auricle, the appendix, and the tail? Must man, a million years hence, roam the world a moiety of his former self?

This impending catastrophe can be aborted by teaching the child to be ambidextrous, as Heaven intended him to be. "Bring up the child in the (two-sided) way he should go, and when he is a man he will not depart from it." For, to suggest that the human race is one-sided for any reason other than habit—i.e., certain acts becoming fixed by reiteration in the retentive subconscious mentality—savours of that well-known fallacy in logic, *petitio principii*.—Yours, etc.,

W. NUNAN, M.D.,
L. Police Surgeon.

BOMBAY,
17th February, 1928.

ASPHYXIA NEONATORUM.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—Experience has convinced me that the lives of numerous infants are sacrificed in India owing to the neglect by midwives and doctors in attendance to render first aid to apparently breathless infants. Recently I was called upon to attend a Hindu female aged 16 years in her first pregnancy. The membranes had been ruptured long before, the second stage of labour had been unduly prolonged, and the patient was very exhausted. Having adopted the usual antiseptic precautions I delivered the child by forceps under chloroform anaesthesia. It was in a condition of white asphyxia and apparently dead. I placed it in a basin of warm water, and commenced artificial respiration. Not until ten minutes later did the child commence to breathe spontaneously. The child, a female, is to-day, 2½ years later, in good health, and the mother has subsequently given birth to a second, male, child.

In another instance after forceps delivery, an interval of twelve minutes during which artificial respiration in a basinful of warm water was carried out elapsed before the child began to breathe spontaneously.

It is my belief that the medical profession in this country is not sufficiently alive to the possibilities of saving many infants who are born in a condition of white asphyxia, and apparently dead.—Yours, etc.,

L. R. DATTA,
Medical Officer.

RAJOURI DISPENSARY, JAMNU STATE,
2nd December, 1927.

AN ABERRANT CASE OF PLAGUE.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—The following case appears to present unusual features:—

Some three days ago I was called in to see a patient who gave a history of continuous fever which had set in suddenly four days previously. Examination showed nothing abnormal except an enlarged spleen, which was just palpable. His mental condition was clear and he did not appear to be in much discomfort. The temperature was stated by the relatives to have been 102.5°F. or lower during the previous three days. I gave him an injection of quinine, though I was not sure that the fever was of malarial origin.

The next day his condition was the same. On the sixth day of the disease three discrete glands near the upper part of the sterno-mastoid muscle on the right side became tender, swollen, and inflamed. The condition of the throat was normal, the patient's temperature only 100°F., and his mental condition clear, and without distress. I accordingly dismissed a diagnosis of plague.

On the seventh day of illness the glands had become matted together into a large tender bubo, and the patient commenced to spit blood in large quantities. He also complained of lancinating pain the left side of the chest, and pleural friction and slight dullness were detected. On sending the sputum to a laboratory for examination, it was reported that *B. pestis* was present in profusion.

Even at this stage, however, the patient's temperature was only 100°F., his mental state clear, and there was no conjunctival congestion.

The case appears to have been an abnormally mild one of plague.—Yours, etc.,

K. V. ADALJA, M.B., B.S.

NAIROBI,
20th February, 1928.

A PRESCRIPTION FOR INTESTINAL COLIC.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—The treatment of simple intestinal colic may seem a simple matter, but such cases are perhaps amongst the commonest everyday ones seen in medical practice in this country. In this connection—and especially for intestinal colic in children—I have found the oral administration of a mixture of equal parts of camphor, menthol, and thymol in water to act almost as a specific. The drugs should be given in a maximal doses for the age of the patient concerned.—Yours, etc.,

ANANDLAL BUCH, L.C.P. & S. (Bom.),
Medical Officer.

JAM KALYANPUR DISPENSARY,
JAM KHAMBHALLA,
24th February, 1928.

Service Notes.

APPOINTMENTS AND TRANSFERS.

Lieutenant-Colonel H. W. Acton, I.M.S., Professor of Tropical Pathology and Bacteriology, School of Tropical Medicine and Hygiene, Calcutta, is appointed Director of the School in addition to his own duties.

Consequent on the grant of leave to Lieutenant-Colonel J. K. S. Fleming, O.B.E., I.M.S., Lieutenant-Colonel H. E. Stanger-Leathes, I.M.S., Assistant Director of Public Health, Delhi, is appointed to officiate as Deputy Director-General, Indian Medical Service, with effect from the afternoon of the 22nd March, 1928.

Lieutenant-Colonel R. Knowles, I.M.S., Professor of Protozoology, School of Tropical Medicine and Hygiene, Calcutta, was appointed, with effect from the 8th March, 1928, to act as Director of the School in addition to his own duties, *vice* Lieutenant-Colonel A. D. Stewart, I.M.S.

Lieutenant-Colonel A. D. Stewart, I.M.S., Professor of Hygiene, School of Tropical Medicine and Hygiene, Calcutta, was appointed to act as Director of the School in addition to his own duties for the period from the 22nd February to the 7th March, 1928, *vice* Lieutenant-Colonel J. W. D. Megaw, I.M.S.

Lieutenant-Colonel W. V. Coppinger, D.S.O., M.D., F.R.C.S.I., I.M.S., Professor of Ophthalmic Surgery, Medical College, Calcutta, and Ophthalmic Surgeon of the College Hospital, is appointed to officiate as Surgeon-General, Bengal, during the absence of Major-General Tate, on leave.

The services of Lieutenant-Colonel J. M. A. Macmillan, M.D., I.M.S., Civil Surgeon, Simla (East), are replaced at the disposal of the Government of the Central Provinces, with effect from the 1st May, 1928.

Major H. E. Murray, M.B., I.M.S., First Resident Surgeon, Presidency General Hospital, Calcutta, is appointed to act, until further orders, as Surgeon Superintendent of the Hospital, in addition to his duties, *vice* Major Kirwan, transferred.

The services of Lieutenant-Colonel C. H. Reinhold, M.C., I.M.S., are placed at the disposal of the Chief Commissioner, Delhi, with effect from the 22nd April, 1928.

Major L. A. P. Anderson, I.M.S., an officer of the Medical Research Department, is confirmed as Assistant Director, Central Research Institute, Kasauli, with effect from the 4th April, 1928.

The services of Major J. R. D. Webb, O.B.E., D.P.H., I.M.S., are placed temporarily at the disposal of the

Chief Commissioner, Delhi, for appointment as officiating Assistant Director of Public Health, Delhi, *vice* Lieutenant-Colonel H. E. Stanger-Leathes, I.M.S., with effect from the afternoon of the 22nd March, 1928.

Major H. K. Rowntree, M.C., M.B., B.S., I.M.S., is appointed to be Civil Surgeon, Simla (East), with effect from the date on which he assumes charge of his duties.

Major E. W. O'G. Kirwan, M.B., F.R.C.S.I., I.M.S., officiating Surgeon Superintendent, Presidency General Hospital, Calcutta, is appointed to act, until further orders, as Professor of Ophthalmic Surgery, Medical College, Calcutta, and Ophthalmic Surgeon, Medical College Hospital, *vice* Lieutenant-Colonel W. V. Coppinger appointed to act as Surgeon-General, Bengal.

The services of Major M. G. Bhandari, I.M.S., are placed at the disposal of the Government of the Punjab, for employment as Superintendent of the Borstal Institute, Lahore, with effect from the date on which he assumes charge of his duties.

Major C. Newcomb, I.M.S., is placed on foreign service under the Indian Research Fund Association, with effect from the afternoon of the 20th March, 1928, until further orders, for employment on nutritional researches.

The services of Major G. Covell, I.M.S., an officer of the Medical Research Department, are placed temporarily at the disposal of the Government of Bombay, with effect from the afternoon of the 19th March, 1928, to undertake a malaria survey of Bombay city.

On reversion from foreign service under the Governing Body of the School of Tropical Medicine and Hygiene, Calcutta, Captain G. C. Maitra, I.M.S., of the Medical Research Department is appointed to officiate as Assistant Director at the Central Research Institute, Kasauli, with effect from the date on which he assumes charge of his duties.

To be Captains.

F. E. B. Manning, 4th August, 1927, with seniority, 3rd April, 1925.

S. Smyth, 4th August, 1927, with seniority, 24th January, 1927.

To be Lieutenants.

J. Quigley, 4th August, 1927, with seniority, 1st September, 1924.

R. A. Haythornthwaite, 4th August, 1927, with seniority, 19th February, 1925.

R. D. Alexander, 21st November, 1927, with seniority, 21st November, 1926.

LEAVE.

Major-General G. Tate, M.B., K.H.S., I.M.S., Surgeon-General with the Government of Bengal, is granted leave on average pay for six months, with effect from the 26th April, 1928, or the date on which he avails himself of the leave.

Lieutenant-Colonel R. McCarrison, C.I.E., M.B., F.R.C.P., I.M.S., an officer of the Medical Research Department, on foreign service, under the Indian Research Fund Association, is granted leave on average pay for eight months, with effect from the date on which he avails himself of the leave. His services are replaced at the disposal of the Director-General, Indian Medical Service, with effect from the date on which he proceeds on leave.

Lieutenant-Colonel Sir F. P. Connor, Kt., D.S.O., F.R.C.S., Professor of Surgery, Medical College, Calcutta, and Surgeon to the College Hospitals, is granted leave from the 28th February, 1928 to the 15th December, 1928.

Lieutenant-Colonel R. Knowles, I.M.S., Professor of Protozoology, School of Tropical Medicine and Hygiene, Calcutta, is allowed leave on average pay for six months, with effect from the 15th July, 1928, or from any subsequent date on which he may avail himself of it, under articles 81 (b) (i) and 82 (b) of the Fundamental Rules.

Major H. Hingston, M.D., I.M.S., Surgeon to His Excellency the Governor of Bengal, is allowed leave on average pay for six months, with effect from the 15th

May, 1928, or from any subsequent date on which he may avail himself of the leave.

Major P. F. Gow, D.S.O., M.B., I.M.S., officiating Professor of Clinical Obstetrics and Gynaecology, Medical College, Calcutta, and Second Surgeon, Eden Hospital, Calcutta, is allowed leave for six months, with effect from the 22nd April, 1928.

Captain L. K. Ledger, I.M.S., an officiating Agency Surgeon, is granted leave on average pay for one month and fourteen days, combined with study leave for seven months and seven days and furlough under Military Rules for three months and ten days, with effect from the 16th February, 1928.

PROMOTIONS.

Lieutenant-Colonels to be Colonels.

John Wallace Dick Megaw, C.I.E., M.B., V.H.S., *vice* Colonel Chintaman Ramchandra Bakhle, K.H.P., retired. Dated 12th February, 1928.

Brevet Colonel William David Acheson Keys, C.I.E., M.D., *vice* Colonel Hamilton Maxwell Cruddas, C.M.G., O.B.E., retired. Dated 11th March, 1928.

Captains to be Majors.

James Edward Ainsley. Dated 29th December, 1927.

Robert Anceel Leembruggen. Dated 1st April, 1928.

Lieutenants to be Captains.

K. M. Bharucha, M.B. Dated 13th October, 1926.

J. D. O'Neill, M.B. Dated 22nd December, 1926.

RETIREMENTS.

Lieutenant-Colonel F. F. Elwes, C.I.E., M.D., retires 28th February, 1928.

The King has approved the retirement from service of Colonel H. M. Cruddas, C.M.G., O.B.E., I.M.S., with effect from the 11th March, 1928.

NOTES.

D. T. M. (Bengal), 1928.

At the examination at the Calcutta School of Tropical Medicine in April 1928 for the Diploma in Tropical Medicine of the Faculty of Tropical Medicine, Bengal, the following 23 out of 31 candidates passed:—

Passed with Distinction.

1. Muralimohan Roy, M.B., Assistant Surgeon, Government of Bihar and Orissa.

Passed.

(Arranged in alphabetical order.)

2. Bantval Subraya Baliga, I.M.&S., Agricultural District Health Officer, Government of Madras.
3. Ditis Chandra Bhattacharyya, M.B., Private Medical Practitioner.
4. Pulin Behari Bhattacharyya, M.B., Honorary Assistant Emergency Officer in Medical College Hospital, Calcutta.
5. Sailendranath Chattopadhyaya, M.B., Private Medical Practitioner.
6. Rajani Mohan Das, M.B., Civil Assistant Surgeon, Government of Assam.
7. Henry Thomas Eling, I.M.D., Assistant Surgeon in the Indian Medical Department.
8. Sourendra Nath Ghosh, I.M.S., D.P.H., District Health Officer, Corporation of Calcutta.
9. Krishnaji Mahadeo Godbole, M.B., B.S., Assistant Surgeon, Government of C. P.
10. Ramachandra Subharama Iyer, M.B., B.S., Assistant Surgeon, Government of Madras.
11. Mandalam Sivaramiah Lakshmanan, I.M.S., District Health Officer, Government of Madras.
12. Jogendra Nath Maitra, M.B., Private Medical Practitioner.
13. Vadakke Kurupath Kochukrishna Menon, M.B., B.S., Assistant Surgeon, Government of Madras.

14. Grace Helen Newell, M.B., B.S. (Lond.), Medical Officer, Baptist Mission Hospital, Ganjam.
15. Ram Rakha, L.M.P., Sub-Assistant Surgeon, Indian Medical Department.
16. Ramaprasanna Roy, L.M.P., Sub-Assistant Surgeon, Government of Bengal.
17. Madan Mohan Saha, M.B., Private Medical Practitioner.
18. Mrityunjoy Sen, M.B., Private Medical Practitioner.
19. Ranajit Kumar Sen Gupta, M.B., Private Medical Practitioner.
20. William Harden Smith, M.B., B.Ch., D.P.H., Sanitary Officer in the Zanzibar Protectorate.
21. James Herbert Theodore, L.M.D., Assistant Surgeon, Government of Madras.
22. Krishnasamier Viswanathan, L.M.S., Municipal Health Officer, Government of Madras.
23. Patrick Wolfe, L.M.D., Assistant Surgeon, Indian Medical Department.

BOMBAY MEDICAL COUNCIL.

THE following summary of the proceedings of the Bombay Medical Council held on the 17th October 1927 is published in the medical press for information.

The Council considered the case of Navroji Ardeshir Cooper, M.D., B.Hy., who had been summoned to appear before the Council on the following charges:—

(1) That in the breach of rule 22 of the Code of Medical Ethics issued by the Bombay Medical Council he displays outside the premises in which he carries on practice on Hornby Road, Bombay, signboards exhibiting the following words:—

(a) Laboratory and Vaccine Institute. Blood, Sugar-Test and Examination of Urine, Sputum, Blood, etc.

(b) 606 Clinic,

Thereby advertising that he adopts in the treatment of certain diseases special lines of treatment;

(2) That in breach of rule 22 of the Code of Medical Ethics issued by the Bombay Medical Council he displays outside the said premises three signboards;

(3) That in breach of rule 22 of the said Code of Medical Ethics he displays signboards of unnecessarily large size;

And that in relation to the said charges he has been guilty of infamous conduct in a professional respect.

The Council held charges (1) and (2) to have been proved to the satisfaction of the Council. The judgment of the Council stands postponed to the next meeting.

The Council considered an application from Mr. V. R. Kane, L.C.P.S., to permit the registration of the qualification of L.M. (Dublin) which is granted by the Coombe's Hospital, Dublin, and signifies Licentiate of Midwifery. The Council decided that as the qualification in question is not registrable in the United Kingdom, it should not be accepted for registration in Bombay, Mr. Benjamin dissenting.

The Council considered an application from the Mysore University (forwarded through the Resident in Mysore and the Government of Bombay) for recognition of the L.M.P. examination of that University. The Council resolved to inform Government that in view of the communication made to the Hyderabad (Deccan) Medical School by the Government of India, it appears that if an Institution not mentioned in the Schedule of the Indian Medical Degrees Act desires to have its diploma recognised, it should be affiliated to one of the Institutions mentioned in the Schedule of the Act, and that as the Mysore University is not so affiliated, it does not seem that the Council has authority to consider the propriety of including the qualifications granted by that University in the Schedule of the Bombay Medical Act.

An application for registration under section 7 (3) of the Bombay Medical Act received from Mr. H. S. Barker who obtained his certificate of qualification from

the Miraj Medical School in 1903 was considered, and the Bombay Government were informed that in the opinion of the Council Mr. Barker may be given the permission applied for.

An application for registration under section 7 (3) of the Bombay Medical Act received from Mr. V. G. Chakradeo, Licentiate of the College of Physicians and Surgeons of Calcutta, was considered, and the Bombay Government were informed that as the applicant was not practising medicine in the Bombay Presidency before the 25th June 1912, he cannot get the benefit of section 7 (3) of the Act.

The Council considered an application from Mr. R. E. Kamat, L.C.P.S., for the restoration of his name to the Medical Register whence it was removed under section 6 of the Bombay Medical Act, and resolved not to restore his name for the present.

On consideration of a letter received from Mr. Roze F. Castellino, L.M.S., the Council resolved that in the case of general practitioners the use of the words "Physician and Surgeon" may be allowed after their names, and that rule 22 of the Code of Medical Ethics be amended accordingly.

The Council considered a letter from Mr. P. K. Jandani, a registered medical practitioner of Sind, claiming a fee for giving a medical certificate in a medico-legal case, at the request of the police, and resolved that the papers be sent to Government with a recommendation that in view of the fact that the practitioner granted the certificate at the request of the police, he is entitled to a fee.

On consideration of certain particulars in connection with the recent election of members to the Bombay Medical Council, which the Registrar brought to their notice, the Council laid it down that every elector should send his voting papers in future in a separate cover.

BOMBAY MEDICAL COUNCIL.

The following summary of the proceedings of the Bombay Medical Council held on the 6th February 1928 is published in the Medical Press for information.

(1) The Council resumed consideration of the case of Dr. N. A. Cooper, M.D., B.Hy., judgment in which had been suspended on the two charges proved against him to the satisfaction of the Council, viz.,

(a) That in the breach of rule 22 of the Code of Medical Ethics issued by the Bombay Medical Council he displays outside the premises in which he carries on practice on Hornby Road, Bombay, signboards exhibiting the following words:—

(i) Laboratory and Vaccine Institute, Blood, Sugar-Test and Examination of Urine, Sputum, Blood, etc.,

(ii) 606 Clinic,

Thereby advertising that he adopts in the treatment of certain diseases special lines of treatment;

(b) That in breach of rule 22 of the Code of Medical Ethics issued by the Bombay Medical Council he displays outside the said premises three signboards.

The Council resolved to further postpone their judgment till the next meeting.

(2) The Council considered the case of Charles Charity Raymond de Souza, M.B., B.S. (Bom.), who had been summoned to appear before the Council on the following charges:—

(a) That in or about May 1925 in Africa he advertised by means of visiting cards upon which he described himself as "Dr. C. C. Raymond, Director, the Neucuro Propaganda for Africa."

(b) That in or about May 1925 in Africa he acted as Agent for a patent medicine called Neucuro and distributed literature or pamphlets extolling the virtues of the said patent medicine.

The Council judged Charles Charity Raymond de Souza to have been guilty of infamous conduct in a professional respect and directed the Registrar to erase his name from the Bombay Medical Register.

(3) The Council considered an application from Dr. V. S. Gupte, M.D., of the University of Minnesota, U. S. America, and other papers and correspondence relating to the same. It was resolved "that the curricula of the M.B.B.S. of the Bombay University and of the

Membership of the College of Physicians and Surgeons of Bombay should be communicated to the Medical Board of the United States of America (through the American Consul in Bombay) with a request that they will state if the Medical Board of the United States of America will permit Graduates and Members of the above two Institutions to appear directly for the State Examinations to practise, on the same terms as those who have obtained their degrees from the "A" class Allopathic Institutions of the U. S. A., to enable the Bombay Medical Council to consider the application for registration from a M.D. of the University of Minnesota and other "A" class Universities and the question of reciprocity between the Bombay Medical Council and such Universities."

(4) The Council considered a reference from the Surgeon-General with the Government of Bombay forwarding, for the remarks of the Council, a memorandum from the Commissioner in Sind in which the question is raised as to the maximum dose of morphia that a medical practitioner should prescribe. The Council resolved to inform the Surgeon-General that the Council discourage large doses of morphia being prescribed by medical practitioners but that in special cases they are allowed to exercise their judgment for the welfare of the patients; that any case of abuse of the drug by a registered medical practitioner can be dealt with by the Council if a complaint is lodged in the matter; and that under the circumstances it is not necessary to impose any limitation under the rules.

BRITISH INDUSTRIES FAIR.

LONDON, FEB. 20 TO MARCH 2, 1928.

An Interesting Vitamin Exhibit.

AMONG the interesting exhibits displayed by Burroughs Wellcome & Co., at the British Industries Fair was "Tabloid" Irradiated Ergosterol, a product which presents Vitamin D, the anti-rachitic factor of cod-liver oil and certain other fish and animal fats. "Tabloid" Irradiated Ergosterol was shown for the first time by this firm at the British Medical Association Exhibition at Edinburgh in 1927, and it is of interest to recall that the chemically pure ergosterol used by the British Medical Research Council in their experiments in 1925, which resulted in the formation of the Vitamin D principle, was prepared and supplied by Burroughs Wellcome & Co.

"Tabloid" Irradiated Ergosterol finds its chief use as an addition to diets known to be deficient in Vitamin D and to supplement the anti-rachitic action of cod-liver oil in cases where the disease is advanced.

A specimen of Vitamin A Concentrate was also displayed in a tube, the contents of which measure only four-fifths of an ounce. It presents the equivalent of Vitamin A contained in one gallon of the finest quality cod-liver oil. The nature of Vitamin A is unknown and the real difficulty with which the manufacturing chemist has to contend, is to ensure that his concentrate really contains Vitamin A. Collaboration between the chemists in the experimental department of the "Wellcome" Chemical Works and experts at the Wellcome Physiological Research Laboratories, ensure that the Burroughs Wellcome & Co. product is a definitely known concentration of Vitamin A.

Members of the profession who are accustomed to recognise "Tabloid" products as standards of purity saw them from a new angle—that of space economisers.

This feature was admirably demonstrated in the centre of the exhibit where the contents of a "Tabloid" Outfit, measuring only 127 cubic inches, were contrasted with the same contents in their ordinary or uncompressed state. They were grouped around and occupied the remainder of the showcase which measured nearly 23 cubic feet.

It was a remarkable demonstration of the compactness and completeness of "Tabloid" Equipments and did much to explain the favoured position held by them with nearly all the famous explorers and aviators in their historic journeys.

"CAPROKOL ANTISEPTIC SOLUTION S. T. 37."

A NEW antiseptic issued by the well-known firm, the British Drug Houses, Ltd., is "Caprokol Antiseptic Solution S. T. 37."

Work of recent years has established that a germicidal solution with a low surface tension is more powerful than one with a higher surface tension; consequently germicides which lower the surface tension of the liquid in which they are dissolved are more effective than germicides which increase, or do not alter, the surface tension of their solvents. A liquid with low surface tension penetrates better—especially in the presence of greasy surfaces—than does one with a high surface tension.

Further, with particles—such as bacteria—in suspension with germicides with low surface tension the actual concentration of the solution is maximal around the surface of the suspended particles. The rate of diffusion of the antiseptic also increases with the decrease in surface tension. Other things being equal, a disinfecting solution with low surface tension is more active than one with a high surface tension.

"Caprokol," it is claimed, is one of the most powerful surface tension reducers known. The symbols "S. T. 37" indicate that on dissolving the solution with water in glycerine and mixing with water, the surface tension of the water can be reduced from 77 dynes per sq. cm. to 37 dynes per sq. cm. The drug, it is claimed, is also non-toxic and has a carbolic coefficient of 72. It destroys even the most resistant bacteria in 15 seconds, and retains its disinfectant power in the presence of organic matter. It is even safe when swallowed in considerable quantities.

"Caprokol Antiseptic Solution S. T. 37" is advocated for use undiluted for application to fresh cuts and abrasions, for granulating surfaces, to disinfect the operative field before any surgical procedure, for topical application in pyorrhœa and other diseased oral and nasal conditions, and for sterilisation of dental root canals; the solution should not be injected into the tissues, however. For irrigation of the urethra, bladder, renal pelvis, etc., a solution of 1 in 2 or 3 parts of water is advocated; for irrigation of large wound surfaces and for wet dressings a solution of 1 in 5 parts of water.

The solution is issued in 3 oz. and 12 oz. bottles, and the agents for India are Henry S. Clark, 8/10, Waterloo Street, Calcutta, who will be glad to supply further information.

Publishers' Notice.

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles will receive 25 reprints *gratis*, if asked for at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions, Advertisements, and Reprints should be addressed to THE PUBLISHERS, Messrs. Thacker, Spink & Co., P. O. Box No. 54, Calcutta.

Annual Subscription to "*The Indian Medical Gazette*," Rs. 16 including postage, in India. Rs. 18 including postage, abroad.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

BY APPOINTMENT TO
H.R.H. THE PRINCE OF WALES

KOLYNOS DENTAL CREAM

THE State of Indiana, U. S. A., Board of Health specified the following qualifications for a dentifrice :

SIX THINGS A GOOD DENTIFRICE SHOULD DO :

1. Check the growth of decay germs.
2. Correct an acid condition of the mouth.
3. Possess a pleasant flavour. (A medicine taste does not necessarily mean efficiency.)
4. Clean the teeth thoroughly without injurious chemicals.
5. Polish the teeth to natural whiteness without harmful grit.
6. Leave the mouth wholesome and the breath pure.

"A dentifrice which does less than this is not a good dentifrice."

KOLYNOS DENTAL CREAM IS :—

1. Antiseptic in the mouth or in the test tube.—
Professor Loeffler, Geh. Medicinalrat,
University of Greifswald.
2. Alkaline, so neutralizes acid.
3. The favourite of children and adults.
4. Contains the ideal cleanser—soap.
5. Utilizes the polishing qualities of non-abrasive chalk.
6. "How clean my mouth feels!"—the exclamation of Kolynos users.

On request our Distributors will gladly send you a dental package, free of charge.

ADDRESS: HEAD OFFICE.

The 7th January, 1928.

Messrs. Bengal Immunity Co., Ltd.,
153, Dharamtollah Street, CALCUTTA.

Dear Sir,

On behalf of our Local Committee, I beg to thank your firm for their assistance during the Far Eastern Association of Tropical Medicine 7th Congress just concluded. The demonstrations at your laboratories were very much appreciated by the members who attended, who had an opportunity of seeing what local enterprise could do in biological research and production.

Yours faithfully,

(Sd.) G. TATE,

Major-General, I.M.S.,
Surgeon-General with the Government of Bengal.

ALOCOL

Colloidal Hydroxide of Aluminium

Successful Treatment of Hyperchlorhydria

"Alocol" is a triumph of colloidal therapy because it is completely free from the marked disadvantages associated with the usual alkaline medicaments.

Take bicarbonate of soda as an example. When in the stomach it is transformed into sodium chloride—the very product which goes to the formation of hydrochloric acid. To combat hyperacidity by such means is to create a vicious circle.

Note the different action of "Alocol." It absorbs excess of hydrochloric acid and the acid-containing mass is finally evacuated from the lower bowel. This colloidal chemical absorption removes from the system the causative acid radicle (Cl) instead of merely neutralising it.

Complete chemical history of "Alocol" with convincing clinical reports, and supply for trial, sent free to physicians on request.

"Alocol" thus prevents reabsorption, accumulation and consequent recurrence of the symptoms of the disease.

"Alocol" leaves intact the acid reaction of the gastric juice and its normal digestive and bactericidal functions. It is the remedy *par excellence* for hyperchlorhydria. The absorbent, healing and sedative properties of "Alocol" also prove of the greatest value in successful treatment of the more serious manifestations, such as gastræctasis, gastrectosis, pyloric and duodenal ulcers, infective enteritis, etc.

Original Articles.

OSTEOMALACIA: ITS EARLY RECOGNITION, MODERN PREVENTION, AND TREATMENT: (A THREE YEARS' "FOLLOW UP" OF 69 PRIVATE CASES).

By V. B. GREEN-ARMYTAGE, M.D., F.R.C.P. (Lond.),
LIEUTENANT-COLONEL, I.M.S.,

Professor of Obstetrics and Gynaecology to the Medical College, and Surgeon to the Eden Hospital, Calcutta.

In view of the fact that throughout the Northern quadrant of India from Peshawar to Calcutta in a thousand townships there are young girls, married women and old ladies suffering from the active disease or some sequelæ of its chronic form, it behoves us to review the clinical aspects of osteomalacia with a view to its modern prevention and treatment. For whereas a few years ago we looked upon this disease as a painful and hopelessly crippling condition, and did not recognise its variegated types, to-day we should be able to diagnose the many diverse clinical forms and definitely state that the disease can be cured or arrested if the proper treatment be carried out.

In order to make the rationale of the modern treatment understood, certain primary facts must be stated, viz:—

1. Any variations from the normal in the blood calcium and phosphorus of osteomalacias depend directly upon the severity of the disease and its duration. The normal percentage of calcium in the blood per 100 c.c. is 10.5 to 11 mgm. and of phosphorus 4 to 5 mgm.

2. Osteomalacia may occur at puberty and resemble late rickets; it may occur in those who have never been pregnant; or occur for the first time in women during or after the menopause. In our experience, the most usual time has been either during lactation or during the third or fourth pregnancy.

3. The menstrual flow in all our non-pregnant patients has been uniformly scanty and irregular.

4. Improving the diet alone in Indian patients has no marked effect on the disease, nor has any benefit been derived from giving any of the derivatives of calcium alone, but if cod-liver oil is added to the diet or given intravenously, there is immediate relief of symptoms:—the hobbling, waddling, groaning cripple in a few weeks walking, sitting or rising without pain.

5. If from poverty or other cause it is not possible to rectify the calcium deficiency in the diet, and yet cod-liver oil is given, exactly the same benefits will accrue. Therefore there must be some element in cod-liver oil which activates the retention of calcium in the system, or which enables the calcium to be utilised, in the presence of sunlight.

6. Osteomalacia is a deficiency disease and is to be placed in the same category as rickets; the deficiency principally is in the fat-soluble vitamins A and D, or the calcium activator content of the diet.

7. There is no pathological evidence whatever that the ovaries are in any way connected with the ætiology of osteomalacia. It is difficult to understand how this erroneous idea started and is still held by a few die-hards. Presumably it gained acceptance because castration not only prevented further pregnancy, but also stopped all menstruation with its consequent monthly drain of menstrual calcium.

8. Radiographs have been taken in a great number of our cases. In some, all that was seen was decalcification or blurring of outline. In others there was the typical bony deformity of the pelvis, sternum, vertebræ or long bones. In one Sikh from Burma and in one Bengali there was the anterior beaked pelvis like the prow of a boat. In a great many there was such crumpling of the pelvis as to make the true conjugate or outlet transverse but two inches or less. In Bengal the funnel pelvis is peculiarly common, not only among Indians but also among Anglo-Indians. The greater frequency of this deformity to-day, not only in India but also in Europe, suggests that its causation may be due to mild osteomalacia or food deficiency errors at puberty, for we have observed that in all these cases there is a history of delayed or irregular onset of the menstrual cycle, probably dependent on deficient calcium activation and vitamin shortage, for the vitamins are to the endocrines what the endocrines are to the economy.

Symptoms.

We particularly wish to stress the point that just as rickets is a deficiency disease with multiple clinical types, so is osteomalacia.

In our series of cases such symptoms as tetany, or hyper-irritability of the muscles with exaggerated knee jerks, and in some cases actual paralysis of the extremities were very common.

In other cases still the symptoms were mainly gastric or intestinal, with great distension and inability to digest food. In some of these the anæmia was very great, and girdle pains a marked feature, resembling the gastric crises of locomotor ataxy.

In most cases worms are present, and it would seem as if in addition to a vitamin A and D deficiency, there was a vitamin B shortage as well.

In some tetany and anæmia were practically the only symptoms in the early stages of the disease; later, the patients having been treated for hysteria by their medical attendants, or having developed girdle and shoulder pains, or having complained of pain in rising and sitting, a further opinion was usually sought.

In other cases we found that the patient, being old and past the menopause, had been treated with iodides and salicylates for months

on the plea of rheumatoid arthritis. Many of these were so crippled that they could not stand or walk and had been anchored to one corner of a room for months.

In some there was almost complete paralysis below the waist line after child-birth, and because they had no pain whatever, the diagnosis had been an organic cord lesion. We have seen these patients walking about within a month of efficient treatment. Others only complained of numbness or pain in the extremities, and in some this numbness was associated with a sensation of ants creeping over the skin, particularly in the waist line and lateral parts of the thigh. In two cases this formication symptom was in the shoulder girdle with only stiffness but no pain, suggesting a mild neuritis or vasomotor disturbance.

In a few, face-ache or tooth-ache with neuralgia was the main complaint, beside the anæmia.

Finally, it is *all-important to remember that the typical bony changes such as the triradiate pelvis of the advanced case are by no means a necessity.*

We have seen patients at puberty and after abortion or full term labour where the signs and symptoms were *entirely muscular, nervous, or tetanoid* and in whom all symptoms subsided after correct treatment. An interesting feature of this type of case is that the disease may occur mildly with such like nervous, muscular or tetanoid symptoms and give rise to no obstetric difficulties whatever, and then suddenly in a subsequent conception become acute, with crumpling of the bones and complete immobility, necessitating Cæsarean section or an extraordinarily difficult craniotomy.

One of the tragedies of osteomalacia is or has been that the obstetrician has not realised that the fœtus suffers with the mother, and fails to get enough calcium when the mother's blood (starved of its fat-soluble vitamins) is deficient in this mineral. The consequence is that the fœtus when born is skinny and its long bones are poor in ostein and chondrin, whilst the epiphyseal zone of calcification is irregular. The tragedy lies in the fact that if the attendants after a normal delivery, or surgeons after a Cæsarean section do not realise this, the infant may rapidly go down hill and die from calcium and vitamin starvation.

It behoves all attendants to remember that both mother and child after delivery require adequate and correct vitamin feeding, for it is a slur upon the surgeon if a Cæsarean baby should die early through ignorance of this fact and negligence of the benefits of sunlight, for sunlight is the essential factor in the cod-liver oil treatment.

Moreover all babies born of osteomalacic mothers later tend to develop rickets. We have seen a great number of these children with typical rachitic phenomena between the years of 1 and 8. Therefore the parents should be warned of the necessity of proper feeding and

sunlight for their children. There is a deplorable tendency to-day in Bengal to give patent milk preparations to all children whom their mothers cannot nourish. Such feeding is a mistake. Fresh cow's or goat's milk is always procurable, and cod-liver oil can be added in the form of one teaspoonful of the 50 per cent. "Collosoil" emulsion of Crookes' twice a day.

Ætiology.

Mellanby, whose work on diet and disease with special reference to teeth, lungs and pre-natal feeding is so well known, postulates that in the prevention of rickets, and we may say also of osteomalacia, three factors are necessary:—

- (a) A sufficient supply of salts and suitable proteins and carbohydrates.
- (b) A sufficiency of the necessary vitamins.
- (c) An activator for calcium metabolism, this factor being bound up with the question of sunlight and movement.

In Calcutta and the plains of India there are periods of the year when vegetables and fresh milk are expensive or unprocurable, and there are localities where the *pardah nashin* restrictions are very rigid.

The Marwari women of Calcutta are peculiarly prone to osteomalacia, and two-thirds of our cases have been seen among this community. The diet of Marwaris consists of wheaten bread, dal, ghee and milk (boiled), cooked vegetables and oil. Their customs do not permit them to touch meat, fish or eggs. They live in tenements or are herded together in large houses in the most crowded parts of the city, and their women rarely go out or have the opportunity of reaching the flat-topped roofs, the result being that although they may arrive from Rajputana strong and healthy, they quickly deteriorate, and owing to the factors A, B, C being defective or diminished, they very readily begin to suffer from one or more of the diverse symptoms of osteomalacia with anæmia.

It may be that the first generation escape, but their children, born and bred in Calcutta, frequently suffer at puberty or after marriage from this disease or rickets. It is no uncommon experience to find female members of long resident Marwari families who have been treated for anæmia with iron and arsenic, for hysteria with bromides and valerian, and for rheumatism with iodides and salicylates, when the whole symptom-complex is merely the result of a food and sunlight deficiency.

Amongst the Mohammedans, owing to their strict *pardah nashin* habits, sunlight and movement deficiencies are perhaps more common factors than food defects alone. Stapleton, writing of the United Provinces, and Vaughan of Kashmir, both emphasise the factors of overcrowding, and the *pardah nashin* as being determining causes of this very frequently seen disease, and are of the opinion that though cod-liver oil is essential, cod-liver oil without

sunlight is of very little use. Our experience amply bears this out.

Cod-liver oil may be separated into saponifiable and unsaponifiable fractions; the anti-rachitic properties are found to be in the unsaponifiable fractions only. This fraction consists principally of cholesterol and phytosterol; if these two substances are irradiated they become anti-rachitic. Rats and dogs fed on irradiated cholesterol develop normally, while those fed with the same substance which has not been exposed to the ultra-violet rays develop rickets.

The skin of animals has much cholesterol, only the brain having more; and since the ultra-violet rays of the sun penetrate only a short distance into the skin, it is to be presumed that these rays activate the cholesterol which exists in the skin, and this is then taken up by the bloodstream and distributed, fresh inactivated cholesterol being brought to the surface in its place. From this it would seem that the skin should perhaps be considered an organ instead of merely a covering.

These biochemical facts are confirmed in the case of rickets and osteomalacia, for the commonest seasons in the tropics to meet with these diseases are the winter months and the rains, when the sun is obscured or people tend to stay indoors in order to keep warm or dry, the consequence being that sufficient cholesterol is not activated by the solar rays, and hence from a vitamine deficiency osteomalacia develops.

Treatment.

The treatment of all disease should primarily be preventive, therefore, seeing that osteomalacia results from dietetic and hygienic errors, there should be no difficulty in eliminating it from the book of India. But it is exceedingly difficult to break through the prejudices of caste and custom. Until sunlight can penetrate verandahs, houses are airy, exercise is possible, and roofs are available for the women folk of all classes of Indian society, and particularly the Marwari community, the disease will not be eradicated. Therefore it should be the aim of City Fathers to see that suitable houses are built, and that the *pardah nashin* inhabitants of a town have the facilities of *pardah nashin* recreation grounds. Where these things are not possible, press, or public health propaganda should clearly demonstrate the folly and danger of lack of sunlight for the women and children of the household, and at the same time adequate provision should be made for an unadulterated milk and food supply.

Improvement Trusts may vastly benefit a town, but in Calcutta dense over-crowding in certain areas must perpetuate the disease, for tens of thousands of women and infant children rarely see the sun except for a brief period at midday when it may shine down into a damp courtyard crowded with cattle and their offal. How often does one not see in narrow alley ways and crowded thoroughfares the sun exclud-

ed by closed shutters, or see dirty sacking over the verandahs to prevent the inhabitants from being observed.

The central well or courtyard system of building may be a cool one, but in crowded cities with fifty to one hundred women and children living in one house, if they cannot all use the roof or freely take exercise thereon, ideal conditions exist for the onset of one of the many symptoms of osteomalacia.

It should be remembered that osteomalacia is not a disease of the very poor who have to earn their living and therefore have few *pardah nashin* restrictions, but is a disease of the middle classes, proud of this custom, who have not the wealth or desire to go out and about and cannot get away to their own country from time to time.

It is difficult to alter the dietetic habits of a thousand years, and we have already remarked on the fact that these people under no circumstance will eat eggs or fish. Moreover they rarely eat any raw vegetables or fruit, the idea of such being unwholesome having quite naturally originated in a country where cholera is endemic.

Everything eaten is boiled may be for an hour or more. Milk is boiled and the vegetable (mustard) oil used in cooking is boiled. In better class families the rice is husked by machinery, and the bran which is thus produced, so rich in phosphates, is given to the cattle. In Calcutta the cows of the wealthier classes are rarely driven out to graze, but are dry fed in dark stables under the living rooms, the result being that the milk supply is vitamine-deficient and the quality of the ghee, a household necessity, extremely poor.

For those who are unable to keep their own cattle it is a matter of vital importance that the ghee supply to a city should be pure and unadulterated.

To the writer it has seemed as if many of the bowel, blood and bone diseases of the women in Bengal can be attributed to an impure ghee supply, or to ghee prepared from the milk of stall and dry fed cattle, for during the hot months cattle which graze on parched *maidans* or stubble grass give milk which is 50 per cent. short of vitamins A and D. Such milk is conducive to rickets in the child or osteomalacia in the mothers who live in the over-crowded parts of a city.

It may be that education, propaganda and time will alter affairs, but these are matters which vitally concern ward councillors and municipalities to-day.

Drugs.

In 1925 and 1926 we began giving calcium in lactate or phosphate form by the mouth, but during the last two years, having got very little result from these, we have substituted injections on alternate days of 2 c.c. of "Collosol" calcium (Crookes). In this form the calcium apparently is taken up by the blood, for

our experience is in agreement with Professor Dixon's that calcium is inert and not absorbed when given by the mouth. At one time we gave parathyroid gland in one-twelfth of a grain dose twice a day, but results were negative.

Cod-liver oil combined with sun baths on the roof or verandah, or in the open field is the essential drug treatment. We order one ounce twice a day, taken alone or in milk. From caste or taste prejudices, at times it is refused, but when once its beneficial results can be demonstrated by the example of another patient of the same community, it will usually be taken. It is the fishy smell and taste which prejudice Marwaris against it.

Ostelin and "Collosol" cod-liver oil have not been nearly so successful as the raw drug.

During the last year if prejudice to cod-liver oil has been very great, or we have thought, despite statements to the contrary, that the drug had not been taken because the symptoms were not alleviated, we have been obtaining astoundingly good results with intravenous injections of sodium morrhuate made up in ampoule form by Smith Stanistreet and Co. We give two injections a week, beginning at 1 c.c. and gradually working up to 6 c.c. These injections are painless and symptomless, they do not offend caste prejudices, and are remarkable in the way they cause subsidence of the muscular and bony pains of the disease. The general health rapidly improves and we have seen patients huddled, crippled and groaning in the corner of a room, or even paralysed, walking about cheerfully within a month.

Intravenous sodium morrhuate is most particularly useful in pregnant patients with acute symptoms of osteomalacia. We have used it in a great number of cases with signal success.

Early in 1926 in addition to the above measures we began giving irradiated cholesterol, prepared according to the technique of Parsons by submitting pure B. D. H. cholesterol in thin layers on a Petri dish to the rays of a quartz mercury vapour lamp for one hour at a foot distance. Two drachms of the irradiated drug are then dissolved in four ounces of liquid paraffin and a dosage of 2 drachms of the liquid is ordered twice a day in addition to the cod-liver oil. We found it was not wise to irradiate more than one week's supply at a time because the drug quickly deteriorates or loses its potency in the tropics.

The effect of irradiated cholesterol is most marked upon the bony symptoms. We have had cases that were refractory or slow in responding to cod-liver oil, in whom improvement has been immediate when this preparation has been given. It is worthy of record that uneducated patients themselves have told us that the white medicine (paraffin) gave them great relief, and the records of 37 patients to whom it was given bear this out.

It should be stated that whether irradiated cholesterol synthesises the anti-rachitic factor

vitamine D, or mobilises the reserves of vitamine A has not yet been determined.

This year in an endeavour to diminish the cost of the above treatment, we have tried Radiostol, but patients have not benefited; presumably the quality of this preparation changes during transit from Europe.

In the tropics with its abundant sunlight, it is rarely necessary to have recourse to ultra-violet radiation by carbon arc lamps, but in a few cases where the pains or the bony lesions have been very marked, we have submitted patients to direct ultra-violet ray treatment with benefit. Babies born of osteomalacic mothers, either naturally or after Cæsarean section, have done very well under ultra-violet rays in the hands of an expert in a few difficult cases.

The essential medical treatment therefore of osteomalacia may be summed up as an improved diet, fresh air, sunlight, cod-liver oil or intravenous sodium morrhuate, and irradiated cholesterol, with or without injections of collosol calcium.

Sometimes it is a good plan to give for a few days santonin or carbon tetrachloride (tetraform) with the object of eliminating possible intestinal parasites before commencing the essential treatment.

We have no intention of discussing the operative measures for osteomalacia, for when once its early diagnosis, prevention and treatment are generally recognised, the necessity for craniotomy or Cæsarean section will become exceptional, for the disease in its early stages can be aborted and cured. Moreover, then we shall rarely see those un-get-at-able and inoperable cases of vesico-vaginal fistulæ which at present in rural India are one of the most terrible sequelæ of this disease.

To give an idea of how common osteomalacia is in Bengal, it may be of interest to state that during the last 30 months out of 2,870 maternity cases which have passed through the labour room of the Eden Hospital, it has been necessary to perform 26 craniotomies and 15 Cæsarean sections for osteomalacic conditions *alone*.

Of the Cæsarean sections 8 were Hindus, 1 was a Mahommedan, 2 were Anglo-Indians, 3 were Marwaris and 1 was a European. Of the craniotomies 18 were Hindus, 5 were Marwaris, 2 were Mohammedans and 1 was an Anglo-Indian. Alas! all these craniotomies could have been obviated were the benefits of ante-natal care and supervision generally understood and practised.

I have to express a great debt of gratitude to Drs. N. L. Barman, G. N. Roy, S. N. Das and Dhaur for the pains they have taken to follow up and so energetically treat and cure so many of these patients, seen in consultation with them.

A NEW ORGANIC AROMATIC COMPOUND OF BISMUTH SUITABLE FOR INTRAVENOUS INJECTION IN THE TREATMENT OF FRAMBÆSIA.

By R. N. CHOPRA, M.A., M.D. (Cantab.),

LIEUTENANT-COLONEL, I.M.S.,

J. C. GUPTA, M.B. (Cal.),

and

M. N. MULLICK, M.B. (Cal.).

(From the Department of Pharmacology, School of Tropical Medicine, Calcutta.)

BISMUTH compounds were used as cicatricising agents in cutaneous lesions as far back as the 17th century, and in 1780 they were used internally for the treatment of gastro-intestinal affections. Balzer (1889) carried out a series of experiments on dogs to test the toxicity of bismuth compounds with a view to their employment against syphilis, but he found them so toxic that he had to abandon their use. Robert and Sauton (1916) tried bismuth preparations in the treatment of spirochaetosis of fowls and found them to be very efficacious. The experiments conducted by these investigators were confirmed by Szarec and Levaditi (1921) who showed that in experimental syphilis of rabbits bismuth compounds had a well marked curative action. They also tried compounds of bismuth against syphilis in man and found that they produced rapid cicatricisation of the lesions of this disease. Since these facts have come to light a number of compounds of bismuth have been put on the market because the cost of treatment with bismuth preparations is much cheaper than with the organic arsenicals. The older preparations of bismuth recognised by the *British Pharmacopæia* such as bismuth subnitrate, bismuth carbonate and subcarbonate, etc., were not suitable for injection and could only be given by the mouth. As only very minute quantities of bismuth are absorbed from the alimentary canal their action was chiefly local on the mucous membrane. During the last decade efforts have been made to prepare a number of new compounds which could be given by the intramuscular or by the intravenous route. Of these tartro-bismuthate of sodium and potassium known by the trade name of "Trepol" was one of the very early preparations which

was put on the market; it is sold in the form of an emulsion in oil and in solution in water. Colloidal suspension of bismuth hydroxide, bismuth oxychloride in suspension in camphor water (bischloral), basic salicylate of bismuth which is soluble in water and is recommended for intravenous use, sodium trioxo-bismuthate which is an aromatic compound containing 50 per cent. of bismuth, and colloidal metallic bismuth are some of the other preparations which are in use. The disadvantage of most of these preparations is that they are not satisfactory for intravenous administration, and even for intramuscular injections most of the compounds that we have tried produced much pain and discomfort to the patient. The insoluble compounds, though not so painful as the soluble ones, are not absorbed quickly and regularly, so there is danger of cumulative poisoning from their use. When given intravenously the bismuth compounds produce agglutination and hæmolysis of the red blood corpuscles and may give rise to emboli and severe reactions. Even such compounds as soluble tartro-bismuthate or colloidal preparations which do not produce hæmolysis and agglutination, produce severe reactions following intravenous injections. Magnus (1924) reported cases of sudden death after intravenous injections of bismuth compounds with symptoms of colloidal shock.

It was for these reasons that we endeavoured to get a compound which could be given intravenously with safety. This was attained through the efforts of Dr. B. C. Ghose, D.Sc., in-charge of the Chemical Department of the Union Drug Company of Calcutta to whom the entire credit of preparation of this compound is due. He succeeded in preparing a soluble organic compound of bismuth which is freely soluble in water and which can be given intravenously without producing any untoward effects. This compound is an organic aromatic compound of bismuth and is practically the bismuth analogue of urea-stibamine. Chemically it may be described as a sodium salt of para-amino-phenyl-bismic acid in combination with urea, and has been given the trade name of "Bisnene." This compound has been given the following formula by its author: $\text{NH}_2\text{—CO—NH—C}_6\text{H}_4\text{BiO(OH)ONO}$. Analysis shows that it contains 50.1 per cent. of bismuth and this is an important fact, as the curative properties of these compounds are proportional to their bismuth content.

Preparation of "Bisnene" and its Toxicity.

The first stage in the preparation of the compounds is the acetyl para-amino-phenyl-bismic acid, obtained by a modification of the well-known Bart's reaction for the preparation of the corresponding antimony compound. The acetyl compound is hydrolysed with caustic soda solution and the para-amino-phenyl-bismic acid condensed with urea. The salt thus obtained is dissolved in water, and made alkaline with

caustic soda solution. The solution is neutralised with dilute acetic acid, saturated with carbon dioxide, filtered, and precipitated with sodium chloride. The sodium salt thus obtained is washed with salt solution and dried in vacuum on a porous plate. The compound thus formed is freely soluble in water (15 per cent. at 33°C.) giving a brown coloured clear solution which has a slightly acid reaction ($\text{Ph} = 5.9$). It is not decomposed by boiling.

Intravenous injections of this compound in experimental animals produce no marked fall of blood pressure and no effect on the respiration. No other untoward effects such as inflammation of the kidneys and the liver, which are usually met with after intravenous injections of bismuth compounds, could be detected in animals even after large doses of this compound. Its minimum lethal dose for white mice is 500 mgm. per kilo body-weight.

"Bisnene" in the Treatment of *Framboesia*.

During the course of his investigations on the prevalence of leprosy in Bihar and Orissa, Dr. Muir came across a number of cases which were presented to him as suffering from leprosy, but which on closer examination were found not to have leprotic lesions. Further examination showed that these patients were suffering from *framboesia* and that this disease was not uncommon among the inhabitants of Singbhum district. Four of these cases were sent to the Carmichael Hospital for Tropical Diseases for further investigation and Lieutenant-Colonel R. Knowles, I.M.S., Professor of Protozoology, handed them to me for treatment after he had confirmed the diagnosis by finding *Treponema pertenue*. Two classes of compounds have been successfully used in the treatment of *framboesia*. It is well known that 2 or 3 injections of organic arsenicals produce most wonderful effects in this disease and lesions which have lasted for fifteen or twenty years disappear rapidly in a short time. In 1923 the senior author in collaboration with Colonel Knowles successfully treated 12 cases of *framboesia* sent from Assam with organic arsenicals, including silver-salvarsan and sulfarsenol.

In this series of cases we tried the effect of the new compound "Bisnene." We gave very small doses to start with, but since no untoward effects were produced the dosage was rapidly increased. We are also trying this compound in the treatment of syphilis and filariasis, and in some cases we have given as much as 3.0 gm. in all without producing any toxic effects. These results will be published in a separate paper. A perusal of the description of these cases given below shows how the lesions rapidly healed under the treatment with this compound:—

Case No. 1.—Doboo Gom, Hindu male, aged 18 years, inhabitant of Gitikendu in Singbhum district. First lesion appeared on the nose two years ago.

Condition on admission:—There is a cauliflower-like growth on the nose extending along the border of the nostrils up to the margin of the upper lip. There is

also an oval growth 2" \times 1" on the chin. Smears from the lesion show *T. pertenue* in small numbers. Wassermann reaction slightly positive.

Treatment:—0.05 gm. of "Bisnene" was given intravenously dissolved in distilled water on 15th November, 1927. A very small dose was purposely given as this was the first dose of this compound given to a human subject. The injection was well borne and no untoward symptoms were produced. On 23rd November, 1927, a second injection of 0.1 gm. was given with the same result; a few days after this the cauliflower-like growth began to shrivel. A third injection of 0.15 gm. of "Bisnene" was given on 29th November, 1927; this was followed by rapid improvement, the ulcer showing signs of healing. A fourth injection of 0.175 gm. was given on 15th December, 1927, and very soon after the ulcers completely healed. The patient was discharged from the hospital considerably improved in general health. Weight on admission 80½ lb.; weight on discharge 93½ lb.

Case No. 2.—Anu Ho, Hindu male, aged 45, inhabitant of Gitikendu, in Singbhum district. Admitted to the hospital on 29th October, 1927. First lesion appeared 5 months ago on the penis. Other members of his family have suffered from a similar condition.

Condition on admission:—Small ulcers 4 in number over the anterior abdominal wall, size varying from 2" to 1" in diameter, oval in shape, covered by dark-coloured hard crusts; there are also three similar ulcers on the right side of the chest and two very small ones about the size of a pea on the left side of the chest. Smears from these lesions showed *T. pertenue* in fair number.

Wassermann reaction moderately positive.

Treatment:—A first injection of 0.1 gm. of "Bisnene" was given on 19th November, 1927, in 4 c.c. of distilled water; no reaction or untoward symptoms were produced. A second injection of 0.125 gm. was given on 26th November, 1927, after which one of the ulcers on the right side of the abdomen began to look cleaner; no marked change in the others. A third injection was given on 5th December, 1927, after which all the lesions showed signs of healing. A fourth injection of 0.175 gm. was given on 15th December, 1927. No reaction was produced and after a few days all the lesions were healed. Weight of the patient at the time of admission was 90½ lb.; at the time of discharge from the hospital was 104 lb. The patient looked much improved in general health.

Case No. 3.—Royu, Hindu male, aged 35, inhabitant of Gitikendu in Singbhum district. First lesion appeared on the right hand nearly four years ago.

Condition on admission:—The fingers of the right hand are thickened, deformed and flexed on the hand; joints fixed; the palm is contracted. Extensive scar present involving the upper part of the right forearm and nearly the whole of the upper arm; the elbow is fixed at right angles by the scar tissue; thickened dry scaly ulcer near the axilla. Left side of the upper portion of chest and neck show marked thickening and has a dry scaly ulcer. Bridge of the nose is flattened; there is a hard nodule on the left side of the bridge of the nose. A few small ulcers can be seen on the lower extremity and other parts of the body. Wassermann reaction strongly positive. No *T. pertenue* could be detected in the ulcers. Patient complains of much pain over the affected area.

Treatment:—First injection of 0.05 gm. of "Bisnene" was given on 18th November, 1927, followed by a second injection of 0.1 gm. on 25th November, 1927. No reaction was produced after the injections but no improvement in the lesions. A third injection of 0.15 gm. was given on 2nd December, 1927. The pains in the elbow and shoulder joints disappeared and the ulcers began to show signs of healing. A fourth injection of 0.175 gm. was given on 15th December, 1927. All the ulcers healed up after this injection and the pains over the joints entirely disappeared. General condition of the patient is much improved. Weight on admission 92½ lb.; weight on discharge 103½ lb.

Case No. 4.—Murm Ho, Hindu male, aged 30 years, inhabitant of Gitikendu in Singbhum district. First lesion appeared on the head three years ago.

Condition on admission:—Irregular depigmented areas of various sizes are present on both the extremities and on the ears; the skin around these white areas is thickened and scaly. In places there is increased pigmentation. Some of the lesions consist of thickened and fissured skin, hard to the touch. Wassermann reaction negative. No *T. pertenue* detected in the lesions.

Treatment:—0.05 gm. of "Bisnene" was given intravenously on 16th November, 1927, followed by a second dose of 0.1 gm. on 24th November, 1927. After this injection the patient began to improve. On 1st December, 1927, another dose of 0.15 gm. was given, and a few days after the surface of the lesions began to clear up. On 15th December, 1927, 0.175 gm. was given. This produced a rapid healing of the lesions but the leucodermic patches remained unaltered. The patient was discharged from the hospital considerably improved in health. Weight on admission 103½ lb.; weight on discharge 112 lb.

Summary and Conclusions.

(1) An organic aromatic compound of bismuth, the sodium salt of para-amino-phenyl-bismic acid in combination with urea, has been prepared which is suitable for intravenous injections. It has been given the trade name of "Bisnene" by the makers.

(2) This compound has a low toxicity, its minimum lethal dose being 500 mgm. per kilo to white mice. It produces no untoward effects after intravenous injection in animals or human subjects. We tried "Bisnene" in four cases of frambœsia and after four injections the lesions rapidly cleared. In this respect the compound acted as promptly as the organic arsenicals.

We are very grateful to Lieutenant-Colonel R. Knowles for kindly allowing us to try this compound on these cases.

A SIMPLE APPARATUS FOR FACILITATING RADIOGRAPHY OF THE LIMBS.*

By J. H. BARRETT,
CAPTAIN, I.M.S.;
Quetta.

As the limbs are X-rayed far more frequently than the rest of the body, it may be of interest to describe briefly a simple piece of apparatus which I find extremely useful as an aid to getting the affected limb in a satisfactory position during the examination.

Briefly it consists of a piece of wood (B) with a short round upright (A) at one end and a shelf (C) along one side. An inspection of the diagram will show what the apparatus looks like, and from the measurements given it can be constructed by any *mistri* of average intelligence.

* Published by kind permission of the Director of Medical Services, India.

The method of using the apparatus is shown below:—

Part under examination.		Method.
Fingers	.. P.A.	Patient rests hand on the shelf.
		Oblique. Patient rests hand against the upright.
Carpus	.. P.A.	Patient rests hand on the shelf.
		Lateral. Patient grips the round upright.
Wrist	.. P.A.	Patient rests hand on the shelf.
		Lateral. Patient grips the round upright.
		Stereo. As for P.A.
Forearm	.. A.P.	Patient rests arm on the main board.
		Lateral. Patient grips the round upright.
Elbow	.. A.P.	As for forearm.
		Lateral. Patient rests elbow on the shelf.
Toes	.. P.A.	Patient rests foot on the main board.

Tarsus	.. Oblique.	Patient rests the plantar aspect of the foot against round upright and the inner aspect of leg against the shelf.
Ankle joint and lower third of leg.	A.P.	Patient presses the plantar aspect along the round upright with his leg resting on the main board.
Ankle joint and lower third of leg.	Lateral.	Turn the apparatus so that the back wall of the shelf support is uppermost and put the inner aspect of the patient's ankle on this, or simply place the ankle on the main board.
Knee joint	.. A.P.	Turn the apparatus upside down and place the limb on it.
	Lateral.	With the apparatus still inverted and with the sound limb in the groove between the shelf and the main board lateral views are quickly and easily obtained.

Remarks.

- (1) The apparatus facilitates the production of standard skiagrams of the limbs.
- (2) It saves time.
- (3) With intelligent patients there is no need to fix the limbs with bands or sandbags.
- (4) It is simple, cheap, and easily constructed.

A SPECIAL X-RAY TECHNIQUE FOR THE EXAMINATION OF THE BODY OF THE MANDIBLE.*

By J. H. BARRETT,

CAPTAIN, I.M.S.,

Quetta.

It sometimes happens in the radiography of bones that where, clinically, periostitis and even superficial bone necrosis seem to be present, one is not always able to demonstrate the lesion on the X-ray film. So that where the clinical signs are marked it is well to X-ray the bone at different angles, so as to get the lesion (where it involves only part of the circumference of the bone) in silhouette, so to speak. I find this method particularly useful in the mandible, ribs and the skull. Suppose for instance there is a superficial necrosis of the external surface of the mandible over an area extending from the angle of the jaw as far forward as the canine tooth. Supposing it happens to be the right side of the lower jaw. By routine methods excellent skiagrams may be obtained of that particular side where the bone may be shown almost from the symphysis to the temporo-maxillary joint. Such skiagrams show the bone with its external surface nearest to the film, and for that reason one would expect a bone lesion to be shown in every case. The contrary, however, is my experience. The explanation appears to be as follows:—In the case of a rather flat type of bone, when the lesion is local and does not extend to the margins of the bone, and when it is X-rayed with the lesion surface nearest the film, then the normal trabeculae of the bone are superimposed on and obscure the abnormal, or when the trabeculae of the lesion are missing (as in bone destruction) the normal trabeculae fill in the space and so the bone looks normal.

Stereo-photographs are sometimes helpful, but stereo-photographs like all X-ray photographs are composite shadows and moreover are not applicable to all cases. So that it seems better to photograph the lesion in silhouette where this is practicable. I have devised a special technique for lesions involving the portion of the lower jaw between its angle and the canine tooth. Its main object is (a) to demonstrate local periostitis or necrosis of the external surface of the mandible, (b) to show the position of fractures in that portion of the bone, and (c) to demonstrate the extent of tumours arising from the bone.

THE METHOD.

Posture.—The patient lies recumbent on the X-ray couch. The back of the head rests on an inclined plane, which has an angle of 22 degrees. The plane is of wood, covered by a soft towel. Suppose the right side of the lower jaw is to be examined. Place a cork (previously steamed and attached to a string) between the left molars, so

as to open the mouth to the maximum consistent with comfort.

Tube Position.—The X-ray tube, with a six inch cylindrical diaphragm, is now centred so that the central bundle of rays will pass through a line drawn through the crown of the left upper canine tooth, and half an inch anterior to the angle of the mandible (right side). To do this the patient's head will be inclined to his right side. The tube should be perfectly horizontal, with anode-kathode line parallel with the couch. The centering will be greatly facilitated by the use of a centering rod or other centering device.

Film Position.—An assistant now takes a film ($6\frac{1}{2} \times 8\frac{1}{2}$), and shakes it in an envelope so that the film touches the long edge of the envelope all the way. The envelope with its contained film is now pressed against the right side of the portion of the jaw under examination, i.e., right side. To ensure rigidity a piece of oblong wooden board ($6\frac{1}{2} \times 8\frac{1}{2}$), covered with lead sheeting, is used under the film. The distance from the kathode to the film should be 18 to 20 inches. The assistant should wear lead-lined gloves. The immobilization of the patient's head is assisted by the use of a sandbag or a weighted band.

GENERAL REMARKS ON THE METHOD.

A high tension transformer or a coil may be used. The latter with a gas tube seem to give the richest skiagrams. The tube it will be seen is used fairly close to the film, as in that way the upper jaw as well as the symphysis of the lower jaw are projected well out of the way. The tube should be working at an alternative spark gap of 5 to 6 inches. Absolute immobility of the part is essential and the patient should hold his breath during the exposure. Short exposures should be used, as there is then less likelihood that movement will occur.

THE METHOD WHEN TWO PHOTOGRAPHS ON ONE FILM ARE REQUIRED.

A thin sheet of lead is required to cover the unexposed portion of the film. The second exposure is made with the X-ray tube at a slightly different angle. Thus the tube should be placed so that the central bundle of rays shall pass (in the case of the right side of the jaw) through the line first right incisor tooth, one inch anterior to the angle of the mandible. In this way a second useful projection of the area may be obtained. Similarly the other side of the jaw may be X-rayed for comparison.

THE METHOD WHEN STEREO-RADIOGRAPHY IS EMPLOYED.

The positions of the patient, the film, and the centering of the tube, are those which I have already described. For the first exposure however the X-ray tube is moved 3 cm. to one side in a direction perpendicular to the line of the body of the mandible. One-half of the film is protected with a lead sheet, and the photograph taken. The film is now "somersaulted" so that

* Published by kind permission of the Director of Medical Services, India.

the reverse (unexposed) portion is pressed under the jaw—as for the first photograph. The X-ray tube is now moved 6 cm. in a direc-

FIG. 1.

FIG. 2.

FIG. 2a.

FIG. 3.

tion opposite to that which was used for the first photograph. The exposed half of the film is covered with lead sheeting and the second photograph taken.

To examine the stereo-radiograph a small oblong or square mirror and viewing lantern are required. By holding the mirror in position between the two images on the single film, very little effort is required to superimpose one image on the other, and thus obtain the stereoscopic effect.

A glance at the figures marked Fig. 1, Fig. 2, and Fig. 2a will show what a skiagram of the lower jaw looks like, when taken in the manner just described.

Fig. 1 is a tracing of a skiagram of the normal jaw.

Fig. 2 is from a case of superficial necrosis of the jaw.

Fig. 2a is a tracing from a skiagram of a case of partial fracture of the lower jaw.

Fig. 3 is a tracing from a skiagram of a normal jaw (Lateral view).

CONCLUSIONS.

1. The method is of value, and without using it (at any rate in certain cases) the radiographic examination of the mandible cannot be considered complete.

2. It may show lesions missed by the usual method of taking only a lateral view of the jaw.

3. It helps to elucidate lesions involving the internal and external surfaces of the mandible.

4. It is valuable in the investigation of—

- (a) Fractures
- (b) Osteomyelitis
- (c) Tumours

5. By combining the method with stereo-radiography, a more exact conception of the various structures may be obtained.

INFESTATION OF THE HUMAN INTES-TINE BY COPRID BEETLES IN BENGAL.

By M. O. T. IYENGAR,

Entomologist, Bengal Public Health Department,
Calcutta.

THE passing of certain live beetles, usually of a small size, by children in some parts of Bengal is a matter of frequent occurrence, especially during the early part of the rainy season. It has been observed by various people from time to time, chiefly by the lay public. Medical men have also noted such occurrences off and on, but there have hitherto been only a few records of such infestations, considering the wideness of the prevalence. Perhaps the first persons to call attention to this subject were Drs. A. C. Dey (1919), S. C. Sen (1919), T. N. Chakravarty (1919), A. C. Dey (1920), and S. C. Sen (1924). The beetles concerned in this infestation are small beetles of the family *Scarabæidæ*, sub-family *Coprinaæ*.

The habits of the beetles concerned in this infestation of children's intestines are such that they are not easily observed. Firstly, they are small; secondly, they mostly infest children who do not understand that there is anything wrong when these beetles come out of the stool they have passed; and lastly, the beetles take to their wings immediately they are liberated. It would be difficult to catch them after they have taken to their wings, and before they commence to

fly they are unrecognisable. These facts explain the fewness of observations on these interesting beetles. There appears to have been some doubt as to the authenticity of these observations, but it may be enough to mention that besides being well-known to the lay public in some districts of Eastern Bengal, there have been several first-hand observations made by medical men. There have also been a few instances in which the beetles were voided after the administration of an enema (Chakravarti, 1919); in one instance (Senior-White, 1920), beetles were found within the intestines in a case at autopsy.

But the identity of these beetles has not been properly understood and medical men as well as the lay public mistook these beetles for the mango beetles of the genus *Cryptorhynchus*. As the infestation by these coprid beetles coincides with the time when the mango is in fruit, these beetles are taken to be those which infest the mango fruit. It was Senior-White (1920) who, for the first time in India, identified specimens of beetles which were voided by children in Ceylon and he identified them as *Onthophagus bifasciatus*. The first of these beetles to be identified from Bengal was by Senior-White and Sen (1921), who also identified them as *O. bifasciatus*. In 1923, the present writer pointed out that besides *Onthophagus*, another genus, *Caccobius*, allied to *Onthophagus*, infested the intestines of children in Bengal. The species concerned in this case was *Caccobius mutans*, Sharp (Iyengar, 1923).

Since 1923, several instances of beetle infestation of the intestines of children have come to the writer's notice and the specimens collected from authenticated cases have been identified. To Mr. G. J. Arrow who rendered considerable help in this direction the writer is much indebted. The specimens from Bengal have been identified as *Onthophagus bifasciatus*, F. After an examination of the series of specimens of this group sent to Mr. Arrow, he has come to the conclusion that *O. birmanicus*, Harr., which was separated from *O. bifasciatus* on account of the long cephalic horn of the male, is really synonymous with the latter, as gradations from the long horned *birmanicus* form to the short horned *bifasciatus* form were to be seen in that series. In view of the identity of *O. bifasciatus* with *O. birmanicus*, Harr., the range of distribution of the species covers the whole of Northern India and Burma.

The following are fresh records of intestinal infestations by *O. bifasciatus*, Schall. (*O. birmanicus*, Harr.).

1. Damodya, Faridpur District, Bengal, Dr. S. K. Sil.
2. Berhamganj, Faridpur District, Bengal, Dr. A. C. Dey.
3. Faridpur, Dr. A. K. Sarkar.
4. Akyab, Burma, Dr. S. C. Sen.

Onthophagus unifasciatus is another species closely allied to *O. bifasciatus*, and this species has also been found to have similar habits of infesting the intestines of children. The following is a fresh record of such infestation:—

Hinoo, Ranchi, Bihar, Dr. H. Prajapati.

(I am indebted to Lieut.-Col. J. G. P. Murray, I.M.S., and Lieut.-Col. R. Knowles, I.M.S., for the specimens and case-history of the patient.)

This is possibly not the only record of *Onthophagus unifasciatus*. The first record of such a habit of this species is possibly from Matale, Ceylon, by Senior-White (1920) who figured the specimen and determined it as *O. bifasciatus*.*

The definite records hitherto of properly determined beetles from authenticated cases of infestation of human intestines by coprid beetles, may be summarised as follows:—

1. *Onthophagus unifasciatus*, F., recorded by Senior-White (1920) as infesting the intestines of children in Ceylon; recorded from children in Ranchi, Bihar, in the present paper.

2. *Onthophagus bifasciatus*, Schall. (*O. birmanicus*, Harr.), recorded by Senior-White and Sen (1921) from Bengal; now recorded in the present paper from Bengal and Burma.

3. *Caccobius mutans*, Sharp, recorded by Iyengar (1923) as infesting the intestines of children in Bengal.

Caccobius mutans is a very tiny black glistening beetle measuring 2.6 mm. by 1.8 mm. and has a smooth body. *Onthophagus bifasciatus* and *unifasciatus* are larger beetles and their outer wings are marked with a broad black band over a brown background. They measure from 2.9 mm. to 4 mm., by 4 mm. to 5.8 mm., but they generally measure about 4.0 mm. by 5.6 mm. The following gives the points of difference between these two species of *Onthophagus*:—

Onthophagus unifasciatus, F. Sexes alike, no cephalic horn, but three elevations on thorax.

Onthophagus bifasciatus, Schall. Sexes unlike, a head horn and three thoracic lobes in the male, and a head carina and three thoracic tubercles in the female.

Onthophagus unifasciatus and *Caccobius mutans* are rare species in Northern India. *Onthophagus bifasciatus* is more common and has been collected by the writer from various parts of Bengal, including the districts of Jaipauri, Faridpur, Dacca, Howrah, Calcutta and 24-Perganas. It is likely that this species is prevalent in most of the districts of Bengal. This insect is found in or near human excrement, either within the hard stools or in the mud just under it. But even here its numbers are few compared to the number of other coprid beetles found in such situations. This insect

* Mr. Arrow in a communication to me says, "The species figured in the paper by Mr. Senior-White is *O. unifasciatus*, which is a common species in Ceylon. It is doubtful if *O. bifasciatus* occurs there."

is fond of darkness, and when exposed to daylight it feels uneasy and quickly flies away. It is often attracted to light at night and specimens have often been collected inside houses near a light at night. This species is usually nocturnal in its habits and specimens may be seen flying into privies during the evenings, and flying away from them at daybreak.

In the province of Bengal, infestation of the intestines of children by these beetles appears to be fairly common, especially in the eastern wet districts. It would be of interest to obtain the notes of medical men who had under their charge cases of intestinal infestation by these coprid beetles. I am indebted to these medical officers for the notes they have sent me.

Dr. B. K. Ray, District Health Officer, Dacca, writes "I have personally observed some of these beetles being passed alive by children, not necessarily suffering from diarrhoea. They resemble the mango beetles and fly away immediately after they are passed in stools."

Dr. A. C. Dey (Faridpur District) writes "I have seen only children below ten years of age affected by these insects, but no adults. The main symptoms of this affection in the children are diarrhoea, flatulence, anorexia and anaemia combined with the passing of these beetles with stools. The insects come out with the stool and staying in it for a minute or two, begin to move and fly away." Of another case in his charge Dr. A. C. Dey says "My patient is a boy of one year, his main diet mother's milk, cow's milk and barley water. Formerly he used to pass eight to ten live beetles per day. The number of beetles passed are fewer now." These beetles have been identified as *Onthophagus bifasciatus*.

Dr. S. C. Sen had under his observation at Akyab, Burma, a case of a similar infestation by *Onthophagus*. The following notes of the case may be of interest. "Padan, a male child aged 4, contracted the disease in the month of July 1923, in the village of Chakdaha, Lomsingh, Faridpur District, Bengal. There he was treated for diarrhoea by many physicians for more than four months but to no effect. He was brought here for a change and placed under my treatment. He was pale and very emaciated. His bowels were very loose, six to seven stools per day; the motions were muddy and of a very offensive smell, and accompanied always with a quantity of thin mucus. He had a voracious appetite and thirst. The stools were examined for hookworm and amoebæ but none were found. The beetles were passed especially when the stools were very loose, sometimes six or seven beetles at a time. The patient had slight oedema of the legs and the face was puffy. There was no rise of temperature. The beetles were seen to fly within a couple of minutes of their expulsion." The specimens collected from this patient have been identified as *Onthophagus*

Dr. S. C. Sen had another case in his charge of which he writes as follows:—"My second case, a boy of two years, contracted the disease in Akyab. He was a frequent visitor to the house of the former child (Padan). He got diarrhoea and started passing stools."

Dr. Prajapati of Ranchi, Bihar, had several cases of this kind under his observation and he sent in the specimens of beetles actually collected by him from one of the cases, and these have been identified as *O. unifasciatus*. The patient was a two year old daughter of a Bengalee clerk residing in Hinoo (a place close to Ranchi). "These beetles" he says, "were produced before me, saying that the patient has been passing these beetles for the past six months, and that the elder sister, aged five years now, used to pass this kind of insect at the age of about two years. At the present time, the elder child is free from the affection." About the beetles themselves, he says, "these beetles were picked out by the father of the child from the body of the hard stools passed. It has also been stated that generally these beetles, after the passage of the stools, make their way out of the stool and fly away." As regards the condition of the patient, he says that "she was anaemic and emaciated but had a voracious appetite." It appears that this affection is frequent at Ranchi. Dr. Prajapati says, "Two more Bengalee clerks report to me that their children too pass these insects off and on. They live in Doranda (near Ranchi)."

Dr. A. K. Sarkar, District Health Officer of Faridpur, writes to say that this disease is very common in the district of Faridpur, and he sent me two specimens of *Onthophagus bifasciatus* which were collected by him from a child.

The manner in which these beetles gain entrance into human intestines is still unknown. At the most only vague guesses have been made as to the probable modes of entry. Two methods readily suggested themselves as to the manner of invasion; either that the beetles enter by mouth or that they do so *per rectum*. As regards entry by the mouth, it is possible that live beetles are accidentally swallowed along with mud or dirt by children, and should such a thing happen, the beetles might be passed out alive with the stools if they are capable of withstanding the conditions within the stomach of the child for the period of their captivity. But a chance entry like this is not likely to cause such definite symptoms as have been found in the case of children that are subject to this trouble. Further, it has been found that the same child passes these beetles off and on, as many as six or seven beetles being expelled with stools in one day. As all these beetles belong to the same species, the view that the infestation is due to accidental swallowing of live beetles along with dirt or mud by children does not hold good. If such accidental swallowing was the cause, we ought to encounter different kinds of insects and it is extremely unlikely that

as many as six or seven of these rather rare species should be swallowed by the child every day.

All these considerations point to some more definite method of entry, either of the adult beetle or of its immature stages. The other possible method of entry of the beetles by the mouth is by means of eggs laid in the food. This view was advanced by Senior-White (1920) with regard to the species infesting children in Ceylon. He suggested that in Ceylon the infection might occur through eggs being deposited on partially decomposed fish, an important article of diet among the Ceylonese. But against this view is the fact that children just about a year old, whose diet consisted solely of milk and barley water, were affected by these beetles, and in such cases the swallowing of eggs with the food is out of the question. In addition to this, we should consider whether it would ever be possible for the larval and pupal stages of these beetles to withstand the wet and anaerobic conditions prevailing within the human alimentary canal until such time as they can emerge out as adults. Adult scarabeid beetles are sometimes capable of withstanding the most trying conditions, but it is doubtful if the larvæ and pupæ are adapted for development under such unusual conditions. Moreover, in none of the cases of beetle infestations have any grubs or pupæ been recovered from the stools even after the administration of purgatives.

The more likely method of invasion was suggested by Sen in the paper by Senior-White and Sen (1921). He suggested that while children defæcate in the open, the beetles gain entrance into the intestines through the anus. This appears to be the probable mode of entry. But it is more likely that instead of the entry of the beetles during the period of evacuation of the child, the beetles effect their entry into the intestines during the time the child is asleep and at night. These beetles which are nocturnal in their habits, are attracted to anything foul smelling. Attracted by the foul smell emanating from the anus of a child suffering from any intestinal disorder, these beetles which are of a small size, could easily effect their entry into the rectum of the child while it is asleep. The sensation caused by the beetles trying to gain entrance into the rectum would relax the sphincter muscles and thus the beetles would effect an entry. The beetles which have been collected from children are so small that they could easily effect their entry per rectum, as easily as they come out of it. *Caccobius mutans* especially is very small.

In support of this hypothesis, we have the instance of coprid beetles of the genus *Macropocopris*, a genus which is closely allied to *Onthophagus*, which usually inhabits the droppings of the wallaby in Australia. These beetles cling to the fur of the wallaby and await its droppings, and as soon as the wallaby evacuates, they jump on to the droppings and live on them.

This is their normal life. But often enough, it has been found that they effect their entry into the cloaca of the wallaby and live inside its lower intestine. Arrow in 1920 described two species of this genus, and in describing the habits of these beetles he says "two species (of *Macropocopris*) were found by him (Dr. Illingworth) attached to the fur of wallabies, evidently awaiting the droppings which form the food of most of the group. Specimens were found even within the cloaca." In the present instance of the species of *Onthophagus* and *Caccobius*, it is very likely that the beetles, which normally live on human excrement, occasionally enter the rectum of children in a manner similar to *Macropocopris* cited above.

It has been said that generally more female specimens are collected from children than male specimens. But it should be noted that judging the sex of specimens by the presence or absence of cephalic horns is very unreliable. In *Onthophagus unifasciatus* both the male and the female are closely alike, the male having no cephalic horn. The same is also true of *Caccobius mutans*. In the case of *Onthophagus bifasciatus*, some of the males have only a very small horn and as such are not easily differentiated from the females. In cases where the males are not easily made out, the determination of the sex of a specimen is usually difficult. Arrow (1920) has found a constant feature by which the sex of the specimens could be ascertained. "A careful examination of the shape of the last ventral segment," he says, "will enable this to be done without difficulty. In the female, this segment is of nearly equal breadth throughout, whilst in the male it is always considerably narrowed in the middle."

I am greatly indebted to Mr. G. J. Arrow of the British Museum for much valuable help received from him. I should also acknowledge my indebtedness to the several medical officers mentioned in this paper for the notes and specimens they sent me.

A NOTE ON THE BREEDING AND HABITS OF THE EYE-FLY, *SIPHONELLA FUNICOLA*, MEIJ.

By D. N. ROY, M.B., D.T.M. (Cal.).

(From the Department of Medical Entomology of the School of Tropical Medicine, Calcutta.)

Introduction.—This year while organising a research on *Naga sore* in the tea gardens of Assam, Dr. C. Strickland, Professor of Medical Entomology in this institution, suggested that an

of the flies (*vide* Chart); and I also took up the investigation of the breeding-places of the fly.

Breeding in the laboratory.—Attempts to breed the fly in the laboratory failed, though Patton was able to raise them very easily when they were kept in ordinary test-tubes; thus he succeeded in studying the whole life-cycle. I was never able to get either egg or larva to hatch out under these conditions.

Natural breeding-places.—Patton tried to find the natural breeding-places by picking out larvæ similar to those which he had bred out in the laboratory from various places and then rearing them. As he had failed Dr. Strickland suggested the "meat-safe method." A large number of small, square mosquito nets were taken into the

Showing the incidence of *Naga sore* and Epidemic conjunctivitis in a Tea Estate in Assam during 1924-25.

attempt should be made to determine the natural breeding-places of *Siphonella* flies. These flies are not only a serious pest during May, June and July, but the general opinion is that they are directly responsible for the spread of *Naga sore* and epidemic conjunctivitis.

In the sequel I investigated this opinion, but the short time at my disposal did not permit me to trace the connection between these flies and epidemic conjunctivitis, except for confirming the fact that the seasonal incidence of the diseases coincided very closely with the prevalence

field but as it was found that the meshes were large enough to permit the flies to escape through them, the inside was lined all round with long-cloth, which was stitched to the net. A large number of these were spread on the following:—

1. Human faces—either in the shade or in open fields.
2. Cowdung—fresh and decomposed.
3. Horse dung—fresh and decomposed.
4. Rotten jack fruit.
5. Bark from the trunk of trees together with mounds of white ants.

6. Dung and urine and sodden earth in cattle sheds.

7. Decaying leaves and branches of trees.

8. Droppings of fowls.

9. Decaying leaves of bananas.

The nets were spread and left for two to three days when they were examined for the presence of any insect which had bred out. If a fly was present it was captured for identification. On no occasion was it found possible to leave the nets spread out for long as they were disturbed by children, cattle, jackals and sometimes by elderly people. Holes made by beetles in the curtains were common. Only dung and urine and sodden earth in cattle sheds yielded the flies and then on four occasions, the numbers which bred out being 5, 4, 3, and 1.

Habits.—A brief description of the habits of these flies is as follows:—They are very active on a hot sunny day, but none can be found when the air is cool or the sky cloudy. They rest on thatch, strings, and small strips of cane hanging down from the roof. Within two to three days the portions of the straw where they have rested may be found to have turned black and are covered over with a web inside in which some of the flies will be seen hiding. On a sunny day in the morning and in the afternoon many will be noticed resting on the grass. They feed on warm human excretions, on the exudates of ulcers of man and of animals, putrid sloughs of ulcers, the discharge from the nostrils or eyes and from the rectum of cattle, and cow and horse dung, fresh and decomposed. These flies are always found in large numbers in cow-sheds, much more so than in other rooms of the same house. There are as a rule very few in the open fields. I observed a striking fact about their distribution in Srimangal, where very few could be noticed; this is a place about two miles from the tea garden in which I was working, where I saw large numbers of the flies.

Unlike house-flies they seldom sit on ulcers but usually settle on the healthy skin surface at the margin and feed there. This no doubt protects their feet and wings from getting wet which would make their flight difficult, and may have an important bearing on the propagation of diseases through their feet and wings.

Their mouth parts are adapted for sucking and not for piercing, but the statement that "they doubtless can act as scarifying organs, enabling the fly to remove dried scab to reach serous exudation below" as mentioned by Senior-White, cannot be supported from my observations. What they have been found to do is to forcibly try to push their proboscis through a rent in the scab and thus get at the exudation below.

They could not be kept alive in the laboratory under any circumstances for more than six days.

The accompanying chart showing the seasonal coincidence of Naga sore and epidemic conjunctivitis has kindly been provided by Dr. R.

Murphy, Medical Officer, Luskerpore Tea Estates, South Sylhet, to whom my thanks are due.

OBSERVATIONS ON THE ANTIMONY (UREA-STIBAMINE) TEST FOR KALA-AZAR.

By A. N. BOSE, M.R.C.P.,
MAJOR, I.M.S.,

S. K. GHOSH DASTIDAR, M.B., D.T.M. (Bengal),
and

B. N. BAGCHI, B.SC., M.B.

(From the Department of Pathology, Prince of Wales' Medical College, Patna.)

IN the *Indian Medical Gazette* for June 1927, Chopra, Gupta, and David described a new serum test for kala-azar. These workers observed that when certain organic compounds of antimony were brought in contact with the serum from kala-azar patients in a miniature test-tube, a thick flocculent precipitate was formed at the junction of the two; whereas with non-kala-azar sera no such precipitation occurred. This reaction of the kala-azar blood was so characteristic that these observers developed it into a test for the diagnosis of kala-azar. They tried a number of organic compounds of antimony, but showed a preference for urea-stibamine for carrying out this test. Napier (1927) extended these observations to a large number of cases and corroborated the findings of Chopra and his collaborators, but preferred weaker solutions of antimony compounds. As kala-azar cases are frequently seen in Patna, we tried this test, but at first found it somewhat confusing. During the meeting of the Far Eastern Association for Tropical Medicine held in Calcutta during December last, Col. Chopra was good enough to demonstrate this reaction to the senior author and we decided to apply it to a number of cases, both kala-azar and non-kala-azar, which came under our observation in the Hospital of the Prince of Wales' Medical College, Patna, in order to test its diagnostic value. In their original paper the authors used undiluted serum and a 4 per cent. solution of urea-stibamine, but as it was found to be giving positive results in some non-kala-azar cases, in a paper read before the Far Eastern Congress, Col. Chopra pointed out that doubtful cases could be eliminated by using a 1 in 10 dilution of serum. In his experience if the serum was diluted ten times and the test performed with this dilution precipitation occurred only with kala-azar sera and never with non-kala-azar sera. In our series of cases we used (a) undiluted serum, (b) 1 in 5 dilution of serum, (c) 1 in 10 dilution of serum; we also employed 4 per cent., 2 per cent. and 1 per cent. solutions of urea-stibamine. The tubes used were 55 mm. long and 3 mm. in diameter, and the serum was diluted with normal saline instead of

N. B.—W. R. = Wassermann Reaction ; + + + = Strongly positive ; + + - = Moderately positive ; + - - = Slightly positive ; - - - = Negative ; 0 = Undiluted serum ; 5 = Diluted serum 1 in 5 ; 10 = Diluted serum 1 in 10.

distilled water. The age of the serum, which was always kept in an ice chest, varied from a few hours to 3 or 4 days.

A perusal of Table I will show that of 66 samples examined, 5 from perfectly healthy and normal individuals gave negative results in all dilutions of the serum and with all 3 solutions of urea-stibamine.

Of the 61 pathological sera, 3 were known to be from kala-azar patients and 58 from patients suffering from other diseases: 3 kala-azar cases gave marked positive reactions in all dilutions with both 4 per cent. and 2 per cent. solutions, while with 1 per cent. solutions the undiluted sera gave a positive reaction and the diluted sera gave varied results. The Wassermann reaction was negative in all 3 cases.

Of 58 sera from patients suffering from other diseases, the 1 per cent. solution gave negative results in all dilutions; the 2 per cent. solution gave similar results, except in 3 cases where undiluted sera only gave a doubtful reaction; the 4 per cent. solution on the other hand gave with (a) undiluted serum, 4 positive and 3 doubtful results; (b) 1 in 5 serum, 5 doubtful results; (c) 1 in 10 serum, all negative reactions.

The Wassermann reaction showed 25 strongly positive, 1 moderately positive, 4 slightly positive, and 28 negative reactions. A positive Wassermann reaction did not appear to influence the reaction in any way. Only 2 samples with a positive Wassermann reaction gave a slightly positive urea-stibamine reaction in undiluted serum, while the same sera gave doubtful reactions in 1 in 5 and negative in 1 in 10 with a 4 per cent. solution: 2 samples with negative Wassermann reaction gave similar results as above. It appears, therefore, that 1 in 10 diluted serum with 4 per cent. solution of urea-stibamine gives better results and minimises the possibilities of error, especially in well-developed cases of kala-azar.

We next took up a series of 24 cases (Table II) to study the comparative serum response to the formol gel and urea-stibamine tests. All 13 cases from the kala-azar ward gave a positive reaction with a 4 per cent. solution in all dilutions, and varied in reaction with 2 per cent. and 1 per cent. solutions. Ten cases showed a positive formol gel reaction; 3 negative formol gel cases had a full course of treatment. Not one of the 11 non-kala-azar cases taken from the general ward gave a marked positive reaction with the formol gel or antimony (urea-stibamine) test. A doubtful reaction was, however, obtained in 2 cases with formol gel and in 5 cases with 4 per cent. urea-stibamine solution; 2 of these 5 cases were negative at 1 in 10 dilution.

CONCLUSIONS.

From the series of cases studied by us we feel justified in drawing the following conclusions:—

1. A 1 in 10 dilution of serum gives a negative antimony test in all non-kala-azar cases.

2. A dilution of 1 in 10 of serum gives better results than undiluted serum or a dilution of 1 in 5, in differentiating kala-azar from non-kala-azar cases.

3. A 4 per cent. urea-stibamine solution gives more positive results than weaker solutions.

4. The factors responsible for a positive Wassermann reaction do not appear to influence this test.

5. The reaction appears to be a specific one for kala-azar serum.

6. The reaction lasts longer than the formol gel reaction after a course of treatment.

Our grateful thanks are due to Lt.-Col. H. R. Dutton, I.M.S., Professor of Medicine, Prince of Wales' Medical College, Patna, for permitting us to carry out this investigation in the Patna General Hospital.

ELECTRO-CARDIOLOGY AND SOME OBSERVATIONS ON INDIANS.*

By RAI S. C. BANERJEE BAHADUR,
Assistant Professor of Physiology, Medical College, Calcutta.

THIS evening I shall lay before you the highly technical subject of electro-cardiology. It was by the invention of the string galvanometer by W. Einthoven, a Dutch physiologist in 1901, that the study of the electrical variations associated with the activity of the various chambers of the heart was made possible. In Calcutta this subject has been introduced only lately, as the electro-cardiographic apparatus was obtained for the Medical College Hospital in 1925 by the personal efforts of the recent Principal, Col. Barnardo, who is foremost in maintaining that the electro-cardiograph is essential for the modern diagnosis and treatment.

Importance of Electro-cardiology.—During the last thirty years, largely owing to the work of Sir James Mackenzie, Sir Timothy Lewis, Professor Starling and their pupils, the attention of the medical profession has been particularly focused on the study of the cardiac

muscle. It is upon the condition of the muscles of the heart more than upon the condition of the valves, that the ultimate basis of the patient's outlook for life depends. Till recently the diseased state of the valves used to draw our attention to the heart and was the only valuable aid in diagnosis and prognosis of diseases of the heart; but the indication of the cardiac efficiency really rests with the power of the cardiac musculature, which indeed determines the capability of the patient for work and the prognosis of the case. How often, in the absence of any obvious disease of the valves, is our attention not directed to the heart and we are led to neglect a condition of the cardiac muscle which certainly is rather more important and more dangerous than a diseased condition of the valves. From the electro-cardiogram we can have definite information of the degree of damage to the cardiac muscle.

Again, in rheumatic infection not only the valves but also the cardiac muscles are involved in the pathogenic process. This is corroborated by the presence of Aschoff's bodies in the heart muscle, coincident with the implication of the valves. Hence not only the signs of valvular disease but also an idea of the condition of the cardiac muscle is necessary for every cardiologist. Some go so far as to say that close differentiation between the various valvular lesions has only an academic value, and after all the absence of loss of compensation which is dependent on the integrity of the cardiac musculature is the chief factor.

Though there are three main structures in the heart which may produce symptoms, it is the cardiac muscle which is the principle factor.

1. *The conducting system of Tawara or the genetic system of Mackenzie* is concerned with every activity of the heart. Any impairment of this structure is of importance in so far as it interferes with the proper action of the heart muscle. The electro-cardiograph is the instrument for definitely diagnosing such defects.

2. *The valves* are the second structure that give rise to symptoms. Any damage to them is of importance only in so far as it embarrasses the cardiac muscle in its proper work.

3. The third structure is the muscle, and the chief problem resolves itself into the finding out the integrity of the muscle and the state of its efficiency.

There may be variations in the rate and the rhythm of the heart, but these are without any prognostic significance unless they embarrass the proper working of the heart muscle. Information about cardiac muscle is best obtained by the electro-cardiograph, hence the great importance of electro-cardiology.

There are certain features of the normal and abnormal heart beat which can be best studied by the electro-cardiogram. From it one can easily study the time of propagation of the wave of excitation and contraction either through the auricle or the ventricle; moreover, the interval

between the auricular and the ventricular complexes of the tracing gives a very accurate measure of the time of transmission of the impulse through the bundle of His. Any abnormal point of origin of the stimulus for contraction (e.g., ectopic beats) or any abnormal direction of propagation of the wave (e.g., bundle lesion), will produce a definite change in the form of the tracing and will thus indicate the abnormal condition of the musculature or the conducting system. Hence the special value of the electro-cardiogram in diseases affecting the cardiac muscle and the conducting system.

It is to be noted, however, that the extent of movement shown in an electro-cardiogram is not in proportion to the strength of the contraction. It is an accurate representation of the difference of electric potential between the two electrodes as the stimulus travels along its normal or abnormal paths.

A few preliminary anatomical and physiological considerations may not be out of place here. It is well known that the heart continues to beat even when removed from the body, thereby indicating that there are within the heart certain structures which possess the property of causing the various chambers of the heart to contract in an orderly fashion.

Lately several important discoveries regarding the structure of the heart have been made in close succession. For instance the discovery of the auriculo-ventricular bundle by His and Stanley Kent in 1893, and of the auriculo-ventricular node and the branches of the auriculo-ventricular bundle, one going to each ventricle, by Twara in 1906, and of the exact location of sino-auricular node by Flack and Keith in 1907 completely changed our conception of the working of the heart.

The sino-auricular node is situated at the junction of the superior vena cava with the right auricle. The cardiac impulse is said to be produced by a biochemical action of the cells in the node, which are the remnant of the primitive tissue from which the heart was developed. The products of these cells pass from one cell to another, and when they reach the cells attached to the muscles they have accumulated in sufficient strength to start the auricular activity, and the two auricles are involved in simultaneous contraction. The cardiac impulse then reaches the auriculo-ventricular node, situated near the bottom of the right auricle, and passes down the bundle of His and its branches to their final ramifications amongst the Purkinji's fibres. The impulse is thus conducted to the inner surface of the two ventricles and the contraction spreads from the endocardial surface through the cardiac muscle to its pericardial surface.

It is well known in physiology that the activity of any living tissue is accompanied by the production of variations in the electric potential, which can be made manifest by suitable instruments; consequently the activity of all muscular

tissue is associated with the production of electrical energy; i.e., when a portion of muscle passes into a state of activity, it becomes relatively negative to the portion of the muscle at

experiment; when a strip of muscle, preferably a muscle with parallel fibres, is connected with a delicate galvanometer by two non-polarised electrodes placed at its two ends, no electrical

FIG. 1.

rest. This is called the *action current* of the muscle by physiologists, and is the fundamental basis of electro-cardiography. Sir Timothy Lewis has clearly demonstrated this by a simple

variation is detected by the galvanometer if the muscle be uninjured and at rest. When such a muscle is stimulated at one extremity, however, an electrical disturbance passes as a wave

from the stimulated end (i.e., from the portion of the muscle brought into activity) to the portion of the muscle at rest. (This will be made quite clear from Fig. 1.)

When a strip of muscle PD is stimulated; one end P, it becomes active and so relatively negative to the other end D, which is inactive at that particular moment, and the galvanometer indicates the presence of a current by its swing in one direction (Fig. 1a). As the wave of excitation travels along the muscle from P to D, when it arrives at D the highest point of deflection is reached (Fig. 1b). A moment later the whole muscle is in activity and becomes iso-electric and the galvanometer swings back to its original position, showing that no current is flowing through it (Fig. 1c). A little later when the activity begins to subside at P, D remains active, and so becomes relatively negative to P, and the galvanometer swings in the opposite direction; when the deflections of the galvanometer are recorded, and a *diphasic* curve is produced (Fig. 1d).

highly complex nature, with the muscle fibres passing in various directions, the graphic record of the action current of the whole heart consists of a series of complicated waves for each heart beat; a resultant of the action currents of the muscle fibres of the heart.

Waller showed in 1887 that when any two areas of the body including the heart between them are properly led off and connected with a suitable and delicate galvanometer, the minute electrical currents generated by the cardiac activity could be easily detected and recorded, and that it is unnecessary that the heart should be exposed for recording them.

In his experiments Waller used the capillary electrometer, which, though very sensitive to indicate the presence of minute electrical currents, was quite inadequate to give a faithful record of the quickly varying currents produced during the contractions of the chambers of the heart. He was unable, however, to correlate the different electric curves with variations in the action of the different chambers of the heart.

FIG. 2.

If the strip of muscle be stimulated at D (instead of at P as in the first part of the experiment) and the wave of excitation travels along the muscle in the opposite direction, a diphasic curve is produced but its phases are inverted (Fig. 2b). Hence the form of the curve produced is governed by the direction in which the wave of excitation travels through the muscle. It is now generally accepted that the wave of excitation precedes the visible wave of contraction and there is a definite relation between two (in a muscle), but for practical purposes both are regarded as part and parcel of one and the same process. As the cardiac musculature is of a

The invention of the string galvanometer by Einthoven in 1901 removed this want. He succeeded in correlating the various electric curves recorded by the string galvanometer with the activity of the different chambers of the heart, both healthy and diseased.

Electro-cardiology commenced with the invention of the string galvanometer, and the electrocardiograph constitutes its practical application for clinical purposes.

The principle of the string galvanometer is based on the fact that whenever a current of electricity passes through a magnetic field at right angles to the lines of force, it tends to be

deviated to one side or the other according to its direction. The extent of deflection varies directly with the intensity of the current passing through it, the magnetic fields remaining constant.

In the electro-cardiograph, the action currents of the heart are led (by connecting the extremities of the subject in accordance with the standard leads) through an exceedingly fine silvered quartz fibre, suspended between the poles of a powerful electro-magnet in its magnetic field. Strong light from a Pointolite lamp or arc light is concentrated on this fine fibre by a condenser. The shadow of the fibre, magnified by a microscope, is projected on to and recorded photographically on a sensitive plate or film, moving at a fixed rate.

There is an appliance for indicating the time taken by each wave of the tracing, which in all modern electro-cardiographs is a rotary time-marker worked by an electro-magnet and a vibrating bar. With its help the beam of light falling on the camera (containing the sensitive plate) is interrupted at intervals of $1/25$ th second; and vertical lines are produced in the

in the origin and propagation of the wave of excitation.

The time occupied by each wave can be calculated from the number of vertical lines covered by each: the interval between the two vertical lines represents $1/25$ th of a second. The horizontal lines are 1 mm. apart. The height of an excursion from the upper border of the base line is the measure of the voltage producing it.

Normal Electro-cardiogram.

In each cycle of a normal electro-cardiogram there is a small upward wave known as the "P" wave. This is followed after a certain interval by a series of upward and downward deflections called the "QRS" group of which the upward deflection is known as "R." There may be a downward deflection preceding "R" known as the "Q" wave, and another downward deflection after "R" called the "S" wave. Both Q and S or either of them may not always be present even in tracings taken from healthy individuals. The "QRS" group corresponds with the wave of excitation through the ventricle. Following the "QRS" group there is a short interval producing

FIG. 3.—Normal Electro-cardiograms. European. Aged 28 years.

tracing of certain intervals which represent $1/25$ th second. Thus the time occupied by each phase of the electro-cardiogram can be easily and accurately measured.

Any pair of areas of the body which is connected with galvanometer is called a "lead" or "derivative." Almost every different lead shows a different electrical current from the same heart. It becomes necessary therefore to follow a definite method so that records taken from different patients may be compared. The following leads from the extremities have been universally adopted, viz.:—

- | | | |
|------------------------|----|---------|
| Right arm and left arm | .. | Lead I. |
| Right arm and left leg | .. | " II. |
| Left arm and left leg | .. | " III. |

In following this standard method of connecting the patient with the galvanometer, we must have the same direction in each lead each time the record is taken; thus the work of comparing records taken from the same patient at different times is facilitated. Any wave taking an abnormal direction indicates an abnormality

a horizontal or nearly horizontal base line, ending in an upward generally broad deflection called the "T" wave. Each cardiac cycle of a normal electro-cardiogram consists of an *auricular-complex*, from the rise of the "P" wave to the beginning of the "QRS" group, and a *ventricular-complex* from the beginning of the "QRS" group to the end of the "T" wave.

The "P" wave represents the difference of electric potential produced during the spread of the wave of excitation through the auricle from its origin at the sinus node, i.e., auricular systole. The ventricular complex represents the ventricular systole. The P-R interval marks the length of the time taken by the impulse to travel from the auricle to the ventricle, i.e., the auriculo-ventricular conduction time or the A-V interval.

There are differences of opinion as to the interpretations of the "QRS" group and "T" wave.

There is practically no marked difference in the "P" waves in the tracings of apparently healthy Europeans and Indians.

FIG. 4. Bengali. Aged 28 years. Muscular.

FIG. 5.—Normal Electro-cardiograms, Indians (Bengali).
Aged, 90 years, 6 months. Height, 5'-5½".
Weight, 9 st. 5 lb. Chest girth, 35"FIG. 6.—Punjabi. Aged 31 years. Height, 5'-3½".
Weight, 9 st. 1 lb. Chest girth, 34½".FIG. 7.—Aged 30 years. Height, 5'-6½".
Weight, 10 st. 10 lb. Chest girth, 34½".

The P-R interval is generally found to be slightly longer in Europeans. The average P-R interval in the Indians (Bengalis), is 0.14—0.16 second, whereas in Europeans it is generally 0.16—0.18. The duration of the ventricular systole, as measured by the R-T intervals of the electro-cardiograms, is distinctly greater in the Europeans. The average ventricular systole of Europeans (as given in books) varies from 0.34—0.42, but the average of the few cases I have done here is 0.34—0.38 second, whereas the average for the Bengalis is 0.28—0.30. The latter figure is reached only by a few muscular subjects. There is a marked difference here. How can this be accounted for?

It is well known in electro-cardiology that in cases of marked ventricular hypertrophy the duration of the ventricular systole is increased; so much so that tracings of such cases at times can only be differentiated with difficulty from tracings of bundle-branch lesions by other distinguishing factors. Thus it is concluded that the increase in the ventricular mass causes increase in the duration of the ventricular systole. Consequently decrease in the ventricular mass decreases the duration of the ventricular systole. This lower reading may be accounted for by the less muscular mass in the ventricles of Bengalis. From the weights of hearts of cases of accidental death it has been ascertained that Europeans' hearts weigh on an average about 12 ozs., whereas the Bengali's heart's weight varies from 7½ to 9 ozs., of which the former figure represents the weights of female hearts. (The figures are taken from the records of the Calcutta Police Morgue.)

In the few cases examined by me there is not much difference in the electro-cardiograms of the Hindus and Mohamedans of Bengal.

The ventricular systole time of Punjabis and Nepalis (though only a few cases were observed) approaches very closely to the European systole duration of the ventricles, being 0.34—0.36 second, and so higher than the Bengalis.

CASES.

Sinus Arrhythmia.—(Fig. 8), D. P. Chowdhuri, a boy of 11, had an attack of influenza about 8 months previously. During convalescence once he became almost unconscious and after that his pulse used to be irregular; when he came for electro-cardiography his pulse was markedly irregular, 100 per minute. There was no abnormal auscultatory sign.

There is no abnormality in the auricular and ventricular complexes. The irregularity is in the duration of the diastole (T-P interval), showing the impulse for cardiac contraction originating irregularly in the sinus node.

Extra Systole.—(Fig. 9), European male, aged 42. Nothing abnormal except irregularity of the pulse.

The electro-cardiogram shows the presence of ventricular extra-systole E.S. in lead II—by the abnormality of the form of ventricular complex and the compensatory pause.

Auricular Flutter.—(Fig. 10), N. J., a Mahomedan male, aged 35, was admitted to the Additional Physician's ward of the Calcutta Medical College Hospital with symptoms of heart failure.

Previous History:—About seven weeks prior to his admission he noticed swelling of his legs and began to feel breathless on exertion. The heart dulness was increased, mostly transversely; the apex beat at the 6th intercostal space 1½" to the left of the mammary line; diastolic and pre-systolic murmur at the apex.

Pulse irregular, 64 on lying down, but on sitting up rose to 85 per minute.

Diagnosis:—Mitral stenosis and myocarditis.

The electro-cardiogram shows continuous regular undulations of the base line, in leads II and III, characteristic of auricular flutter. The P waves are inverted and there are three P waves to one ventricular complex which is superposed on them—showing a promiscuous auricular contraction having no relation to the ventricular systoles. The tracing was taken when the patient was fairly well on the way to recovery.

Auricular Fibrillation.—(Fig. 11), K., Mahomedan male, aged 18, tram driver by occupation, was admitted to the Additional Physician's ward with dyspnoea, cough, ascites and weakness.

Previous History:—Occasional attacks of fever lasting 7 or 8 days for the last four years. Dyspnoea and ascites with enlargement of the liver and spleen for the last six months. Size of the heart increased transversely—apex-beat irregular, diffuse, in the 5th left intercostal space ½" external to the mid-clavicular line. Pre-systolic and systolic murmur at the apex. (The 2nd sound at the apex was often accompanied by a murmur.) Pulse very irregular, rate 80 in the recumbent position, but on sitting up rises to 88 per minute. There were a few rhonchi in the lungs, but no abnormality of the arteries. Albumen was present in the urine without casts.

Diagnosis:—Double mitral disease with myocardial degeneration.

The electro-cardiogram shows absence of regular P waves with irregular undulation of the base line varying in size and form characteristic of auricular fibrillation. The tracing also shows ineffective, irregular, promiscuous origination of auricular contractions without any relation to the ventricular systoles.

Myocardial Damage.—(Fig. 12), J. W., Anglo-Indian male, aged 15, was admitted to Col. Sandes' ward, Medical College Hospital.

Previous History:—About three months previously he had pain in the pericardial region after finishing a football match.

Complaints:—Palpitation and pain in the præcordial region whenever he plays games or runs races.

Examination:—Apex beat in the 4th interspace about 2½" from the mid-sternal line. Heart increased towards left. Pulse regular, of good volume and tension, 64 per minute. Functional test causes no discomfort except on running as stated above.

Auscultation:—Revealed no abnormality, arteries good, urine no albumen.

Diagnosis:—Hypertrophy of the heart.

Electro-cardiogram.—P wave—markedly bifurcated in leads II and III indicating asynchronism of the auricles. QRS group notched, and its duration increased, 0.16 sec., indicating myocardial damage (this cannot be definitely diagnosed by any other means). The tracing also shows right ventricular predominance. (The time marker stopped working when the tracing of the lead III was being taken.)

Ventricular Predominance.—(Fig. 13). By the electro-cardiographic method one can investigate the condition of the cardiac musculature as well as that of the bundle-branches. It has very little to do with valve lesions directly. It is only when the valve lesions affect the mass of the cardiac musculature that they influence the form of the electro-cardiographic tracing. For instance, in cases of disease of the aortic valves there is

increase of the mass of the left ventricle and electro-cardiograms show left ventricular predominance.
In cases of mitral stenosis of the right side of the heart the cardiac muscle hypertrophied and right

ventricular predominance is shown in electro-cardiograms; as well as auricular hypertrophy (which cannot be diagnosed by any other means).

FIG. 8.

FIG. 9.

FIG. 10.

FIG. 11.

FIG 12

Mitral regurgitation also produces secondarily right ventricular hypertrophy, after overtaking the left ventricle, but early cases of mitral regurgitation show left ventricular predominance.

which I received from him in this connection. He not only obtained this instrument, overcoming various difficulties, but took particular care in

FIG. 13.

In Fig. 13 the R wave in lead I is the largest of all R waves in the three leads, and consequently is larger than the R wave in lead III. There is no S wave in lead I, but the S wave in lead III is very large and even larger than the R, in lead I. In the lead II S is larger than R.

Right Ventricular Predominance.

many details in connection with its installation and working.

I also desire to express my gratitude to Col. A. C. McGilchrist for his valuable advice in working the apparatus, as well as to Pro-

FIG. 14.

The R wave is the largest in lead III but there is no S wave; whereas in lead I the R wave is small but the S wave is very large.

Before concluding this paper I should be failing in my duty if I did not record my gratitude to Col. Barnardo. I take this opportunity of offering my thanks to him for the great help

fessor T. Kar for helping me in this connection.

My thanks are also due to Major J. C. De, Police Surgeon, Calcutta, for the very valuable help I received from his records at the Police Morgue, Calcutta.

ANÆSTHESIA OF THE ABDOMEN.

By W. F. BRAYNE, B.A., M.B., Ch.B.,

LIEUTENANT-COLONEL, I.M.S.,

Civil Surgeon, Mandalay,

and

D. C. SEN GUPTA, M.B. (Cal.),

Assistant Surgeon, Mandalay Hospital.

IN connection with the article in this subject by Major H. E. Murray, M.B., Ch.B. (F.R.C.S.), in your issue of March 1928, it appears to us that an account of the anæsthesia of the upper abdomen as practised in the Mandalay Hospital might be of interest.

The only anæsthesia now used here for surgery of the whole abdomen is "twilight sleep" plus "split spinal." This has been used for gastric operations, splenectomy, nephrectomy (by the anterior route) and all other operations in the upper and lower abdomen.

The technique is as follows:—

(i) *Twilight sleep*.—The patient is placed in a dark quiet room with a towel over the eyes. One and a half hours before operation a hypodermic injection of morphia gr. $\frac{1}{4}$, scopolamine gr. $\frac{1}{200}$, is given.

Half an hour before operation another hypodermic of scopolamine gr. $\frac{1}{100}$ is given. The patient is brought into the theatre 10 minutes before the operation with a towel over his face.

(ii) *Split spinal*.—Ten minutes before the operation the patient is turned on his side on the operation table and after careful skin sterilisation, 1 c.c. of a 1 per cent. solution of novocaine is injected into the skin and subcutaneous tissues over the intervertebral space between the 12th dorsal and 1st lumbar vertebræ and also over the space between the 4th and 5th lumbar vertebræ.

One c.c. of Stovaine-Billon solution (May and Baker) containing 0.05 gram of stovaine in glucose, is injected intrathecally between the 12th dorsal and 1st lumbar vertebræ, and 1 c.c. between the 4th and 5th lumbar.

Care must be taken that the cerebro-spinal fluid flows freely before the stovaine is injected. If only an occasional drop comes, the anæsthesia will probably fail.

The prick of the needles used in giving the spinal anæsthesia sometimes wakes the patient. The patient is then told that he will be given chloroform. A few puffs of chloroform from a Junker's inhaler puts him to sleep again, and the operation is then finished without any more chloroform. A few whiffs more are given if the patient wakes up at any time during the operation, and sleep is again immediately induced. Two syringes must be used for the stovaine so that the 2 c.c. ampoule can be divided accurately into two.

This method is, in our opinion, the ideal method of anæsthesia for all abdominal

operations. The patient lies peacefully asleep with his eyes covered during the whole operation, and muscular relaxation is perfect. One is never at the mercy of the anæsthetist, and the sewing up of an abdomen is as easy as opening it.

The patient gets back to bed while still asleep, sleeps on for two or three hours, and there is none of the vomiting and distress, to say nothing of the strain thrown upon stitches, caused by the vomiting after a general anæsthetic.

We usually reckon on 45 minutes perfect anæsthesia, but in one case with extensive abdominal injuries which involved amongst other things the removal of the right kidney, the patient was still sleeping 1 hour 25 minutes after the injection, while stitches were being put in $1\frac{1}{2}$ inches below the ensiform cartilage.

A further advantage of this method is that it can be used in cases where chloroform is contra-indicated. We find that there is no danger in putting the patient in the Trendelenburg position immediately after the injection. Normally of course the patient is only put in this position after the abdomen has been opened.

COMPLICATIONS.

Headache.—Patients sometimes complain of a slight headache, which lasts a day or two.

Temperature.—There appears to be a slight rise of temperature, lasting a day or two, which is due to the spinal anæsthesia and not to the operation.

Malaise, nausea and vomiting.—Very rarely occur on the operating table. Diffusible stimulants soon put this right.

Hot water bottles.—Are extremely dangerous even if properly covered. An early case of ours lost half her foot from this cause. The best plan is to forbid them, either during or after the operation.

NOTES ON A CASE OF "BLACK TONGUE."

By RICHARD GREEN, M.B., B.S.

(From the Institute for Medical Research

Kuala Lumpur, F. M. S.)

THE following case of "black tongue" was referred for further diagnosis by Dr. G. A. Dunlop of Kuala Lumpur, who had noticed yeast-like organisms in smears from tongue scrapings.

Details of Case.—Mr. C. L. W., European, act. 36, presented himself for examination showing the following interesting abnormality:—The dorsal surface of the tongue was covered with moist black fur which had been present for the past two months.

Previous History.—There had been no severe illness at any time, but three years ago the patient had had a similar pigmentation of the tongue which had lasted for three or four months.

General Examination.—Thin, somewhat nervous type of individual, otherwise healthy;

occasional sufferer from indigestion; stating that at the present time he was overworking and smoking too much. No medicines containing iron were being taken to account otherwise for the condition.

A.—Microphotograph of yeast-like organisms from a 48 hours culture. X—470.

Condition of the Tongue.—The dorsal surface of the posterior two-thirds of the tongue showed greatly hypertrophied and elongated filiform papillae which were dark brown to black in colour, giving the tongue the appearance of being carpeted with moist black fur.

B.—Microphotograph of yeast-like organisms within epithelial cell from a tongue scraping. X—470.

Patches of these papillae could be easily and painlessly removed with forceps leaving a smooth surface which did not bleed.

Microscopic Features.—The epithelial cells of the blackened hypertrophied papillae were found to be covered 4 or 5 deep with yeast-like organisms varying in length from 2μ to 5μ and staining Gram positive. A number of budding forms were seen and some reproduction appeared to be taking place within epithelial cells.

Cultural Characteristics of the Yeast-like Organism.—Various culture media were inoculated with scrapings from the tongue, and the organism seen on and apparently within the epithelial cells grew after 24 hours incubation at 37°C . in the form of small white opaque pin-head colonies which were later subcultured on other media.

The most favourable solid media for its growth were found to be dextrose and maltose agar. On both of these it grew readily at room temperature.

After one month's growth on Sabouraud's maltose agar the culture assumed a dark brown colour similar to that observed on its original source, the tongue.

Apart from the favourable media mentioned, portions of the culture were kept on sterile plaster-of-Paris blocks in Petri dishes containing

sterile water in order to estimate the various methods of reproduction of the organism under somewhat unfavourable conditions.

During its growth under these conditions no mycelial elements were found at any time, no ascospores were formed, no down growths into the media were observed, and reproduction appeared to take place by budding only.

Fermentation tests showed the formation of acid and gas in glucose and laevulose.

Bacteriological Diagnosis.—Castellani's classification of the yeast-like fungi is as follows:—

(a) Asci present—

- 1 Mycelium absent = *Saccharomyces*.
- 2 Mycelium present = *Endomyces*.

(b) Asci absent—

- 1 Mycelium absent = *Cryptococcus*.
- 2 Mycelium present = *Monilia*.

The organism isolated from the tongue scrapings showed on culture the absence of both asci and mycelium.

It was therefore regarded as one of the *Cryptococcus* group, and would appear to correspond with a yeast-like organism described by Castellani and Chalmers (1919) and Brumpt (1922), this organism being found by Lucet (1901) in cases of "black tongue."

Discussion of Diagnosis.—A brief extract from Castellani and Chalmers (1919) is given as follows:—

"*Cryptococcus lingua-pilosæ* Lucet (1901), found by Lucet and others in cases of so-called "black tongue." It appears on the surface of

hypertrophied lingual papillæ in the shape of roundish bodies with double contour 3μ to 6μ in diameter. Grows easily on sugar media. Glucose and lævulose fermented. Attempts to reproduce the disease have failed. Guégan and Thâon believe that this fungus becomes pathogenic only when associated with *Nocardia lingualis*."

In a case of monilia infection of the tongue Zeisler (1927) has reported that the organism was agglutinated by the patient's serum at a dilution of 1 in 4,000.

In the case of C.L.W., regarded as a cryptococcus infection, an emulsion of a 24 hours subculture of the yeast-like organism from the tongue was used in performing an agglutination test with the patient's serum, two other sera from healthy individuals being used as controls.

The organism was found, however, to form clumps after two hours, not only in the patient's serum and the two control sera, but in the

physiological salt solution also used as a control. Wright's capillary tube technique was used in performing these agglutination tests.

Treatment.—The condition disappeared within a few days on painting the tongue with Lugol's iodine solution diluted 1 in 5 with water and the internal administration of a simple alkaline gentian mixture. The hypertrophy of the papillæ rapidly decreased and the black coating faded through varying shades of dark brown to light brown to normal colour.

Comments.—One similar case occurring in a medical student was seen by the writer in Australia about seven years ago, but no bacteriological examination was made at the time.

Castellani and Chalmers (1919) report other cases of "black tongue" said to be due to one of the higher fungi, *Rhizopus niger*, found by Ciaglinski and Hewelke in cases of black mycosis of the tongue.

Twelve cases of "black tongue" are reported in the Nigerian Annual Medical Report (1926), but in these the coating was membranous and at first dry and white, later turning to black. Constitutional disturbances and fever accompanied the condition which cleared up at the end of five days, when spirochaetes of relapsing fever type were found in the patient's blood. In this series of cases the organism found on the tongue is stated to be a fungus "probably of the oïdium type."

In the case of C.L.W., regarded as deserving of report at some length, there were no constitutional symptoms associated with the "black tongue."

STANDARDS FOR MACLEAN'S UREA CONCENTRATION TEST IN HEALTHY INDIANS.

By H. STOTT, M.D., M.R.C.P.,

LIEUTENANT-COLONEL, I.M.S.,

Professor of Pathology and Physician, King George's Medical College, Lucknow,
 and

V. S. MANGALIK, M.B., B.S. (Lucknow),

Officiating Lecturer in Pathology, King George's Medical College, Lucknow.

THE value of Maclean's urea concentration test in Europe has become widely recognised, and its application to diseased conditions of the kidney in India has been very general. But in the interpretation of the degree of urea concentration in any given case at the bedside we were handicapped by a want of knowledge of the standard of urea concentration by the healthy kidneys of the normal Indians, after the usual oral dose (15 grams) of urea. Was the standard for Indians the same as the standard for Europeans, differing as these two big groups do so largely in their daily dietary, and hence presumably differing in the strain daily thrown on the kidney throughout a life time?

1. Maclean has already published in his "Renal Disease" the percentage concentration of urea, using the described technique of his test in healthy Englishmen in three age groups as under:—

TABLE I.

Urea concentration test in healthy Englishmen.

	Ages.	Urea Concentration.
Group I ..	15—25 years	3.00%
Group II ..	26—45 years	3.3%
Group III ..	46—65 years	2.72%
Group IV ..	All ages	3.0%

2. We therefore examined 60 healthy Indians, 30 vegetarians and 30 non-vegetarians with no discoverable renal or cardio-vascular disease. Twenty persons (10 vegetarians and 10 non-vegetarians) were in each age group, and we determined with Maclean's technique the urea concentration percentage with the following results:—

TABLE II.

Urea concentration test in healthy Indians.

	Ages.	Urea Concentration.
Group I ..	15—25 years	3.0%
Group II ..	26—45 years	3.27%
Group III ..	46—65 years	2.6%
Group IV ..	All ages	3.03%

These results demonstrate that there is no difference in the power of urea concentration,

either at all ages or in the different age groups, between the healthy kidney of the normal Indian and the normal Englishman in spite of the marked dietetic differences.

In both Indians and Englishmen the power of urea concentration lessens as age increases.

3. In Maclean's technique not more than 120 c.c. of urine must be voided during the second time of the test. The following shows that healthy Indians excreted less urine during this second hour than did Maclean's Englishmen.

TABLE III.

Maclean's urea concentration test.

Age group.	15-25 years.	26-45 years.	45-65 years.
Healthy Indians ..	51 c.c.	66 c.c.	45 c.c.
Healthy Englishmen	103 c.c.	96 c.c.	112 c.c.

4. Amongst our 38 Indian patients with parenchymatous nephritis, the urea concentration percentage worked out as follows:—

TABLE IV.

Urea concentration amongst Indians with parenchymatous nephritis.

Age group.	15-25 years.	26-45 years.	46-65 years.	All ages.
Indians ..	1.9%	1.2%	1.3%	1.5%
Englishmen (Maclean)	1.3%

5. As has been indicated, the concentration test for healthy Indians was estimated for 10 vegetarians and 10 non-vegetarians in each age group. The 38 cases of parenchymatous nephritis consisted of 22 vegetarians and 16 non-vegetarians. A comparison of urea concentration as between vegetarian and non-vegetarian, healthy and nephritic, is set out in the following table:—

TABLE V.

Urea concentration in vegetarian and non-vegetarian Indians.

Age group.	15-25 years.	26-45 years.	46-65 years.	All ages.
Healthy vegetarians ..	3.07	2.95	2.60	2.87
Healthy non-vegetarians	3.48	3.12	2.84	3.14
Nephritic vegetarians ..	2.05	1.22	1.50	1.59
Nephritic non-vegetarians	1.68	1.20	1.10	1.32

From this table, it would appear that healthy non-vegetarians concentrated urea better than healthy vegetarians, but once the non-vegetarian's kidney is inflamed it would appear to concentrate urea less well than the inflamed vegetarian's kidney. The deductions suggested by this table will, however, require fuller consideration.

CORRIGENDUM.

With reference to Capt. Karamchandani's article on p. 249 of our issue for May 1928, the following corrections should be made; p. 251, column 1, para 3 (small print), line 10, delete "although she had taken 510 grains (34 gms.) of quinine sulphate orally."

After "P. vivax infection," on p. 251, column 2, para 3 (starting with No. 426), line 6, add "although he had taken 510 grains (34 gms.) of quinine sulphate orally."

Indian Medical Gazette.

JULY.

THE BENGAL MEDICAL (AMENDMENT) BILL, 1928.

A VERY important Bill which is now under the consideration of the Bengal Legislative Council (in committee) is the Bengal Medical (Amendment) Bill, 1928. It is of importance, not only to Bengal, but also to the other provinces of India in which the introduction of similar legislation may be under consideration.

Under the Bengal Medical Act, No. VI of 1914, there was created the Bengal Council of Medical Registration, consisting of the following 15 members:

(a) A President and 7 members nominated by the Local Government.

(b) One representative of the Calcutta University.

(c) Six representatives of the different classes of medical practitioners.

The duties of the Bengal Council of Medical Registration, as defined in the Act of 1914 are similar to those of the General Medical Council of Great Britain, and were defined as follows:

(i) To maintain a register of medical practitioners holding recognised qualifications, who pay the registration fee, and to register their names.

(ii) To decide what titles or qualifications granted by universities or other examining bodies shall entitle a practitioner to registration.

(iii) To call on medical colleges and schools training students for registrable degrees, or desirous of recognition, to furnish such information as may be necessary to enable the Council to judge of the efficiency of the instruction given therein.

(iv) To depute its members to be present at examinations for registrable qualifications.

(v) To remove the names of registered practitioners from the register under the conditions laid down in Section 25.

In the introduction to the amending Bill, the Government of Bengal make the following statement:

"It is considered that the time has come to make the Council a more representative body by including members elected by the staffs of the Calcutta School of Tropical Medicine and of other recognised medical colleges and schools which are already in existence, or which may come into existence from time to time. It is also proposed to include a representative of the Railway Board which employs a large number of medical men. As it is not desirable to make the Council too unwieldy, it is proposed to cut down the Government nominees from 7 to 3, and to

reduce by one the number of representatives of the graduates and licentiates in medicine and surgery of the Calcutta University. The opportunity has been taken to give the Council specific power to inspect medical institutions, to extend and define the power of the Council to act through committees for inspection and other purposes, and to authorise the payment of fees for attendance at committee meetings and of travelling allowances for such attendance and for visits of inspection. Other amendments are consequential."

We give further details of the amending Bill in our Current Topics section in this issue, but it is obvious that the Bill has two main objects: (a) to make the Council much more democratic than it is at present, and (b) to make its powers of inspection of standards and examinations greater. Both objects will naturally appeal to the members of the medical profession in Bengal.

This being the position of affairs, a joint public meeting of the general medical practitioners in Bengal and of the Bengal Medical Association was held in February 1928, to consider the proposed amending Bill, and we have been asked to give publicity to the resolutions passed at that meeting. The report of this joint meeting is signed by Sir Nilratan Sircar as President of the Bengal Medical Association, and by Dr. Sundari Mohan Das as Principal of the National Medical Institute, and is published in our Current Topics section also.

The resolution begins with the usual abuse of Government, and a refusal to look the facts in the face. Fourteen years have passed since the Bengal Medical Act was passed, "and instead of a progressive measure we find a highly reactionary Bill for placing the whole of the independent profession, consisting of over 6,000 registered practitioners under the domination of a Government department." The resolution then goes on to demand the creation of a much more democratic Council than is suggested in the amending Bill, the abolition of the proposed representative of the Railway Board, and that the President shall not be nominated by Government, but elected from among the members of the Council.

Let us now try to face the facts under existing conditions in Bengal. The Bengal Council of Medical Registration is admittedly an *ad hoc* body created on lines similar to the General Medical Council of Great Britain. If we examine and contrast the duties and composition of these two bodies respectively, we may note the following points:

(i) Medical registration. This is mainly a matter of trained clerical staff under proper supervision and is not a matter of controversy.

(ii), (iii), (iv) Decision as to registrable qualifications; furnishing of information by medical colleges and schools; and inspection of institutions and examinations. In this connection we think that anyone who thinks the

situation over must admit that such matters can only be dealt with by those who have had personal experience of medical teaching and examination. It would be manifestly absurd to expect a body of representatives of the general medical practitioners of Bengal to decide whether standards of teaching and examination were adequate or not in the various branches of medical science. Even as it is, the Calcutta University has recently raised the standard for its M.B. degree very considerably in accordance with the wishes of the General Medical Council of Great Britain; and the new standard has been decided upon, not by a body of general practitioners, but by a Board of Medical Studies selected from among members of the Faculty of Medicine of the University. For those who desire to become registered practitioners in Bengal without undergoing the more rigorous test of a university M.B. examination, there is the License of the State Medical Faculty of Bengal. The expert in each branch of medical science can be trusted to see that the standard of teaching and examination in his own particular science is kept up to the mark; what is wanted is a leavening, but not a majority, of representatives of the general medical profession to see that the expert keeps within bounds, and does not ask for too much.

(v) This refers to the disciplinary side of the Council's activities, where a medical practitioner may be called upon to defend himself against a charge of professional misconduct brought against him. For this purpose a mixed tribunal containing perhaps a majority of general practitioners would be best, since the latter are often in a better position to appreciate the difficulties which practitioners are often faced with than are consultants, and teachers and examiners.

* * * *

The crux of the whole matter, however, is as to the composition of the Council. Certain modifications of the Bill have already been made in committee. Thus it has been decided to eliminate the proposed representative of the Railway Board, and in his place to increase the number of representatives elected by the medical graduates of the University of Calcutta from 2 to 3; also to delete the word "temporary" with regard to the recognition of medical schools.

The existing Bengal Council of Medical Registration consists of a President and 7 members nominated by the Local Government—all of whom are likely to be officials; a representative of the Calcutta University, who may or may not be an official; and 6 representatives of the different classes of medical practitioners in the province; a body containing 8 or possibly 9 official members in a total of 15 members. Let us compare with this the constitutions proposed (a) by the amending Bill; and (b) by the joint public meeting and the Bengal Medical Association. Under the present circumstances, these would be as follows:

Constitution as proposed by Government, and amended in committee.	Constitution as proposed by the resolution and the Bengal Medical Association.
(a) Nominated President, <i>viz.</i> , the Surgeon-General with the Government of Bengal (Official).	(a) President to be elected from among members.
(b) Nominated by Government; 3 members (Probably official).	(b) Nominated by Government....3. One of whom may be from the Calcutta School of Tropical Medicine (Probably official).
(c) Calcutta University. Representative....1.	(c) Calcutta University...1.
(d) Representatives of the Calcutta Medical College (probably an official), and of the Carmichael Medical College, Belgatchia. (Non-official)....2.	(d) Representatives of the Calcutta Medical College (probably official)....1 and of the Carmichael Medical College....1 (Non-official).
(e) One representative each of the Campbell, Dacca, Mymensingh, and Burdwan Medical Schools.... (Probably all officials). One representative each of the Calcutta Medical School, National Medical Institute, and Bankura Medical School....3 (Non-official).	(e) Two representatives between them (probably both official) of the Campbell, Dacca, Mymensingh, and Burdwan Medical Schools. Two representatives between them (non-official) of the Calcutta Medical School, National Medical Institute, and Bankura School.
(f) Representatives of registered University graduates....3.	(f) Representatives of registered University graduates....4.
(g) Representative of M.B. University graduates, registrable in Great Britain....1.	(g) Representatives of University graduates, registrable in Great Britain....2.
(h) Representatives of licentiates, not registrable in Great Britain....2.	(h) Representatives of licentiates....4.
(i) Representative of the Calcutta School of Tropical Medicine....1 (Probably official).	(i) <i>Vide</i> (b) above.

TOTAL.—21 members, of whom 10 are likely to be official, and 11 non-official.	TOTAL.—20 members, of whom 6 are likely to be official, and 14 non-official.
---	--

A study of the above figures shows at once the wide gap which yawns between the proposals of Government, and those of the Bengal Medical Association. It also shows how untenable is the claim made by the latter body that the Government proposals would place "the whole of the independent medical profession in Bengal under the domination of a Government department."

Now it is not sufficiently recognised by the general public—or, indeed, sometimes by the medical profession itself—that the most important part of the duties of the General Medical Council of Great Britain are those concerned with the inspection of examinations, regulation of standards of medical education, and standardising curricula. The general public never hear of

these branches of its activities, so they are apt to think that the sole function of the Council is to deal with sensational cases of "conduct infamous in a professional sense," which result in much newspaper publicity. A similar ignorance with regard to the local Bengal Council of Medical Registration seems to be responsible for the present agitation to entirely democratise that body, regardless of the fact that its present composition is already more democratic than that of the General Medical Council of Great Britain.

The latter body consists of 42 members, of whom no less than 26 represent the universities and other examining bodies of England, Scotland, and North Ireland. These representatives are not elected by the graduates, but are selected by the governing bodies of these institutions, so that they represent the academic point of view. Of the remainder, 5 are nominated by the Crown—of whom 1 is a layman, and the other 4 are eminent senior members of the profession, 5 representatives of the dental profession, and six direct representatives, elected by the body of general medical practitioners complete the total. In Great Britain there are only 6 representatives of the total of over 30,000 general medical practitioners in a body of 42; in the Bengal Medical Council, as at present constituted, there are 6 representatives of 6,000 general practitioners in a Council of 15 members. The amending Bill leaves this number of 6 unaltered, but includes representatives of other institutions.

The Council of Medical Registration of Bengal is no more a Government department than is the General Medical Council of Great Britain, which exercises powers delegated to it by the Privy Council under the Medical Acts. In this country the system of administration is different, and the channel of devolution more complicated, but the result is the same; the powers of the Council are clearly defined in the Bengal Medical Act of 1914, and within the limits of that Act the Council is free to do as it pleases.

Most of the other objections raised have been met by the modifications which the amending Bill has undergone in committee.

With regard to the constitution suggested by the Bengal Medical Association, we would point out that in the Calcutta University official and non-official Fellows have equal rights, and that the Faculty could not be split up in the manner proposed for electoral purposes. To allot only 2 members to represent the Government medical schools and 2 to the non-official schools would be a most inequitable arrangement, since the licentiates passed out from the latter are—and for many years to come must necessarily be—only a small minority of the registered practitioners; whilst the number of representatives of general practitioners proposed—10 in all—would be too large in a body which has to discharge the important functions in relation to medical education outlined previously.

As the Calcutta School of Tropical Medicine trains candidates for the Diploma in Tropical

Medicine of the Faculty of Tropical Medicine of Bengal, and also candidates for the Diploma in Public Health of the Calcutta University, it is only fair that it should have one representative on the Council.

The position of the Surgeon-General of the Government of Bengal is peculiar. It is inevitable that he must be a member of the Council, seeing that the bulk of the students in medicine in Bengal are studying in Government medical colleges and schools, whilst as head of the medical department of Government he could hardly attend the meetings of the Council in any other capacity than that of President.

In conclusion, we may add that, in the opinion of many it is open to question whether, in view of the great importance of maintaining a high standard of medical education, and the difficult questions likely to arise as new medical schools come up for recognition, Government has not already gone too far in surrendering its power of nominating members. Elected members are notoriously liable to be chosen for their political views, rather than for their knowledge of the subjects to be dealt with, and politics should have no concern with medical education. The doctor should never forget that he is a citizen, but on a political platform he is out of place.

A Mirror of Hospital Practice.

AN UNUSUAL CASE OF "STRANGULATED HERNIA."

By C. H. REINHOLD,

LIEUTENANT-COLONEL, I.M.S.,

Civil Surgeon, Delhi.

KALEY, a Hindu male, aged 25 years, came to the Ludovic Porter Hospital, Meerut, on 13th April 1928.

He had a swelling on the left side of the scrotum the size of a Bombay mango; hard and tender to the touch but resonant on percussion, marked restlessness and an anxious facies. The temperature was 99° and the pulse 105.

The duration of the condition was 4 days.

The patient stated that he had noticed this swelling coming down into the scrotum, especially on standing, for about three years, but a little pressure was applied sometimes with a little pressure was applied sometimes with difficulty. From the condition of the patient a diagnosis of strangulated hernia was made, and he was at once prepared for operation. On making the usual incision it was found that there was no constriction of the neck of the sac or strangulation of the gut which was of normal appearance; but the sac was full of bloody fluid; the internal ring was large and patulous, but the mesentery of the loop of bowel in the sac was a solid hæmatoma. The only difficulty experienced in reducing the intestine into the abdomen was caused by this condition of the mesentery, but it was successfully manoeuvred

through the internal ring without having cause to enlarge it; after reduction the internal ring admitted one finger comfortably. The operation for radical cure was completed and the patient returned to bed. He made an uninterrupted recovery; his wound healed by first intention, and the patient was discharged cured on the 28th April 1928.

The special features of this case are:—

(1) that there was no strangulation of the bowel, as appeared certain before operation, and (2) the unusual amount of blood-stained fluid in the sac, considering the condition of the bowel.

The questions arise:—

(a) Was the hæmatoma of the mesentery due to thrombosis by trauma, the result of forcible taxis? This was denied by the patient, and his friends; though undoubtedly some efforts must have been made to reduce the hernia.

(b) Was this a case of embolism of the mesenteric artery with infarction? Or

(c) Was it a case of thrombosis of the mesenteric vein in a herniated loop of bowel unassociated with trauma?

Against (a), one would expect at least some bruising of the loop of bowel if sufficient taxis had been used to produce the extensive hæmatoma found. There was no such bruising. Against (b); an embolism would produce more effect on the loop of bowel concerned than was seen. The loop looked perfectly healthy and of a good colour; there was no suggestion of congestion, duskiness or gangrene.

Regarding (c) thrombosis due to stasis in a dependent loop of gut in an old-standing hernia of three years' duration seems to be the most likely diagnosis; but this is admittedly uncommon, and the patient was a healthy young man and not debilitated, as one would expect in considering predisposing causes.

Clinically the case as first seen was a typical strangulated hernia, though perhaps the symptoms were not as severe as one would expect after four days obstruction, and I think no surgeon would have held his hand and refused relief by the knife.

But, in the light of what was found at operation, might not a natural cure have taken place?

The thrombosis was obviously not progressive, and he never looked back after the operation.

I have never seen a case of this nature before, and would be interested to hear the experience of other surgeons.

My thanks are due to Dr. Wahid-ud-din Haider, now Civil Surgeon of Meerut, for his skilful assistance and subsequent care of the patient.

A CASE OF HYSTERICAL BLINDNESS.

By S. P. SHROFF, F.R.C.S.,

Banarsi Mansions, Chandni Chowk, Delhi.

ON 6th April 1928, when I was working in my consulting room, I got a telephone message

to the effect that a young man soon after coming from the church suddenly got blind, and requesting that I should see him immediately. I asked his relatives to bring him to the office, and within half an hour he was there. Notes on the case are appended:—

L., a Roman Catholic, aged 26 years, healthy in appearance, by occupation a clerk.

Family History.—Father alive, aged 51 years. Mother died of heart failure when the patient was 2 years old. No brothers. One half-sister, 14 years old and healthy.

Habits.—Fairly active, smokes 25 cigarettes a day, a teetotaler, eats meat in fair quantities and is fond of reading particularly at night.

Physical Examination.—The patient when he entered into my room was brought by the aid of two friends and was completely blind. He had not even perception of light as he failed to appreciate a strong electric light which was in front of him.

Cornea.—Clear.

Anterior Chambers.—Normal.

Pupils.—Regular and active.

Tension.—Normal.

Fundus.—As far as could be seen with the undilated pupil, was normal.

I put in 0.5 per cent. of atropine before making another examination and engaged him in conversation and found tremors of the lips and fingers. From his replies to questions he seemed a man of emotional nature. I made another dark-room examination and again failed to find anything abnormal there. I made up my mind as to the diagnosis (i.e., hysterical blindness). In order to be sure, I asked him to call again next morning and prescribed in the meantime a blue pill to be taken at night and followed up by magnesium sulphate in the morning. He went back with his relatives to the chemists to get the medicine. On the way the young man had a violent sneeze and immediately recovered his sight. Next morning he entered my room unaided which confirmed my diagnosis of hysterical blindness. To make matters doubly sure, I sent him to a well-known physician to overhaul him. The physician did not find anything organically wrong with him, except that he had a few bad teeth which required looking after. All his organs were sound and healthy; his reflexes were exaggerated. I think, it would be well if I quote the physician's own words. "He (the patient) has told me all his history and I conclude that it is a case of hysteria." The treatment needs no special comment.

ELECTRO-COAGULATION (DIATHERMY.)

By P. P. LALVANI, L.C.P.S. (Bom.),

X-Ray Department, Civil Hospital, Karachi.

G. P., a cultivator, aged 45, residing in Gorabari in Karachi district, suffered from rodent ulcer.

PLATE II.

History.—The condition started as a small pimple on the inner canthus of the left eye, which gradually increased to the size of a large pea. After about two weeks it burst and discharged pus. The ulcer was dressed by a local doctor but continued to grow towards the nose

FIG. 1.—Before treatment.

and also downwards towards the cheek. It was very painful and in about two months the pain was so severe that he was unable to sleep at night. The left eye became swollen and could be opened only with great difficulty. The first photograph was taken when I first saw the

FIG. 2.—After treatment.

patient, i.e., six months after the appearance of the growth. It shows a hard nodular ulcerated growth involving the left inner canthus and the left side of the nose as far as the *alæ nasi*. There

were also a few nodules over the lower eyelid. There was considerable swelling of the tissues surrounding the growth. The case was seen by Lieut.-Col. I. Davenport Jones, I.M.S., Civil Surgeon, Karachi, who was of the opinion that it was a rodent ulcer.

Treatment.—The growth, along with a little healthy tissue round about and also the nodules on the lower eyelid, were electro-coagulated with the diathermic knife at one sitting on March 28th. This was done under novocaine infiltration anæsthesia. That evening there was considerable swelling of the left side of the face. This swelling subsided in about four days and the slough over the electro-coagulated area separated in two weeks time. The pain disappeared entirely after the electro-coagulation. It took about three weeks for the ulcer to heal up completely. The second photograph was taken five weeks after treatment. It shows a soft scar over the area. There is no ectropion of the lower eyelid and the patient can open the eye fully.

Diathermic electro-coagulation is preferable in such cases where the growth is situated in the vicinity of the eye, as the resulting scar after surgical operation will pull the eyelid and cause ectropion. With diathermy the scar is very supple and does not pull the eyelid.

I am greatly indebted to Lieut.-Col. I. Davenport Jones, I.M.S., Civil Surgeon, for his kind encouragement, valuable advice, and permission to publish notes on this case.

A RARE CASE OF DERMAL LEISHMANOID.*

By UPENDRA NATH BRAHMACHARI,
M.A., M.D., PH.D., RAI BAHADUR,
and

SIRIS CHANDRA BANERJEE,
Sub-Assistant Surgeon.

AFTER attention was drawn by one of us (U. N. B.) to skin eruptions due to infection with *Leishmania donovani*, Acton in collaboration with Napier has described the following stages of this disease:—

- (1) An early de-pigmented stage.
- (2) A later nodular stage.
- (3) A xanthoma-type of the disease in which there is a tendency towards fibrous tissue formation, and constriction of venules and subsequent dilatation.

It is stated by these authors that the nodules appear in the place of de-pigmented patches.

Generally speaking, cases of dermal leishmanoid come for treatment when both the nodules and de-pigmented patches are present in the skin. The present case is therefore of much interest, as it showed an erythematous patch over the face and a few nodules over it with complete absence of de-pigmentation in any part of the body, confirming the view of

*Read at a meeting of the medical section of the Asiatic Society Bengal in April 16th, 1928.

one of us that the disease may first show itself in the form of patches of erythema over the skin before the appearance of de-pigmentation or nodules.

History.—About three years ago the patient had an attack of kala-azar, was treated with about thirty injections of sodium antimony tartrate, and was apparently cured. About a year ago he noticed a small patch over the bridge of the nose which gradually extended and assumed the present size. A few papules appeared subsequently over the erythematous area.

Present Condition.—Patient is a healthy individual. There is no enlargement of spleen or liver. There is no fever. Blood culture is negative. There is no anaesthesia over the erythematous patch nor over any other part of the body, nor is there any thickening of the nerves. A careful examination of the scrapings from the face showed the presence of a few Leishman-Donovan bodies after a prolonged examination. No lepra bacilli were found from these scrapings.

The case is of interest as such cases very rarely come under observation. Generally speaking, cases that present themselves for treatment show definite de-pigmented areas, with or without nodules either inside them or in independent foci in the skin.

A word about the nomenclature of the disease. Various names have been suggested, one of the latest being post-kala-azar dermal leishmaniasis (Acton and Napier, 1927). But of all the names suggested the name dermal leishmanoid appears to be the most convenient, on account of its simplicity, and especially in view of the fact that the disease is now frequently recognised under this name and it may appear without any previous treatment with antimony for visceral leishmaniasis.

Note.—Some years ago Dr. Brahmachari exhibited a patient, who had previously suffered from kala-azar, suffering from a nodular condition of the skin; he was able to show that these lesions contained leishmania and suggested the name "dermal leishmanoid" for them.

The name was not altogether satisfactory. The suffix "oid" denotes "resemblance to the thing indicated by the preceding element of the compound," to quote from a well-known medical dictionary. Syphiloid suggests a lesion resembling syphilis, but not necessarily caused by the *Treponema pallidum*. Now the most striking thing about these lesions was their lack of resemblance to any previously described leishmania lesion, [except possibly the lesions described by Thomson and Balfour (1909) for which they suggested the name Leishman nodule]. On the other hand, working on the same analogy leishmanide would have been a more suggestive name. It has subsequently been recognised (Acton and Napier, 1927) that this nodular form is only one stage in the series of pathological changes caused by this parasite in the skin.

The whole series of changes are due to a widespread infection of the skin by leishmania; the lesions are confined to the skin proper, the epithelium never being invaded at any stage. The name "dermal leishmaniasis" is, therefore, descriptive. There are, however, two other forms of leishmaniasis which affect the skin; in both of these the epithelium also is nearly always affected, so that the name cutaneous leishmaniasis is perhaps more suitable for them. Nevertheless, one of

these, oriental sore, is very frequently referred to as dermal leishmaniasis; so, to avoid all risk of confusion it was necessary to qualify further the condition under discussion. It is quite true that all patients suffering from this condition do not give a history of having been treated for kala-azar. About half the patients in Acton and Napier's series gave this history. There is, however, no difference between the lesions of the patients who do, and of those who do not, give this history, so that it is almost certain that the aetiology of the condition in each group is the same; that is to say, they have all at one time suffered from a generalised leishmania infection. It is purely an academic question whether or not one is justified in referring to the transitory generalised leishmania infections as kala-azar. Post-kala-azar dermal leishmaniasis is a clumsy name, but it defines the condition; the alternative, post-generalised dermal leishmaniasis is certainly worse.

Dr. Brahmachari's claim on the score of priority is sound, but only as far as the nodular phase, the phase which he described, is concerned.

FLOATING SPLEEN: SPLENECTOMY: RECOVERY.

By J. B. VAIDYA,

MAJOR, I.M.S.,

Civil Surgeon, Guntur.

E., a female aged 40 years, was admitted on 5th March 1928 for a tumour in the abdomen and distension due to fluid. She was having attacks of pain in the abdomen for the last two years and had noticed a small movable tumour in the abdomen. She delivered 10 months back and had had no trouble during labour. The child is living. A month before admission, she was getting fever with rigors for 15 days. At this time she noticed that the tumour was increasing in size and the abdomen was getting distended. She had also a dragging sensation in the abdomen. She was branded in a few places on the abdomen.

On admission the patient had a big distended abdomen with fluid in it, and oedema of the feet. The measurement was 40 inches. A hard tumour could be felt lying in the lower part of the abdomen below the umbilicus. The long axis was placed transversely and it extended towards the right of the middle line. The tumour could be moved upwards and laterally to some extent.

Owing to the branding marks on the skin, operation was postponed for some time till the skin got healthy. The patient was put on mistura alba, and iron and strychnine. On 22nd March 1928, the size of the abdomen was reduced, the measurement being 29½ inches; on 28th March 1928 there was a further reduction in the size to 28½ inches round the umbilicus. The tumour could now be felt much better.

A ridge and a notch could be felt, and suspicions of its being the spleen were strengthened.

The abdomen was opened on 3rd April 1928. There was no fluid in the peritoneal cavity at all. The tumour was found lying below the umbilicus with its long axis placed transversely. It was found to be the spleen which had got displaced. The splenic region was empty. There were a good many weak adhesions to the intestines which were separated gently. The great omentum was adherent to the convex surface of the spleen, which was facing downwards and forwards. These adhesions were removed under ligature. Three silk ligatures were used in different places to the pedicle. The pancreas was not attached to the hilum and did not come in the way while dealing with the hilum and the pedicle. The spleen weighed $1\frac{3}{4}$ pounds. The abdomen was closed by through and through sutures.

The patient had a rise of temperature up to 102°F . for two days after the operation, after which it gradually came down to normal in 10 days. The wound healed by first intention and there was no distension of the abdomen or any other untoward signs after the operation. The blood count on 13th April 1928 was as under:—

Red blood cells	..	3,087,500	per c. mm.
White blood cells	..	8,125	" "
Hæmoglobin	..	50	per cent.
Colour index	..	0.8	" "
Polymorphonuclears	..	81	" "
Lymphocytes	..	12	" "
Large mononuclears	..	4	" "
Eosinophiles	..	3	" "

One of the interesting features of the case was the complete disappearance of the fluid in the abdomen with rest and mistura alba.

FATAL EXFOLIATIVE DERMATITIS AS A COMPLICATION OF SANOCRY SIN TREATMENT OF PULMONARY TUBERCULOSIS.

By J. M. TALATI, M.B., B.S., D.O.,
S. R. M. Tuberculosis Dispensary, Karachi.

D. W., a well-built but poorly nourished male Mohammedan (Khoja) about 48 years old, was admitted with a history that he had come to Karachi only 2 days back from Gwadar where he suffered from a more or less dry cough for about 6 months, hæmoptysis in very slight quantity twice (the last attack being about one month back), and fever off and on, but continuous for the last few days with slight chills without perspiration. His brother and his first wife died of tuberculosis and some of his children died from "weakness." On admission (16th May 1927) his temperature was 99.6° , weight 8 st., and there were signs of consolidated patches in both lungs, particularly the right upper and the left lower lobes. His sputum though "negative" on admission, was soon found to be "positive." After about 3

months routine treatment, although his chest showed signs of some improvement (fewer adventitious sounds being heard), his weight had slowly decreased by 6 lbs., his sputum was still full of tubercle bacilli, the general improvement was not considered satisfactory, and it was decided to put him on sanocrysin treatment.

Sanocrysin was then administered intravenously (dissolved in fresh, sterile distilled water)* in doses and on dates as mentioned below:—

1st Injection.—19th August 1927, dose 0.1 gm.

2nd Injection.—24th August 1927, dose 0.1 gm., i.e., after 5 days' interval.

3rd Injection.—2nd September 1927, dose 0.25 gm., i.e., after 9 days' interval.

4th Injection.—12th September 1927, dose 0.25 gm., i.e., after 10 days' interval.

5th Injection.—21st September 1927, dose 0.5 gm., i.e., after 9 days' interval.

6th Injection.—3rd October 1927, dose 0.5 gm., i.e., after 12 days' interval.

During the course of injections the usual necessary precautions were taken as far as possible; the urine was constantly examined before and after the injections and never showed any trace of albumen. The febrile reactions after the injections were very slight and transient. There were no focal reactions, and fairly long intervals were given between the injections (about 5 to 7 days' interval is considered quite sufficient and safe for the doses employed). In one and a half months he gained nearly 3 lbs. in weight (often patients lose weight under Sanocrysin treatment); his general health improved; and his chest signs cleared up except for a few fine dry rales.

He presented himself again on the 12th October 1927, i.e., after 9 days' interval, for another injection. While preparing his arm for the injection, it was noticed that in the bends of his elbow, localised to the flexor surfaces only, he had a slight eruption, just like ordinary heat-rash, which he said was only a day or two old and there was no noticeable itchiness about it. His urine showed no trace of albumen, there were no gastric or intestinal symptoms, neither any affection of the mucous membranes of the mouth and gums, and no fever. He was, therefore, given a dose of 0.6 gm. Sanocrysin which caused him a sharp febrile reaction; and by the 14th October he had developed a well marked extensive and very itchy eruption, papulo-macular and covering almost every part of the body. There was now no doubt that the eruption was due to metallic poisoning from gold (in sanocrysin) and immediate steps were taken to counteract the same. On the 14th and 15th he was given sodium thiosulphate in 1-gramme doses intravenously, ichthyol in pill form internally, and an oily preparation with sulphur and acid salicylici for external application. By the 16th, however, his whole body

* I am still using the sterile distilled water, but I have lately been advised to try normal saline solution instead.

was so covered with eruptions, which had turned vesiculo-pustular, and his skin so puffed and cedematous that no veins could be got at. At the advice of my colleague in charge of the venereal clinic, who also unfortunately happened to have had the sad experience of having one of his patients develop exfoliative dermatitis after neosalvarsan treatment, it was decided to try contramine. He was given 0.25 grms. contramine intramuscularly on 20th, 21st, 22nd, 24th, and 28th October. The mucous membranes of the eyes, nose, mouth and intestine were all affected, there was mucopurulent conjunctivitis, gingivitis and severe stomatitis, and diarrhoea set in about the 23rd. Although the eruptions showed signs of retrogression and drying up under the treatment, the uncontrollable itching continued and almost maddened the patient at times. The exhaustion caused thereby, aided by the severe diarrhoea, finally carried off the patient on 6th November. His urine till very near his end (i.e., up to 1st November, after which he was under treatment of another medical man) never showed any signs of albumen.

There are various points of interest in this case:—

(1) A severe exfoliative dermatitis following sanocrysin treatment appears to be very rare. Professor Arthur Ellis(1) reports a case from the London Hospital. Professor S. Lyle Cummins(1) and (2) (South Wales Sanatorium, Talgarth) reports that "One of Dr. Watson's cases developed exfoliative dermatitis, presumably from metallic poisoning, after 6.25 grms." Dr. G. Marshall (Guy's Hospital), though not definitely mentioning exfoliative dermatitis, says "severe reactions with exanthem and albuminuria have been observed, although small doses were employed."

(2) A fatal end caused by exfoliative dermatitis appears to be rarer still. I have come across only two instances in the literature available here; the first case I cannot lay my hand to, but the second case was reported by Morland and Zimmerli (3) as "one case in which the skin reaction was so severe as to shorten the life of the patient."

(3) The dermatitis appeared after a total of only 1.7 grms. of sanocrysin. The patient received 2.3 grms. inclusive of the last dose, which was given after the dermatitis had just started, as will be seen from the history of the case.

(4) The doses given were very moderate, compared to those given by the originator or to those even now used in Europe. It has, however, been found advisable to reduce the doses still further and I am using it now in something like the following doses: 0.1 gm., 0.1, 0.2, 0.25, 0.35, 0.5, 0.6, 0.75, 0.85 and 0.9 grams. (Sanocrysin is available in India in 0.1, 0.25, 0.5 gm. doses; the above course can, therefore, very easily be given without wasting any drug

by opening the necessary number of the ampoules of required dosage).

(5) The intervals between the doses were longer than usual and each dose was repeated.

(6) There were no other poisoning symptoms or danger signals. In spite of constant watch no trace of albumen was found during the whole course.

(7) The rash appeared at the bend of the elbows, itchiness was not noticeable, and as it simulated ordinary prickly heat, its significance was at first missed. It, therefore, appears that any kind of skin rash appearing during the course of sanocrysin treatment should be carefully watched and further injections suspended till either the rash disappears or proves to be something innocuous.

THREE INTERESTING PHOTOGRAPHS.

By J. B. VAIDYA,

MAJOR, I.M.S.,
Civil Surgeon, Guntur.

1. A boy aged nine years; 25 inches in height; the lower extremities are very small and

the fingers of the hands are very rudimentary. He holds articles in the clefts of his fingers by extending and bringing them together. Intelligence is good.

2. Child aged about one year. Born with the tumour. The tumour is longer than the head. There is a very big gap in the cranium

2.

3.

through which the contents of the tumour extend.

3. Conjoined twins. Died three days after birth. This photograph was obtained through the courtesy of Mr. Sharfuddin, photographer, Guntur.

AFEBRILE *B. TYPHOSUS* ENTERO-COLITIS.

By B. P. TRIBEDI, M.B.

From the Department of Pathology, Medical College and Hospitals, Calcutta.

PATIENT N.—aged 24 years, a fifth year student of the Calcutta Medical College, brought a sample of his own faeces on 3rd September 1927 for examination for *Entamoeba histolytica*.

History of the case.—The patient had been getting slight griping pain and passing diarrhoeal motions with mucus almost every day for the last two years. He had had two courses of emetine and salines, and stovarsol treatment but with no effect.

His stool was examined macroscopically and seen to be semi-solid with a large amount of mucus; microscopically—no amoebæ or cysts were found; there were a few red cells and a large number of pus cells. The specimen was plated and a heavy growth of *B. typhosus* was obtained. A second sample of stool was examined and that was practically a mass of mucus with very little faecal matter at all. A pure growth of *B. typhosus* was isolated from the washed mucus.

A catheter specimen of urine was cultured and found to be sterile.

Blood agglutination reaction by Dreyer's method with organisms of the enteric group was done with the following result:—

B. typhosus—Positive up to 1 in 833.

Para A and B—Negative in all dilutions from 1 in 25 upwards.

Blood Count:—

Total leucocytes—5,300 per c.mm.

Total erythrocytes—4,230,000 per c.mm.

Differential Count:—

Polymorphs	..	68 per cent.
Lymphocytes	..	28 "
Large monos	..	1 "
Eosinophiles	..	3 "

The patient had had no rise of temperature throughout and he had been carrying on his usual activities. He had no history of any fever except in his infancy, the exact nature of which could not be determined.

It was apparent that the case was one of *B. typhosus* infection and the symptoms were attributed to it. An autogenous *B. typhosus* vaccine was made and the initial dose—5 millions—was given to the patient.

After the first dose, the symptoms, viz., griping and loose mucoïd motions, greatly diminished. After the next dose—10 millions, the symptoms practically disappeared. He was

given a full course of vaccine treatment, and was completely restored to health.

On two occasions subsequently his fæces were examined culturally and no growth of *B. typhosus* was obtained.

Comment.—It is interesting that such a condition of the bowel caused by *B. typhosus* should have continued for such a long period without giving rise to any other manifestations; the vaccine treatment seemed to act specifically.

DELAYED PUTREFACTION AFTER BURIAL: A CASE OF MEDICO-LEGAL INTEREST.

By INDULAL S. DAVE, M.B., B.S.,

Medical Officer, Civil Hospital, Kadi (N. Gujrat), Baroda State.

I HAD occasion to perform a post-mortem examination on a dead body twenty-five days after its burial. The circumstances in which it was buried and the appearances on exhumation are so important that they may be found of interest to the medical profession.

On a cold winter night in January a man was murdered by throttling and then buried at a distance of about two miles away in a field. After burial the ditch was made up as before, so no doubt arose and the site was kept moist constantly by the flowing of water daily for agricultural purposes. Water was also percolating and the period between burial and exhumation, three weeks, happened to be the coldest part of the year. Twice during the season frost had damaged the crops in this country. So, naturally, the flowing water, the percolating water and eventually the dead body had a very low temperature.

The appearance on exhumation was such that the whole body was intact, features fully recognizable, and it looked as fresh as if buried quite recently. Though decomposition had started, it had only reached such a degree as to suggest that the man had died 48 or 72 hours before. In the post-mortem notes the description is as under:—

Rigor mortis absent; post-mortem lividity on hinder parts; cuticle peeling off; abdomen swollen; skin separated from flesh at many places.

No external injuries except a depression on either side of neck in front; pomum adami had been fractured and the depressions on either side of it were found to have ecchymosis underlying, as shown on dissection.

Brain—liquefied.

Heart, lungs, liver, spleen and kidneys decomposed.

The stomach contained 2-3 ozs. of partially digested *khichadi*.

Signs of asphyxia were also marked. The right side of the heart was full of dark blood; lungs partially collapsed; colour of heart, lungs, mucous membranes of stomach and intestines, liver and spleen was darkish.

So there was no difficulty in forming the opinion as to the cause and mode of death. But the time of death could not be ascertained from the post-mortem examination only, as the process of decomposition was retarded a great deal.

The points of interest are:—

The dead body remained as in a refrigerator due to the cold of the season and absence of air. The water was flowing about 2 feet above the body and the soil was wet at exhumation even some depth below the dead body.

Though one would expect adipocere to have formed in a warm country like India, there was none in the present case as the weather was not warm. Lyon's *Jurisprudence* says "the process occurs more slowly in damp soil than in water."

As to retardation of putrefaction, the following facts may be observed:—

(1) Bodies putrefy more rapidly in summer than in winter.

(2) Bodies putrefy more rapidly in air than in water, and less rapidly in earth.

(3) Protection from air retards onset and progress of decomposition.

(4) Decomposition in running water is slower than in standing water.

Under the circumstances mentioned, the comparatively fresh appearance of the dead body was not incompatible with death having taken place 25 days previously.

SOME OBSERVATIONS ON THE ANTI-MALARIAL PROPERTIES OF PLASMOCHIN.

By AKHIL RANJAN MAJUMDAR, M.D., B.M.S.,
Physician, Campbell Medical School and Hospital, Calcutta.

SEVERAL papers have been published testifying to the value of plasmochin as an antimalarial drug of high potency. The advantages claimed for it are:—

(i) A very small dose, 1—1½ grains daily, is sufficient to control fever.

(ii) Unlike quinine, it produces no nervous symptoms during its administration.

(iii) It quickly removes the crescents from the peripheral blood.

Quinine is long in the field and it has an established reputation as a practically infallible drug in the active stage of malarial infection; it is not easy to find a drug to rise superior to it or even approach it sufficiently near, but plasmochin promises well.

Dr. O. Urchs, M.D., of the Havero Trading Co. very kindly put a liberal supply of plasmoquinine compound at my disposal and I at once set about to make some observations on it.

This sample was in tablets, each containing.

Plasmochin, gr. 1½.

Quinine Sulphate, gr. 2.

These tablets, therefore, contained a little quinine also and I was told that this combination considerably added to the potency of plasmochin, specially for malignant tertian infections.

The daily dose of plasmochin is about 1—1½ grains and so for that purpose 6 tablets must be given in 24 hours. But this with my sample would contain 12 grains of quinine as well.

Twelve grains of quinine itself can control the fever of benign tertian infection. So I decided to try this compound in a dose, the quinine content of which was not likely to control fever, though this would at the same time reduce the dose of plasmochin below the prescribed therapeutic limit.

A well nourished young Mahommedan male was admitted with sharp fever. He was somewhat dazed. The spleen was slightly enlarged.

CAMPBELL MEDICAL.

Name...Ali Mahammed. Caste...Mohamedan, Male Age...25.
Disease...Cerebral malaria.

Case No. 1.

The blood film showed a fairly heavy infection with malignant tertian rings. He was at once given quinine bihydrochlor. gr. x, intramuscularly. Next day he was given plasmochin compound 6 tablets and the day after the temperature came to normal. The dose was at once reduced and he was put on three tablets a day; this means quinine sulphate, 6 grains, and plasmochin, ½ grain, a day. The temperature remained normal for 3 days and on the 4th day it shot up again. He was given 5 tablets and the next day 4 and no more. The temperature came to normal and remained so for another 6 days—during the time no parasites and no crescents were found in the peripheral blood. After this he left the hospital.

Case No. 2.—A rather cachectic Hindu boy was admitted with markedly enlarged liver and spleen. From the general clinical picture, blood count and globulin precipitation test, kala-azar was diagnosed and he was given an injection of urea-stibamine 0.05 gm., but the temperature shot up higher still. The blood was again examined and benign tertian parasites were found. He was given plasmochin compound 6 tablets for 2 days and 4 tablets for one day and no more. The temperature came down to normal

and remained so for the next 4 days and no parasites were found in the blood. The anti-kala-azar treatment was then resumed.

Case No. 3.—A well-built Hindu male was admitted for the treatment of intermittent fever. His spleen was slightly enlarged. Blood slides were taken at the height of fever and benign tertian parasites were found. He was given plasmochin compound tablets 6 one day and 4 on the next and no more. The temperature came down to normal and remained so for the next four days while he was in the hospital.

Case No. 4.—A Nepalee woman was admitted with high fever. The spleen was slightly

Case No. 3.

enlarged and the liver was just palpable at the costal margin. She was complaining of terrible headache and was frequently vomiting a bile-coloured fluid.

She was put on an alkaline mixture and hydrarg. subchloride in fractional doses. The blood was examined and malignant tertian rings were found. She was at once put on plasmochin compound 6 tablets a day. These were continued for three days and the effect is best shown in the temperature chart.

These tablets did not aggravate the vomiting, as sometimes happens with quinine tablets, and there was no other discomfort except a certain amount of cinchonism.

She was apparently healthy before the attack, but this short fever of 4 or 5 days duration made her very anæmic, the hæmoglobin value falling as low as 35 per cent. She was, therefore, put on a mixture of iron and arsenic.

The blood was again examined on the 6th day after admission and on the day of discharge but no malarial parasites were found. The spleen was no longer palpable.

Remarks.

Though the number of cases were very few, it was amply proved that plasmochin was a powerful antimalarial drug. The temperature was brought down quickly with a very minimal quantity. None of these cases had any disagreeable symptoms, probably because a very small dose was given to all of them.

THE USE OF INTRAVENOUS QUININE AND ARSENIC IN ALGID CASES OF MALARIA.

By S. J. BELLGARD, L.T.M., D.T.M. (Bengal),

Medical Officer, E. B. Railway, Bochagunj.

DINAJPUR district is reckoned as one of the hyperendemic areas of North Bengal, and needless to say has a high malaria death rate.

In the bad season, i.e., from July to October, malaria is at its height and its incidence is aug-

mented by the influx of non-immune labour for railway construction work.

The following are the common algid forms encountered; (a) cerebral, 60 per cent. (b) abdominal, 30 per cent. (c) pulmonary, 10 per cent. I had one case of a cutaneous petechial eruption in a young Punjabi, whose blood on microscopic examination showed numerous malignant tertian rings, the petechiae disappearing after one "A. A. Q." injection intravenously (arsenic, adrenalin and quinine).

A few notes on the species of *Anopheles* found, with their seasonal changes.

The paddy fields afford a good bed for mosquito breeding during the monsoon months. *A. culicifacies* was the common species found in July and August; and towards the close of the monsoon *A. sinensis* and *barbrostris*. *A. umbrosus* and *funestus* were also found in dirty stagnant water surrounded by wild vegetation.

The table below shows that the following three species were numerous during a smart epidemic in September last year.

(a) *A. barbrostris*, (b) *A. sinensis*, and (c) *A. culicifacies*.

Species found.	Number found.	Dissection showed.
<i>A. funestus</i>	.. +++	Sporozoites.
<i>A. barbrostris</i>	.. +++	Zygotes.
<i>A. sinensis</i>	.. +++	"
<i>A. culicifacies</i>	.. +++	Sporozoites.
<i>A. umbrosus</i>	.. +	Nil.
<i>A. philippinensis</i>	.. +	Zygotes.
<i>A. gigas</i>	.. +	Nil.
<i>A. vagus</i>	.. +	Nil.

There was a smart epidemic of malaria among the railway staff in early September, 1927, which was not unusual, owing to an influx of a large number of apparently non-immune labourers having joined the construction from Bihar and the United Provinces.

The men came early in August, and in September the epidemic began. I was at first at a loss as to the best procedure to be adopted to tackle it, especially as a good many cases were of algid type in which quinine by the mouth was useless. Finding no other alternative I initially began treatment of all algid cases with the usual quinine and adrenalin treatment by the intravenous route, which in some cases necessitated the use of 2 or 3 injections at intervals of 4 hours before they recovered completely from the algid state.

Arsenic being a useful adjunct to quinine in malaria and beneficially used in malarial cachexia for its hæmoglobin producing effect by its action on the bone marrow, etc., I ultimately decided to try the effect of arsenic and quinine together by the same route intravenously in malaria. This undoubtedly gave me far more satisfactory results than quinine alone for the following two reasons.

- (1) Its action was quicker and more lasting.
- (2) Relapses were fewer.

The attached table gives the total number of cases treated over a period of two months (September and October) with quinine alone, and with quinine and arsenic together.

Technique of Preparing the Injection.—In a sterile glass tube dissolve the quinine bihydrochloride in 20 c.c. of normal saline, then add liquor arsenicalis hydrochlorici and heat over a spirit lamp. Aspirate the contents of the tube into a 20 c.c. sterile hypodermic syringe, add 10 minims of liquor adrenalin hydrochlor 1:1000 (P. D. & Co.) and inject, preferably at the bend of the elbow.

Dosage.

Age	Quinine	Liq. Arsenic Hydrochlor.
6—10	3—4 grs.	m i.
11—15	5 grs.	m ii.
16—20	7 grs.	m iii.
21 and over.	10 grs.	m iv.

required 3 or 4 injections daily, followed by a tonic of arsenic, iron and strychnine for 3 weeks.

I might mention finally that there was no mortality from malaria among the railway staff, in spite of the numerous algid cases encountered.

The majority of the patients responded quickly to one injection, the temperature coming to normal within 3 or 4 hours after the injection.

This injection has proved valuable on railway construction work, where one has to deal with large members of ignorant labourers who utterly refuse to take any form of quinine by the mouth, as a good many of them have a belief that the administration of quinine causes insanity.

The labour strength is also kept up to a working percentage which is a great help to the engineer in charge in the progress of the work, and financial saving in the budget.

Total number of algid cases Treated.	BLOOD EXAMINATION.				Total number treated with quinine alone.	Average number of injections given per man.	Relapses.	Percentage of relapses.	Total number treated with arsenic, quinine.	Average number of injections per man.	Relapses.	Percentage.
	M. T.	B. T.	Q.	Mixed.								
During the year 1927.												
791	490	70	20	211	483	2	217	45%	308	1.23	68	22%
(including private cases).						4 hourly				6 hourly		

Non-pregnant women and debilitated men were given 7-grain doses.

Once the patient recovered from the algid state he was put on to a mixture consisting of arsenic, quinine and strychnine t.d.s. for three weeks continuously.

Precautions.

1. The solution and syringe must be sterile.
2. The solution at the time of injection should be of the same temperature as the patient.
3. The injection should be made as slowly as possible; 1 minute for every c.c., to prevent acute dilatation of the heart.
4. The proper technique in administering intravenous injections must be observed.

Its Use in Relapsing Cases.

The results of using this method in chronic relapsing cases have been very encouraging.

Dr. C. J. Newman, District Medical Officer, E. B. Railway, Saidpur, obtained good results in his cases, although one bad European case necessitated the use of two injections.

In my series of relapsing cases, I found that malignant tertian cases responded very well, but the mixed malignant and benign tertian cases

Current Topics.

Calcutta Branch of the B.M.A.

A branch of the British Medical Association has been formed in Calcutta to include that portion of Bengal which lies to the south and west of the river Ganges. Will members of the British Medical Association residing in that area (who are *ipso facto* members of the Branch) kindly forward their names and permanent addresses to the Honorary Secretary (Dr. John M. Henderson, The School of Tropical Medicine and Hygiene, Calcutta). This procedure is necessary in order to bring the list of Branch members up to date.

Members of the medical profession living in the above area and desirous of joining the Association may obtain application forms from the Honorary Secretary.

The Bengal Medical (Amendment) Bill, 1928.

We publish below an abstract from the *Calcutta Gazette* of the chief items of this Bill, which, in the main, represents an attempt to make the constitution of the Bengal Council of Medical Registration a more democratic one than it is at present.

Whereas it is expedient to amend the Bengal Medical Act, 1914, in the manner hereinafter appearing;

It is hereby enacted as follows:—

This Act may be called the Bengal Medical (Amendment) Act, 1928.

For section 4 of the Bengal Medical Act, 1914 (hereinafter referred to as the said Act), the following shall be substituted, namely:—

Constitution of Council.

"The said Council shall consist of the following members, namely:—

(a) A president to be nominated by the Local Government;

(b) Three members to be nominated by the Local Government;

(c) One member to be elected from among the members of the Faculty of Medicine by the Senate of the Calcutta University;

(d) One member to be elected by and from among the staff of each Medical College or School permanently affiliated to the Calcutta University or to any other University hereafter established within Bengal;

(e) One member to be elected by and from among the staff of each institution in Bengal other than those mentioned in clause (d) which is or may hereafter be recognised permanently by the Bengal Council of Medical Registration for admission of its students to the Licentiate standard of examination of the State Medical Faculty of Bengal;

(f) Two members to be elected by registered practitioners who are graduates or licentiates in Medicine or Surgery of the University of Calcutta;

(g) One member to be elected by registered practitioners who are qualified to be registered under the Medical Acts;

(h) Two members to be elected by registered practitioners other than those referred to in clauses (f) and (g);

(i) One member to be elected by and from among the staff of the Calcutta School of Tropical Medicine; and

(j) One member to be elected by the Railway Board; Provided that, of the members to be elected under clause (f) or clause (h), one member shall in each case be elected by registered practitioners practising outside Calcutta."

Section 19 of the said Act shall be re-numbered as sub-section (1) of section 19, and the following shall be added to the said section as sub-section (2), namely:—

"The Council shall have power to inspect any such Medical College or School and may for this purpose appoint a Special Committee of not less than three or more than five members of the Council to inspect any such institution and submit a report in regard thereto, to the Council to enable them to judge of the efficiency of the institution."

The Central Medical Association and the Bengal Medical Amendment Bill, 1928.

We are asked to give publicity to the following resolutions passed at a joint meeting of medical practitioners and the Bengal Medical Association in February 1928, with regard to the Bengal Medical (Amendment) Bill, introduced in the Bengal Legislative Council in January 1928. The report is signed by Sir Nilratan Sircar, Kt., M.A., M.D., D.C.L., LL.D., President of the Bengal Medical Association, and Dr. Sundari Mohan Das, Principal of the National Medical Institute, Calcutta.

"The avowed object of the bill is to make the Council a more representative body than it is at present. But unfortunately the provisions proposed in it would not only frustrate the object, but would materially divest it of whatever little popular character it has at present.

While introducing the first bill in 1914 the Hon'ble Member-in-charge admitted that a certain degree of control would be placed in the hands of the Government, as that was the "first step" towards self-government in the medical profession and medical education and which

could be transferred to the representatives of the profession within a reasonable time. Fourteen years have passed since then, and instead of a progressive measure we find a highly reactionary bill for placing the whole of the independent profession consisting of over 6,000 registered practitioners under the domination of a Government department. We do not see how the representative character of the Council can be enhanced by severally franchising every one of the half a dozen or more Government medical schools to fill up the seats in the Council, when as a matter of fact every one of these representatives would be officers in the Government Medical Department under the Surgeon-General. A mere copy of the constitution of the British Medical Council which also extends the franchise to all the teaching corporations and licensing bodies independent of government control, has been attempted by proposing similar franchise to government medical schools which at present means four existing and four prospective government schools, all of which are managed and controlled by the Surgeon-General. The existing three non-official schools, being temporarily recognised, have been unjustly excluded from the franchise list.

Then again it is highly absurd to count a nominee of the three European members of the Railway Board as a "representative member" on the Medical Council. Is it held that this board of three individuals, with its all-India jurisdiction should be privileged to "elect" a similar representative on each of the six other provincial medical councils in India? If the privilege is to be given to the Railway Board on the ground of their being employers of a large number of medical men, the claims of mofussil municipalities, district boards and the Calcutta Corporation for similar franchise is even much greater.

The Calcutta School of Tropical Medicine is concerned chiefly with post-graduate teaching and research, and is not primarily concerned with the training of candidates for any registrable qualifications. We are therefore of opinion that instead of granting a franchise to this school it would be fair for the Government to nominate one of the members of their staff to one of the three seats that may be reserved for Government.

We have no objection to larger powers being granted to the Medical Council provided there be a definite non-official majority in the board, but we are afraid that similar powers in the hands of the proposed Council would be highly undesirable.

With regard to Section 2 we beg to suggest the following in place of the proposed constitution of the Council.

(a) One member to be elected from among the non-official members of the Faculty of Medicine by the Senate of the Calcutta University.

(b) One member to be elected by each and from amongst the staff of each medical college or school affiliated to the Calcutta University hereinafter established within Bengal.

(c) Two members to be elected by and from amongst the staff of the medical schools in Bengal established by Government and recognised by the Council of Medical Registration.

(d) Two members to be elected by and from amongst the staff of the non-official medical institutions recognised by the Council of Medical Registration.

(e) Four non-official members to be elected by registered practitioners who are graduates or licentiates in medicine and surgery of the University of Calcutta.

(f) Two non-official members to be elected by registered practitioners who are qualified to be registered under the Medical Acts.

(g) Four non-official members to be elected by registered practitioners other than those referred to in clauses (e) and (f).

(h) Three members to be nominated by Government.

The President to be elected by the Council as is the practice in the Bengal Legislative Council, municipalities and district boards, and the University of Dacca. No Government medical practitioners in service should be allowed to stand for election from

classes (a), (c), (f), and (g), as is the practice in the elections to Provincial Legislative Councils, the Legislative Assembly and Calcutta Corporation.

With regard to Section 10—the term of membership of elected and nominated members should terminate automatically at the expiry of the Council term.

With regard to Section 33—we beg to observe that *mofussil* voters should form a separate electorate from the Calcutta voters, and separate electoral rolls for both should be kept.

The Perforation of Gastric and Duodenal Ulcer.

By SIR BERKELEY MOYNIHAN, *Bart.*, K.C.M.G.,
C.B., M.S., F.R.C.S.

(*The Practitioner*, March 1928, p. 137.)

THIS is such a very important clinical paper, based upon such very extensive personal experience, and constituting such an important contribution to abdominal surgery, that we have taken the following very considerable extracts from it.

Acute perforation may occur either in acute or in chronic ulcers. It affects chronic ulcers far more frequently than acute ulcers. The condition is therefore one of acute perforation in a chronic ulcer. It is necessary to be precise upon this point, for the literature of this subject contains many inaccurate assertions that perforation occurs in acute, rather than in chronic ulcers. In twelve consecutive years at the Leeds Infirmary (1910–1921) there were 61 deaths from perforation of a gastric ulcer; in 60 cases the ulcer was of the chronic variety. There were 117 deaths from perforation of a duodenal ulcer. In 12 of these cases there was an acute ulcer; in 4 of the 12 there was a chronic ulcer also, and it was in every case the chronic ulcer which had perforated. In 8 cases an acute ulcer had perforated. In my own list I find that the great majority of the cases of chronic ulcer which perforated had undergone medical treatment for longer or shorter periods on one or more occasions. The same experience had occurred to Sherren, who records: “218 cases of perforated duodenal ulcer treated at the London Hospital; in 6 only was there no previous history of indigestion.” Similar figures were obtained in 248 cases of perforated gastric ulcer. In hæmorrhage due to a chronic ulcer the same applies. As the majority of these patients had had more than one course of medical treatment—several had been having intermittent treatment for ten years and one for thirty-two—we are perfectly justified in considering them failures of that treatment; and, if surgery was unable to be employed successfully in these emergencies, the mortality is medical rather than surgical. Walton found that of 79 cases of gastric or duodenal ulcer which were fatal, 78 were seen on post-mortem examination to have ulcers of the chronic variety.

It is certain, therefore, that the perforation, whose symptoms and treatment we are to discuss, is concerned, as a rule, with chronic rather than with acute ulcers.

Signs and Symptoms.—The acute perforation of an ulcer is a terrible catastrophe. The patient is plunged at once into a condition of prostration and of unendurable agony unsurpassed, with one exception, in human experience. The pain is almost beyond description. It seizes the patient in a moment, and deals him a blow that he himself may think is mortal. It attacks the whole of the abdomen, and is especially severe in the upper part; it is described as “tearing,” “racking,” “bursting,” “horrible,” “everywhere;” it spreads over the lower part of the chest and even up to the shoulders.

Appearance of Patient.—Within a moment or two the patient's appearance betrays his suffering. The face is pale, haggard, anxious and appealing; the eyes are wide and watchful; the brow and temples are bathed in sweat, the hair soaked. Horrible suffering quickly delves deep lines upon his cheeks. The patient struggles for breath in short, panting respirations which are chiefly costal, the diaphragm making not the slightest movement. The nostrils are wide, the mouth shut, and every expiratory

effort is audible. He complains of cold, and feels cold when a hand is laid on him. The thermometer registers 96° or even a little lower. No movement is made that can be avoided, and words are spoken only in the shortest expiratory jerks, every syllable being part of a deep groan. If a hand is stretched out to touch his body, the patient shrinks from an added terror and will protect himself as best he can with his arms. His legs are soon drawn up. He reaches the very limit of human power to withstand suffering, and his appearance arouses the very gravest anxiety as to his state and may even suggest that death is hastening to him.

Shock.—The condition, indeed, is one for which no other word than “shock” seems fitting. Yet “shock” in the surgical sense is absent. Shock used in its strict sense means the condition in which an increased pulse-rate, a diminished blood-pressure and a reduced blood volume are present. Not one of these is found in the first hour or two after a perforation has occurred. The rate of the pulse is found to be normal, its quality, as a rule, good; the blood-pressure is within normal limits. The blood volume has been measured in only a few of our cases, but that, too, shows no change. It is, therefore, inadmissible to use the word “shock” without qualification to describe the state of a patient who is in the toils of this terrible calamity. There is, of course, the most terrible prostration. Perhaps, apart from severe hæmorrhages, no disease except acute pancreatitis (in which true shock is present) produces so profound a degree of prostration. We must, therefore, not less in the interest of accuracy than in that of the welfare of the patient, cease to use the word “shock” in this connection. Let us speak of prostration, a word which has only a clinical significance. Shock, it is true, comes later in these cases; it comes when peritonitis has developed. But peritonitis is not perforation; it is a late and preventable sequel to perforation. It is the perforation we seek to recognise; the peritonitis we seek to forestall.

Examination of Abdomen.—The examination of the abdomen in this stage reveals a characteristic condition. The muscles are in sternest rigidity. The hand travelling gently over the abdomen finds no soft or yielding area. Every part offers the most inflexible opposition to pressure; the rigidity is obdurate, persistent and unyielding. There is no movement. The diaphragm, largest and strongest of abdominal muscles, is as rigid as the rest, and the shallow, frequent respiration finds in this its explanation. All parts, too, are tender, though the upper abdomen is, as a rule, definitely more sensitive than the lower. One side of the abdomen may be a little more resistant and a little more tender than the other. And this may help to decide whether it is a gastric or a duodenal ulcer which has given way. Only the most gentle examination is permissible; it is unnecessary and indeed inhuman to do more; for the diagnosis of a surgical emergency requiring immediate relief is beyond doubt, and the sooner a dose of morphine is given and preparation made for operation, the better.

Prostration.—The period of initial prostration varies in different cases, and its length depends no doubt upon many factors: the size of the perforation, the condition of repletion of the stomach, the general powers of resistance of the patient, etc. As a rule it lasts not less than an hour and rarely more than two hours. It is followed by a period of reaction. Little by little the pain subsides; though still remaining very severe, the sharp edge of it is blunted. The cold greyiness or pallor of the face is followed by a slight flushing, an indication that the general circulation is becoming more vigorous. The pulse-rate rises, the limbs grow warm, the temperature reaches or slightly exceeds the normal. Relief from an agony that has almost passed belief may persuade the patient that all is well. The victim lifted from the rack fell asleep, though his residue of pain would have seemed acutest suffering but for its comparison with the far greater agony from which he had just escaped.

Pain and Vomiting.—Pain in this period is still present and severe enough. The abdomen is steadily increasing

in size, and its walls have still the same incoercible rigidity as before. Respirations remain hurried and shallow, for the diaphragm is now pressed upwards by the fluid and gas which are beginning to accumulate within the peritoneal cavity. Fluid has gravitated to the pelvis, and the peritoneum there, acutely inflamed, may be recognised as exceedingly tender if a rectal examination is made. It is in this stage, as a rule, that vomiting first appears. This symptom is by no means frequent, and is very rarely severe.

Liver Resonance.—The abolition of liver dullness is often asserted to be a sign of great value in the diagnosis of a perforated ulcer. It appears at a time when the diagnosis should be made without any difficulty; it is a late and not an early sign. The value of percussion is therefore to be regarded as important if it shows an absence of liver dullness, especially if an hour or two before the dullness has been recognised; but unimportant if the liver dullness is found to be normal. In other words, the loss of liver dullness as a positive sign in the absence of meteorism is significant, even decisive; the presence of liver dullness neither helps nor denies a diagnosis.

Progress of Patient.—As time passes, the state of the patient grows progressively and rapidly worse. Vomiting may be repeated, and hiccough, sometimes exceedingly distressing, may develop. The abdomen grows larger and larger, fluid may be present, and a shifting dullness may indicate its quantity. The face grows hollow and the expression strained and weary. The features appear sharp, the skin is livid and sweating, and is often cold and clammy. The pulse deteriorates in value and increases greatly in frequency. The whole condition and appearance of the patient indicate the extreme gravity of the case, and a fatal ending may be expected within three or four days unless operative measures can bring relief.

Diagnosis of Acute Perforation.—After perforation has occurred, there should be no difficulty in making a diagnosis of sufficient accuracy to dictate a policy of action. It is important only to know that something has happened within the abdomen which cannot be relieved by any other than surgical measures. It is not of real importance to know whether it is a duodenal or a gastric ulcer that has ruptured; or whether the pancreas has suffered an acute hæmorrhagic inflammation; or whether the appendix is sphacelated. All these things can be recognised at once when the curtain of the abdominal wall is lifted. The one essential thing is for the medical attendant to recognise that something is threatening life, and that the sooner the threat is removed the better.

All the symptoms and signs related above should be remembered; but for a policy of action it is enough to know that when an acute intolerable attack of agony comes suddenly, and the abdominal wall is at once on guard, intensely resistant and unyielding and everywhere tender, the cause may be this or that, but the remedy lies in operation and in operation alone.

Viscero-sensory Reflex.—When a gross destructive lesion affects any viscus, the sympathetic nerve or nerves communicate their misfortune to the spinal associates who at once raise the alarm. The reflex experienced may be sensory or motor. The viscero-sensory reflex is expressed in hyperalgesia, the viscero-motor in muscular spasm, that is, rigidity in the implicated area. As soon as the parietal peritoneum is involved, however, the effects produced are no longer reflex, but are direct, since this membrane is possessed of its own spinal nerve supply.

The detection of cutaneous hyperalgesia, the viscero-sensory reflex, in any area requires a certain skill. It may be gauged by stroking the skin with a pin held at an angle with the surface; a vigorous scratch must be avoided, for that would discover sensitiveness in all. A short, gentle stroke is first made on the normal skin of the chest or thigh, and then on the abdominal wall. A better method is to pinch a little fold of skin lightly between the thumb and forefinger and draw this away from the underlying muscles. If a disturbed reflex is

present it causes the patient to wince; a quick involuntary movement is made, or a hand lifted to protect the tender part. This method has the advantage that, pressure over the parietal peritoneum being avoided, hyperalgesia can be differentiated from tenderness.

Abdominal Rigidity.—The abdominal rigidity present in cases in which an ulcer has perforated is extreme. No handling, however gentle, however prolonged, discovers one instant of yielding. The muscles remain immobile and unrelaxed throughout; and the diaphragm, strongest of all abdominal muscles, is equally inflexible. The whole contents of the abdomen are surrounded by fixed, firm, unyielding walls, which make no concession to the gentlest hand. The spasm provides the perfect muscular splint for the affected viscera. When this degree of rigidity is present, it infallibly indicates the presence of a lesion requiring surgical assistance for its relief. To this truth there is in my experience no exception. Universal unyielding abdominal rigidity indicates an intraperitoneal catastrophe. In the first few hours no measures other than those of general anaesthesia, and even those with difficulty, can abolish this rigidity. A large dose of morphine may lessen it; it seems powerless to dissipate it completely. This is fortunate; for other symptoms and signs, especially after the administration of an anodyne, and even without this, are apt to fade away, or perhaps to disappear in the stage of reaction. Rigidity remains. It is as true an indication of the presence of a crisis as all other signs and symptoms combined. No practised hand finds any difficulty in distinguishing this form of rigidity from the stiffness of an abdominal wall voluntarily brought about by the patient during an examination which is expected to cause discomfort. If in such cases the hand is kept at rest on the abdomen for a few moments, especially when the patient's mind is distracted by questions, a yielding now and again, especially at the end of expiration, is soon discovered. No voluntary rigidity is ever so incompressible as that excited by a viscero-motor reflex. When the patient is asked to breathe deeply, the free movement of the diaphragm will show that no rigidity affects it. And the diaphragm is as much an abdominal muscle as any. If others are rigid because of a viscero-motor reflex the diaphragm, too, will be motionless.

Differential Diagnosis.—It is necessary to state the problems confronting the diagnostician in the simplest terms. They are these: a patient who lies prostrate and motionless, who has suddenly been seized by an attack of unsupportable agony within the abdomen, whose abdominal muscles are all inflexibly rigid without sign of movement and obdurately resistant to pressure, has suffered a disaster which needs the immediate aid of a surgeon. His condition does not enable us to localize the lesion, but merely to assert its existence.

The examination of a patient so grievously afflicted must be brief; motives of humanity no less than of urgent necessity compel us to hasten in decision and to be quick in action. Recent experience appears to show that the most positive evidence of perforation is derived from an examination by means of x-rays. While the patient's breath is momentarily held, a photograph is taken. The presence of a bubble of gas, free in the peritoneum, above the liver, is conclusive and the earliest evidence of perforation.

The patient may give a history of former attacks of indigestion, which may lead one to suspect, and even to be confident in diagnosing, an ulcer of the stomach or duodenum. The universal rigidity may appear even more perceptible at the upper part of the abdomen; and one side may seem to be more tender or more resistant than the other.

The fact that fluids escaping from the torn duodenum, or from the pyloric region of the stomach, encounter the little hillock in the transverse mesocolon and are deflected to the right, escaping down the outer side of the ascending colon to the right iliac fossa, where some accumulation may occur, accounts for the fact that the localizing signs of appendicitis may sometimes be quickly developed.

Acute Pancreatitis.—This is often said to present great—indeed, insuperable—difficulties in diagnosis. But if this case is carefully studied and examined there need be no hesitation in reaching a definite discrimination between the two conditions. Deaver has said that the chief reason for failure to make a diagnosis of acute pancreatitis is that one does not "think of this disease" at the moment. It is certainly an infrequent condition; the perforation of a duodenal ulcer is common enough; and therefore, probability being the very guide of life, the perforation of an ulcer is at once in the forefront of one's mind. There is much truth in this; for when the diagnosis of acute pancreatitis is made in a case discussed with others, it is often received with immediate assent. There should, however, be not the least difficulty in making an accurate diagnosis in the earliest stages.

Acute Thoracic Diseases.—These may cause the greatest difficulty in diagnosis; no surgeon of large experience is unfamiliar with that close mimicry of an acute abdominal catastrophe which is presented by such diseases as acute diaphragmatic pleurisy, acute pneumonia, and acute pericarditis, especially when they occur in young people. These diseases are often ushered in by acute pain which develops quickly, if not suddenly; and the pain, because of the involvement of the lower dorsal nerves which end in the abdominal wall, chiefly affects the parts involved when an ulcer has leaked. In such cases, too, there is often exquisite surface tenderness and restriction of movement of the abdominal muscles, or even at the first immobility, and a considerable degree of rigidity. All these may appear at a time when the pulmonary or cardiac condition is very slight, or even absent so far as gross physical signs are concerned. It is only by earnest consideration of certain points that a discrimination may be possible:—

(a) The examination of the abdomen by the practised hand will disclose the fact that, though tenderness and rigidity are both present, they are not by any means so striking as in cases of perforation. Surface tenderness may be exquisite and a gentle pinching of the skin almost intolerable; yet deep, firm, but still gentle pressure will be a comfort to the patient. Neither rigidity nor tenderness is universal; a little relaxation of the abdominal wall may be found in the hypogastrium or in the iliac regions, especially at the end of each expiration, and here, too, cutaneous sensitiveness is less acute. Rectal examination discloses no tenderness of the pelvic peritoneum. Indeed, as a rule, a continued observation will be convincing as to the greater implication of the upper as compared with the lower parts of the abdomen.

(b) The temperature is nearly always raised, perhaps by 2, 3, or 4 degrees in thoracic conditions; it is depressed when an abdominal disaster has recently occurred. In some pulmonary diseases the initial or an early symptom may be rigor, and within a short time the sensitive swollen edge of the lip may indicate that herpes is developing.

(c) The respiratory frequency is accelerated out of all proportion to the pulse-rate. There may be 40 respirations or even more to the minute, while the pulse-rate remains near or even below 90. The ratio of pulse to respiration is normally about 40 to 10. If it is 30 or 25 to 10 then the cause usually lies above the diaphragm, and not in the abdomen. This change in the ratio is the most significant of all signs, and in all cases the closest regard must be paid to it.

Acute Appendicitis.—The differential diagnosis between acute appendicitis and the perforation of an ulcer may sometimes present difficulty. This is more especially the case towards the end of the period of reaction.

Both the clinical history and the physical signs, however, should enable an accurate differential diagnosis to be made. In acute appendicitis the onset of pain is never so severe, never overwhelms a patient with its unendurable intensity; it is never quite so sudden, but reaches its greatest height an hour or two, or even more, after the first pangs are noticed. The perforation of an appendix certainly causes a sudden and an exceedingly severe pain, even an agony; but perforation is the consequence of some added factor in an already inflamed

appendix which has declared its infection by signs and symptoms which should easily be recognised. The rule, with few exceptions, if any, is that the perforation of an appendix follows the administration of aperients given because of the abdominal discomfort caused by the inflammation of the appendix. Without aperients there is never perforation.

Abdominal Colic.—An attack of abdominal colic—biliary, renal or intestinal—is often believed to present difficulties of differential diagnosis. There should be none. An attack of colic comes with equal suddenness, but it excites not immobility but agitation and infinite restlessness. A patient struck down by the perforation of an ulcer is motionless; his body is intensely rigid, every active movement is avoided, and every passive movement bitterly resented. Even every act of inspiration is shortened, so as to avoid any slightest abdominal movement. A patient in the agony of colic can find no resting-place. He writhes and groans, and moves about or rolls on the bed or floor in search of the comfortable position he never finds. His arms are pressed to his abdomen, and he welcomes the strong pressure of another hand. There is never any universal abdominal rigidity. There is local stiffness, and the abdominal muscles are tightened in the effort of groaning, but there is not the slightest evidence of general involuntary rigidity. The pictures of the two sufferers are so completely different that it is impossible to suppose that the difficulties in diagnosis can exist for those who have seen the states produced by these two catastrophes.

Profuse Hæmorrhage.—There are occasions when profuse hæmorrhage associated with severe pain may produce a condition requiring to be distinguished from that of perforation. Of these the most common and the most serious is concerned with the rupture of a tubal gestation. There is the same sudden onset of acute abdominal pain, the same immediate prostration, the same acute anxiety for the patient's life. Beyond these there is little resemblance. Blood which escapes, sometimes in very large quantities, into the abdominal cavity is little irritating, one is tempted to say in no degree irritating, to the peritoneum. Its entry is not resented and accordingly does not cause the same extreme response, either visceromotor or viscerosensory, as is made by irritating gastric or intestinal contents. There is therefore not the same agonizing pain, nor is there the same incoercible abdominal rigidity. This catastrophe occurs, as a rule, after the menstrual period has been missed. A sudden severe pain, not of the same prostrating severity as in rupture of an ulcer, but, nevertheless, very acute, is noticed almost at the same moment that a vaginal loss of blood occurs.

Intestinal Obstruction.—Various forms of intestinal obstruction sometimes cause symptoms not widely diverging from those of perforation. There is the same sudden onset of pain, and the same implication of the whole abdomen in the response; there are vomiting, prostration, slowly advancing distension; there is absolute cessation of voluntary intestinal discharge, of flatus as of feces. But there is not the same fierce intensity of the symptoms in any form of intestinal obstruction except one, volvulus. And in this, as in all others, the abdominal rigidity does not approach the metal-like fixity and immobility seen in cases of perforation; nor is the pain so agonizing. There is in obstruction an immediate onset of vomiting and this symptom persists and is uncontrollable. Small quantities are ejected frequently, indicating that the stomach is already over-distended, and is continually being filled, no matter how quickly it endeavours to empty itself. The ejected matters are gastric, then duodenal or jejunal, brown, offensive, and bitter. "Fæcal" vomiting is seen only in cases of gastro-colic fistula, or a few moments before the agony of death. The term "fæcal vomiting," indeed, should disappear from the vocabulary of intestinal obstruction.

Mesenteric Embolism or Thrombosis.—A condition, happily infrequent, which may give for perhaps a few hours at the onset as close a resemblance as any other to acute perforation of the stomach is mesenteric

embolism or thrombosis. There is the same sudden onset of acute intolerable pain; the same prostration, some degree of abdominal rigidity, and a quickly-developing distension of the whole abdomen. But the pain soon becomes intermittent, and is spoken of as "cramp"; blood appears in the stools, sometimes within an hour or two. The patient becomes profoundly collapsed, the pulse-rate rises rapidly, the temperature falls. There is often, though not invariably, an obvious source from which an embolus might be derived, vegetative lesions on the left side of the heart being the commonest.

Tabes Dorsalis Crises.—There is only one matter remaining for discussion. It concerns the mimicry of these cases of abdominal catastrophe by the "crises" dependent upon tabes dorsalis. No case of abdominal disease, acute or chronic, is adequately examined unless the pupillary reactions and the ankle and knee-jerks are observed. Gastric crises may cause symptoms which are mistakenly attributed to organic diseases of the abdominal viscera.

Conclusion.—The conclusion from this discussion is clear. The diagnosis of an abdominal calamity requiring immediate surgical treatment is made when a sudden attack of prostrating and overwhelming agony is associated with an obdurate, unyielding rigidity of an abdominal wall which is everywhere excessively tender and immobile. Shock in the strict surgical meaning is not present. If we wait for it, we are risking the patient's life; for it is not an evidence of perforation, but of the peritonitis which is preventable, and should be prevented. We may not be able to say, when these signs alone are present, that the catastrophe is certainly in one viscus, or certainly in another. It matters little where it is, all we need to know is that wherever it is, and whatever it is, it is irremediable except by surgery. We must reduce this matter to simple terms and that is the only method by which we can succeed. The salvation of a human life is a greater thing than the establishment of a convincing irrefutable clinical diagnosis.

Operative Treatment.—The technical details in connection with the various operations will be found in other works concerned with the craft of surgery. I propose here to discuss only their applications and results. When a perforation has occurred there are obviously two methods of dealing with the gap in the stomach or duodenum. The opening may be closed; or it may be used for the insertion of a tube. The results of surgery, given adequate competence in the operator, depend almost entirely upon the time that has elapsed after perforation.

If the operation be performed early and the conditions are favourable the rent in the viscus is closed. If this closure brings about an immediate stenosis, or appears to threaten or ensure stenosis in the future, the question of the performance of a short-circuiting operation will arise. Alternatively, the rent in the viscus may be enlarged, the ulcer excised, and the incision so sutured as at once to enlarge the calibre of the viscus at the part implicated.

If the operation be performed late—if it is a rescue operation rather than a reparative operation—then the opening in the base of the ulcer may be used for the introduction of a tube, rapidly fixed in position, and employed for days after as a means of introducing fluid food to sustain an almost exhausted or nearly moribund patient. A drain into an overloaded peritoneal cavity is rapidly introduced above the pubes, but time will not allow of more than this.

There is an increasing tendency on the part of most surgeons, I think, to deal, if possible, reparatively with a lesion in the duodenum. The whole ulcer together with the gap in or near its centre is excised, and the resulting opening, perhaps of large size, is so sutured that not only is a stenosis avoided, but a larger calibre of the intestine results.

These conclusions, may be drawn:—

(1) In gastric ulcers affecting the stomach, in parts other than the pyloric antrum, the closure of the perfora-

tion is all that is required. If the patient is in a later stage of the catastrophe, or if the gap is inordinately large, the opening in the stomach may be used for the introduction of a tube; that is the performance of a temporary gastrostomy.

(2) In duodenal ulcers, where the rent is small and surrounding induration absent or of very limited extent, closure of the perforation is all that is required.

(3) In duodenal ulcer where the rent is larger and induration more extensive, one of two courses may be followed:—

(a) The ulcer may be infolded and gastro-enterostomy or gastro-duodenostomy performed.

(b) The rent may be enlarged, the ulcer excised, and a plastic operation which secures an enlargement of the passage from the stomach may be performed.

(4) In duodenal ulcer, where the gap is very large and induration excessive, one of two courses may be followed:—

(a) The ulcer may be closed as much as possible, and the gap filled by a plug of omentum, gastro-enterostomy being performed.

(b) The opening may be used for the performance of temporary duodenostomy.

The two methods are both unsatisfactory and are only to be used in the last stage of the emergency.

The questions of irrigation and of drainage are decided by the extent and quality of the peritoneal contamination or infection.

COMPLICATIONS.

(1) *Subphrenic Abscess.*—This is perhaps the most serious of all. It is due to an extension of the contamination or infection which spreads from the site of perforation in consequence of the extravasation of the contents of the stomach or duodenum. It is slightly more common on the left side in cases of gastric ulcer; on the right side in cases of duodenal ulcer; but each variety of ulcer may cause an abscess upon either side. The evidences of its development do not, as a rule, begin until after the fifth day; by the tenth day they are usually definite. From this time their severity increases rapidly unless relief is given.

(2) *Residual Abscess.*—The material extravasated from the ulcer, together with the fluid poured out freely from the peritoneum, may collect in small or large amounts in various parts of the abdominal cavity. In consequence of adhesions which so quickly form, some fluid may be shut off, increase in quantity, and because of the infection rarely virulent, but never absent, result in the formation of an abscess. Gravity decides that the pelvis shall be most frequently the site of such a collection.

The signs which result depend therefore upon the position taken by the collection of fluid. If the pelvis is filled, a swelling recognised most easily, and in an earlier stage, by rectal examination will develop. An absence of mucus in the stools for a few days is the signal that proctitis is present; and the rectum must then be examined. The finger impinges upon a tense, doughy swelling which feels as though a tennis ball were impacted deep in the pelvis. Day by day this bulging of the anterior wall of the rectum will increase; and if there is no urgency may be allowed to increase until it is evident that a quite definitely circumscribed abscess is present. Then a small opening made by one thrust of the sharp end of a pair of scissors will open the abscess, and its contents will soon drain away. Rectal drainage is far preferable to abdominal drainage.

(3) *Parotitis.*—This is among the most serious of all the complications which may follow after this operation. We now recognise that it is due to an infection extending up Stenson's duct from a mouth which has not been kept clean. The prevention of parotitis is a question of careful nursing. It is a tedious matter, no doubt, to have to attend hourly to the toilet of a patient's mouth, clearing away impurities and lodgments, and keeping the mucous membrane moist. But it must be done. The patient must help by flushing the mouth almost incessantly with some agreeable, fragrant, slightly antiseptic

fluid; and he may keep his saliva flowing by the use of chewing gum. A dry mouth is not only a discomfort, it is a real danger.

(4) *Pulmonary Complications.*—These are of many kinds. Diaphragmatic pleurisy, empyema, basal pneumonia and pulmonary embolism have all been observed. Infection spreading through the diaphragm is responsible in some cases; and inhalation of vomited material during the operation in others.

(5) *Gastric or Duodenal Fistula.*—This may follow the giving way of the suture which has temporarily closed the base of the ulcer, or may be due to leakage occurring after removal of the tube inserted into the stomach or duodenum through the rent. It is always an extremely serious complication, and in duodenal cases is almost invariably fatal.

The Indigenous Systems of Medicine.

AN interesting and very outspoken address on this subject was delivered by Major D. R. Ranjit Singh at a meeting of the Allahabad Medical Association on Friday, April the 13th, on the occasion of his return from a tour of study in Europe. Major Ranjit Singh's views are that to endow the ancient systems of Indian medicine is to waste the taxpayer's money. We take the following abstracts from his address from the Allahabad *Leader* of April 16th, 1928, with due acknowledgments to our contemporary.

"Ever since my visit to Europe I have been feeling no end of disappointment as regards the backwardness of my country in regard to public health, the low vitality of our nation, the decreased power of resistance, and last but not the least important of all, our appalling mortality all round. These facts may not affect our legislators who are laymen, but surely it strikes me that we who have qualified ourselves in all the branches of modern medical science by virtue of which fact our responsibilities should be proportionately greater, are doing practically nothing to help our dumb millions. There are then some other aspects which have prompted me to sound a note of warning to my countrymen and these are the backward swing of the pendulum as regards the propaganda in connection with the revival of the old and obsolete systems of the healing art. The encouragement of the Vaidic and the Unani systems has been so well received by the laity in the Legislative Council that I am conscious of the great anger and opposition that I may arouse by laying before the unsuspecting public the real facts and the dangers to which we are being led by vote-catching legislators. India having admittedly had a glorious past, also possessed its own systems of healing. They are still in vogue and are still being practised largely in the urban areas where our medical graduates unfortunately have not established themselves so far. These systems are undoubtedly thousands of years old, and to my mind are standing to-day where they did thousands of years ago. China, I am sure, boasts of a still older civilization than ours and it would be interesting to know why the Chinese people who are not like us dominated by a foreign Government have not revived their indigenous systems, and why they have taken to modern scientific medical appliances as in every other country such as Egypt, Turkey and Greece, which have quite as old, if not older, civilizations than ourselves. We as medical men ought to be aware of the psychology of the mind that has made the pendulum of our country in our legislatures swing back with such evident disadvantage. I am second to none in admitting that our country possesses thousands of herbs which have very efficacious medicinal properties, but to say that our old systems which have been stagnating during the last two thousand years should be revived as they were, is, I think, nothing else but an irony of fate, and in my humble opinion is on the one hand either based on the ignorance of the legislators or to some extent on their seeking popularity for votes. Imagine that while some of our most useful hospitals are being starved for want of modern

appliances, the legislatures have been granting money lavishly for the Unani and Vaidic systems.

I have been misunderstood before and would not like to be misunderstood again and, therefore, I want to clear the point that while I am a great advocate of getting modern medical science translated in our own vernaculars, I do not want by any means to be a party to putting our country back in the scale of civilization by popularising unscientific, old and obsolete systems. We are all aware of the very commonplace argument trotted out by the advocates of these systems that in our urban and mofussil areas it is only these systems which prevail and that they also claim a certain percentage of cures, but here again we medical men are fully aware of the fact that as long as there is life and vitality there is a constant effort on the part of the diseased system to combat disease and mend itself by a natural process. I, therefore, hold that most of the so-called cures are due to this and not so much to the correct diagnosis and subsequent medication. None can challenge that the modern methods of diagnosis are every day taking us nearer and nearer to correctness, and that there can possibly be no comparison between the old methods of diagnosis and the present diagnosis made by modern appliances such as x-rays, etc. I feel almost confident that if our medical associations took it upon themselves to enlighten the lay public and explain to them the details of this enormous waste of public money which is being allowed in our Councils for reviving the indigenous systems, it will come to a stop.

I call this one of the moral duties of the modern Indian medical practitioners and if you all agree with me, I would ask you to send your formal resolutions protesting against the *callous waste of taxpayers' money in this direction*. I have already referred to the backward condition of our public health and the appalling mortality in our country. I now want to draw your special attention to these two heads and ask you to search your hearts, and say if we medical men have a clear conscience of having done our duty in this matter. I personally hold that here is again a vast field for our activities. Let our medical associations tackle the health problems of the larger towns and advise the local bodies and see that they do their duty and reach the standard of other civilized countries. Indeed I feel that we as practitioners of medicine in our individual capacity can do a lot of good by keeping our eyes on preventive medicine even in our private visits, while a few sentences of friendly advice given to the friends of the patients about certain crude facts of hygiene can go very far.

I have referred also to the decreasing vitality of our nation, and here I ask you to consider whether we have ever given enough thought to this question. The bulk of our population is vegetarian and has always depended on milk and its products as parts of our food. Milk gives us all the necessary ingredients for maintaining our vitality. I am not exaggerating facts when I say that it is almost impossible to get pure and genuine ghee and milk in large towns. While visiting some of the tuberculosis sanatoria in the West I was told by a number of experts that in their opinion it was the milk-shy families which were predisposed to tuberculosis of lungs. Can we not exert our pressure on local bodies and local legislatures to wake up and realize the responsibilities which they owe to the nation and grapple with this measure as best as they can?

Personally, I have always held that a medical man can always be a very useful member of our local boards, as in matters of public health and hygiene our country is admittedly centuries behind the rest of the civilized world. Is it not an irony of fate that here in Allahabad where our medical association has been granted a representation on the local municipal board and where we have an important public health committee, the chairman of even this committee should be a non-medical man?

Another most important question that is being discussed specially in over-populated centres of civilization such as New York, London, Paris, Berlin and Vienna is the question of the ethics of contraception.

In a country like India where starvation looms large at least as far as the masses are concerned, but where the procreative capacity unfortunately is still on the increase, the question whether contraceptive methods should or should not be widely explained to the laity is indeed of momentous importance. Personally I am in favour of enlightening the public on all questions relating to sexual hygiene, prevention of venereal disease, and lastly, though not the least important, the question of contraceptive methods should be explained and taught publicly.

As medical men we might also exert our influence and press the question of civic survey being immediately carried on in all our larger municipalities. And while talking of the subject I am very gratified in informing you that the civic survey of Allahabad which was initiated by me while I was chairman of the Allahabad Improvement Trust, when completed, had really opened my eyes to the gruesome details regarding the infantile and general mortality due to various endemic and epidemic causes in our town. Indeed, I felt very much gratified when the Secretary of the Garden City Association of London appreciated the civic survey as brought out by the Allahabad Improvement Trust under my administration and said that we had actually taken the wind out of the sails of his association as we had completed a work which they were only contemplating to get done. I believe the Government of Madras have, since, introduced the question of civic survey in their larger municipalities.

League of Nations' Health Organisation Publications.

THE attention of public health workers in India may be drawn to a recent small brochure published by the Health Section, League of Nations, Geneva, giving a list of their publications with notes on each and prices. This was published in March 1928, and copies are available on application to the League. The most important publication, perhaps, is the *International Health Year-Book*, that for 1927 being the third published. Other important publications dealt with are the *Annual Epidemiological Reports*, the *Statistical Handbooks* for different countries, which give details as to methods of collecting and registering vital statistics, the publications of the Malaria Commission, and the reports of Special Studies and Investigations.

The Publications of the Voluntary Service Fund.

WE referred on p. 52 of our issue for January 1928 to the work and publications of the Voluntary Service Fund, 36, Friday Street, London, E. C. 4. This Fund is one which runs a strong and vigorous propaganda in Great Britain on behalf of vaccination, and public health workers in India may be interested to know of its publications. We have recently received a more complete set of these publications, a note on which may be of interest to our readers. They include the following:—

(i) *Facts that you ought to know about Small-pox and Vaccination*.—This is a small 8 page pamphlet issued at 2d. each, or 15s. per hundred for general public distribution, illustrated with photographs of small-pox cases. It is very well got up and printed.

(ii) *Small-pox Hints for Health Visitors and Welfare Workers*.—By W. McConnel Wanklyn, M.R.C.S., L.R.C.P., D.P.H. This is an 8 page brochure published at 1s. per copy, giving the necessary information to health visitors and welfare workers about small-pox and vaccination, with notes on how to diagnose the former disease, and on the necessity for vaccination.

(iii) *The Accurate Diagnosis of Small-pox*.—This is a reprint of a post-graduate lecture delivered at the London Hospital Medical College by Dr. Wanklyn, and is sold at 6d. per copy.

(iv) *A Survey of the Present Position of Small-pox and Vaccination as affecting this Country*.—This is a

reprint of an address delivered to the Society of Medical Officers of Health. No price is stated.

(v) In addition to the above, the Fund also issue copies of an extremely striking photograph. This shows a mother suffering from small-pox, who was admitted to a small-pox hospital, and delivered there. The infant was vaccinated on the following day and did not contract the disease, although suckled and nursed by the mother. The mother and infant are shown together, and the photograph is a striking one by way of propaganda.

The Voluntary Service Fund also issue several other publications by way of propaganda against small-pox and in favour of vaccination, and will be glad to supply information to enquirers.

A Fraudulent Label.

A TYPICAL instance of what goes on in the Indian drug market has been brought to our notice by the manufacturers of "Sanmetto." Sanmetto is obtained from the saw palmetto tree, and is used as a sedative and diuretic, being prescribed frequently in cases of gonorrhœa. It is manufactured by the Od Chem. Co., New York.

The packages of the spurious product which is being sold on the Indian market are an exact duplicate of the genuine Sanmetto labels, with three interesting differences. In the false label the word "substitute" is printed in place of "substitutes"; the word "of" is transferred from one line to the next; and "prosecution" is misspelt "procecution." Also the heavier leaded type is a little thinner in the spurious label than in the genuine one. Otherwise the two labels are identical. The manufacturers of Sanmetto claim that the drug sold in the spurious packages readily ferments and is most injurious to health.

As matters stand at present in India, we take it that the manufacturers of Sanmetto have no course open to them other than to prosecute the makers of the spurious article in the civil courts in the hope that possibly a conviction may result. This is a most unsatisfactory state of affairs and calls for legislative reform.

Sciatica and its Treatment.

By ANTHONY FEILING, M.D., F.R.C.P.
(*British Med. Journ.*, March 1928, p. 389.)

IN his Hunterian lecture on the subject of sciatica Dr. Feiling dealt with the subject of treatment as follows:—

It is obvious that in this, as in every condition in medicine, successful treatment depends on an accurate diagnosis, although palliative treatment may, of course, temporarily relieve all the symptoms. The treatment of the secondary forms of sciatica is clearly that of the causal factor, but where that is unfortunately not amenable to direct treatment we must be content with methods designed to mitigate discomfort and suffering.

Let us consider first the treatment of those cases where a real neuritis or perineuritis of the nerve is present. As previously indicated, a careful search for etiological factors will have been made, and any diabetic element in the case noted and treated. In the severe and acute cases rest in bed is nearly always essential. The application of a splint to the affected leg is sometimes advised, but in my experience this can seldom be tolerated; indeed, the maintenance of any position of the limb for long at a time is often almost impossible. Undoubtedly the most useful local method for the relief of pain is the application of heat in some form or another, whether this be achieved by poultices, fomentations, radiant heat, or diathermy. The last, when available, is a most useful method. Ultra-violet rays with the mercury vapour lamp or the tungsten are applied locally are also of value in the relief of pain.

Many authorities think highly of the value of electricity, either in the form of the simple constant current or of ionization. I must confess to having been little impressed by these methods of treatment, and now

seldom employ them. For slighter cases some benefit may be derived from counter-irritation, whether this be effected by strong liniments or ointments, or by blisters, or by the old-fashioned method of painting with concentrated hydrochloric acid, but in any severe case such methods are generally of doubtful value. In the early stages of an acute neuritis massage is definitely contra-indicated.

I cannot deal in any detail with all the innumerable drugs which have been used in this disease, either as supposed cures or as mere relievers of pain. Any condition amenable to medicinal treatment, such as constipation or urinary infections which may be a factor in the causation, must, of course, receive prompt treatment. The salicylates and the iodides are about the only drugs which seem to have any direct effect on these cases. The intravenous injection of sodium iodide has been advised, but I cannot say that I have found this method to possess any particular advantage over the ordinary form of medication by the mouth.

Analgesic drugs will nearly always be needed in cases of any severity, especially for the relief of pain at night. Aspirin, phenacetin, phenazone, may all be tried; "dialacain" is a useful compound, and I have also found "allonal" of value. A mixture of drugs which I have found effective is a cachet containing 5 grains of aspirin, 5 grains of pyramidon or amidopyrin, and a small dose of heroin, say one-eighth or one-quarter of a grain. It need hardly be said that the use of morphine should be restricted as much as possible, although in really bad cases its use for a time will be almost imperative.

Cases of sciatic neuritis which do not yield fairly rapidly to treatment along these lines, say in two or three weeks at most, may be very advantageously treated with injections of saline solution into the nerve trunk—a method which marks a distinct advance in our therapeutic armamentarium. This method is particularly indicated in cases where there is definite evidence of the presence of a true neuritis, such as marked tenderness on pressure on the nerve and loss of the ankle-jerk. The best sites for the injection are just below the sacro-sciatic notch and at a point on a level with the tuberosity of the ischium. The method is now well known, so that I need not enter into all the details, but it is important to make certain that the point of the needle should enter the sheath of the nerve before the solution is injected; the sensations of the patient are the best guide to the position of the needle. Pain may be lessened by a preliminary anæsthetization of the skin with novocain and by injecting 1 or 2 c.cm. of the novocain solution into the nerve as soon as the point of the needle enters the nerve sheath. A considerable bulk of saline solution must be injected; I have been in the habit of using 100 c.cm. The pain produced at the time is not as a rule of great severity or of long duration, and can be controlled by an injection of $\frac{1}{4}$ grain of morphine. The patient should remain in bed for at least twenty-four hours after this little operation. In many cases it is advisable to repeat the injection at a different point in the trunk of the nerve after an interval of three or four days.

Another method of value in these cases of sciatic neuritis is the injection of oxygen. A needle and tubing are attached to a cylinder of oxygen, the flow being carefully graduated; the needle is inserted so as to lie in close proximity to the nerve trunk, and enough of the gas is injected to produce a definite ballooning of the tissues.

The stretching of the nerve trunk by forcible manipulations is probably of little service. In a very few cases which have resisted all other methods of treatment it may be justifiable to cut down on the nerve and freely incise the sheath in a longitudinal direction—a procedure which has given relief in cases which had previously proved intractable.

If we believe that we are dealing with a case of "central sciatica," that is sciatica due to vertebral lesions, it will manifestly be of little service to inject the trunk of the nerve. In such cases very great

temporary relief may be obtained by an epidural injection. In this method a needle is passed into the sacro-coccygeal foramen and the solution injected into the epidural space in this region, where it can come into immediate contact with the nerve roots. Various solutions have been used for this purpose—normal saline, novocain, and, what I have always used personally with quite good results, a 40 per cent. solution of antipyrine, of which 10 to 20 c.cm. may easily be injected. It is advisable to anæsthetize the tract of the needle with novocain, and to have the patient either lying on the affected side or in the genu-pectoral position; a long needle is also essential, especially in fat subjects. As a rule, the relief afforded by this manœuvre is almost immediate, and often quite dramatic; it is easily repeated if needed. This last procedure, coupled with the local and continued application of heat in some form or another, is usually successful in relieving most cases of central sciatica. Any focus of infection must be treated, and some help is afforded, I think, by the use of one of the many varieties of so-called protein shock therapy, such as the intramuscular injection of milk or the intravenous injection of *B. coli* or T. A. B. vaccine.

Immobilization is the essential factor in the treatment of these central sciaticas. This is obtained by means of a plaster jacket, to be worn daily for increasing periods until it can be tolerated continuously. It is later replaced by a celluloid corset, which is worn for a prolonged period, six months at least, or even a year.

On the other hand, in the more chronic cases of this kind I have become convinced of the great benefits to be derived by carefully designed manipulations under an anæsthetic. Manipulative treatment, again, according to some observers is the only method of useful treatment in cases believed to be due to chronic subluxations of the sacro-iliac joint. In many of the cases of chronic sciatic pains following trauma, even where there is no reason for thinking that this joint has been affected, much benefit often follows manipulations or mobilization.

Reviews.

ANTHELMINTICS AND THEIR USES IN MEDICAL AND VETERINARY PRACTICE.—By Lieut.-Col. R. N. Chopra, M.D., I.M.S., Professor of Pharmacology, Calcutta School of Tropical Medicine, and Dr. Asa C. Chandler, Ph.D., formerly Hookworm Research Worker, Calcutta School of Tropical Medicine. Baltimore: The Williams & Wilkins Co., 1928. Pp. 291, with 65 figures. Price, \$5.00.

In this book the whole subject of the treatment of worm diseases in man and animals is clearly and fully set forth, and it undoubtedly fills a gap that has existed for a surprisingly long time in the literature of therapeutics. The book is well arranged, being divided into three sections.

Section 1.—General considerations. This deals with the history and evolution of the use of anthelmintics, and a long chapter is devoted to brief references to the parasites of man and animals, which gives a handy bird's-eye view of the subject of worm parasites. One or two omissions in this portion may, however, be noted. *Fasciola hepatica* is not included among the parasites of man, and the genera *Syngamus* and *Oxyuris*, both common parasites of poultry, are not included. Regarding *Syngamus*, however, this omission is rectified in later chapters. There is next a long synoptic key occupying nine pages on the diagnosis of worms and eggs found in faeces. This key is divided into three sections, viz., (1) tapeworm segments and adult nematodes; (2) larvae of tapeworms and nematodes; (3) helminthic ova. The method of construction of this key is unusual in that cross references to points of diagnostic difference are made by using numbers in brackets, which necessitates working backwards as well

as forwards through the key, and at first this is somewhat confusing. Also the inclusion of the nematodes of man and all the domestic animals in a single section somewhat adds to the confusion. There are five plates consisting of sixty-five figures showing most of the worms and eggs found in faeces; the figures of the eggs are excellent and will prove of considerable assistance in diagnosis, but it is doubtful if the outlines of tapeworm segments and such a figure as that of *Trichinella spiralis* will convey much to the reader. One also remarks the omission of the heads of *Tania solium* and *T. saginata*, as well as drawings of *Hymenolepis nana*. There is no indication as to whether any or all of the drawings are original as no acknowledgments are made. The final short chapter of this section is very interesting as it explains how anthelmintic action of drugs depends on their chemical composition.

Section 2.—Anthelmintics acting on parasites in the gut. This is necessarily the longest section of the book, and it gives a full description of the source, chemical composition, toxicology, and methods of use of all the efficient anthelmintics. Not the least useful part of this section is a brief description of many drugs that have been lauded as anthelmintics, but which accurate investigation has shown to be valueless.

Section 3.—This section is also a very complete exposition of our knowledge of the subject up to the present time. In a book of this nature it is naturally necessary for the authors to draw on the literature very extensively, for the experience of no single group of workers can cover the treatment of all worm parasites, and that they have made full use of their opportunities is shown by reference to the lengthy bibliography. When one comes to examine this very full list of authorities in detail one is disappointed to find that many of the references are not quoted in the text, and also that numerous authorities are cited in the text, either with or without dates, to which no reference can be found in the bibliography. Also there are some references where the dates in the text and the bibliography do not agree, and in others no dates are given whereby the references may be traced; further, once or twice when joint authors are quoted they are given in one order in the text and in the reverse order in the bibliography, which makes it difficult to trace them. In a few instances it was noted that neither the alphabetical nor chronological order has been strictly followed. There are some errors in spelling and omission of letters from words, but these are infrequent and are so obvious that they will never lead to misreading of the context. The book is well printed in clear large type, and there is a full index enabling rapid reference to any subject. The above criticisms are only those of detail, and in making them the reviewer does not wish to detract from the undoubted value of the book, but draws attention to them in the hope that they may be corrected in future editions. It is a book which everyone concerned with the treatment of worm infections whether of man or animals cannot well afford to be without, and the price, viz., five dollars brings it well within reach of all practitioners.

P. A. MAPLESTONE.

A TREATISE ON KALA-AZAR.—By **Rai Dr. Upendranath Brahmachari Bahadur, K.I.H., M.A., M.D., Ph.D.,** Fellow of the Asiatic Society of Bengal. London: John Bale, Sons and Danielsson, 1928. Pp. 252, with 12 plates, mostly in colour, and 39 other illustrations. Price, 21s. net.

THE first impression which one obtains on glancing through this sumptuous book is the extremely high standard of publication reached. The author and publishers alike are to be most warmly congratulated on the get up and appearance of the volume. It is printed throughout on the very best quality of paper, it is profusely illustrated with colour plates which are admirably reproduced, whilst the numerous photographs and micro-photographs are excellent. The style of the book indeed far exceeds anything which could have been published in India, and the medical profession in India may well take pride in the publication of such a book, written by an Indian medical research worker of long experience,

and published in so admirable a fashion by British publishers.

The book is largely a translation from the author's chapter on kala-azar in Mense's *Handbuch der Tropen Krankheiten*, Vol. IV (1926), but the original chapter has been considerably enlarged and much new matter incorporated.

The first chapter deals with the history, geographical distribution and epidemiology of kala-azar, and is illustrated by a good series of maps very well executed. The aetiology of the disease and the morphology of *Leishmania donovani* are next considered in detail. The author has quoted the early description of the parasite by Leishman (1904), but at that period the true systematic position of *Leishmania donovani* had not been recognised, and Leishman's description is not entirely an accurate one. By way of correcting this, the author has quoted extensively from the description of *Leishmania donovani* given by Christophers, Shortt and Barraud (1926), an account which has always appeared to the reviewer at least to be unnecessarily complicated. Both accounts, however, are historical ones and are perhaps rightly included in a treatise.

After a chapter dealing with inoculation experiments in animals, the author next passes to the difficult subject of the transmission of the disease, and here we have an admirable summary of the many years of work carried out by a host of different workers, and of all the conflicting views which have been put forward. The recent work on the sandfly *P. argentipes* is very well summarised, though we are nowhere informed what view the author himself takes on the transmission problem. He quotes, without comment, Shortt's final summing up against the view that *Leishmania donovani* is a natural insect herpetomonad.

Chapters 9, 10, 11 and 12 deal with the symptomatology, complications, diagnosis and differential diagnosis of the disease. In the reviewer's opinion this is undoubtedly the most admirable section of this fine book. It is written by a clinician with a life-long experience of kala-azar; the photographs and temperature charts are excellent, the tables for differential diagnosis useful. Throughout, adult kala-azar is differentiated and described separately from infantile kala-azar. In Chapter 13, the pathology of the kala-azar is very fully dealt with, illustrated by coloured plates and original micro-photographs.

The reader will naturally turn to the chapter on treatment with much interest, since the author is the discoverer of urea-stibamine, and he will not be disappointed. The full history of the discovery of the drug, and of the consecutive papers published on it is given. A summary is also given of the author's work on the relationship between the chemical constitution of the antimony compounds and their therapeutic properties, and of papers read at the Seventh Congress of the Far Eastern Association of Tropical Medicine held in Calcutta in December, 1927. Every different method of treatment is described, including even the oral administration of antimony in Castellani's mixture, and the author's special technique for the intravenous injection of metallic antimony. There is no doubt that Dr. Brahmachari's discovery of urea-stibamine is the most outstanding contribution which he has made to the progress of tropical medicine, and his own account of his discovery is of great interest. We think, however, that the author might have given more credit to Professor Schmitz for his many years of patient investigation into the pentavalent antimony compounds. Once the pentavalent arsenical compounds had been introduced for the treatment of trypanosomiasis, the testing of the possible pentavalent antimony compounds in the treatment of kala-azar was almost inevitable, and workers in Germany and Great Britain investigated the problem, as well as Dr. Brahmachari in India. The first compound produced and tested (in 1916) was stibenyl; this gave good results in Europe, but poor results in India. In 1921, Dr. Brahmachari discovered that urea could combine with stibanilic acid, and this resulted in the production of urea-stibamine. Whilst the urea-stibamine

treatment is undoubtedly in universal use to-day, and whilst it has saved thousands of lives in Assam and Bengal, the testing of other compounds should be proceeded with.

Chapter 16, which gives an account of "dermal leishmanoid," is again original and profusely illustrated with coloured plates and micro-photographs, though the patient depicted in Plate IX appears to have become more jaundiced since his portrait first appeared in this journal in 1922. In the section on prophylaxis a useful abstract is given from the official instructions in Assam for the treatment of cases.

In the appendix, laboratory methods are given in full detail. Plate XII, of the normal and abnormal cells of the blood, taken from Knowles' and Senior-White's *Malaria, its Investigation and Control*, has been very much better reproduced from the original drawing in this book than in the former work. The addendum gives an account of recent work in China, a further account of the histo-pathology of the disease as experimentally induced in hamsters, and draws attention to the recent, thick film methods of Shortt and of Brahmachari and Sen.

The bibliography contains some 2,000 references, and will prove invaluable to workers on kala-azar; it includes all the papers by workers on Indian and Mediterranean kala-azar. Though it has clearly been put together with great care, it is not quite free from mistakes; thus of the seven papers by B. M. Das Gupta cited, four are incorrectly referred to A. S. Das Gupta.

We must warmly congratulate Dr. Brahmachari on the publication of this volume, whilst India may take a legitimate pride in so fine a work by an Indian worker.

ANNALS OF THE PICKETT-THOMSON RESEARCH LABORATORY. VOL. III. RESEARCHES ON THE STREPTOCOCCI.—Edited by David Thomson, O.B.E., M.B., Ch.B., D.P.H. London: Baillière, Tindall and Cox, 1927. Pp. 301, with 57 plates and 5 coloured plates. Price, 42s. net.

THIS third volume of the Annals of the Pickett-Thomson Research Laboratory is a monograph on the streptococci, or rather it is the first half of a two volume monograph on this subject. The main part of the volume—and to the general medical bacteriologist by far the most valuable—is contributed by Drs. David and Robert Thomson, the Honorary Director and Pathologist, respectively, of the laboratory. They have attempted, as they claim, to compile a reference work of value to the research worker and to present to him a more or less organised mass of information on the work which has been done on the subject up to the present time, and they have certainly succeeded. In two hundred and fifty pages they give a brief résumé of all the important work that has been done on the subject, to which they add their own personal experience and their own opinions wherever views of different workers are divergent; these pages together with the excellent bibliography of more than one thousand references justify its position in the library of any well equipped bacteriological laboratory, and make it a *sine qua non* to the research worker who proposes to tackle this very difficult subject.

There is a chapter on the differentiation and classification of non-hæmolytic streptococci by the use of Crow's medium, written by Dr. H. Warren Crow himself. He points out that the technique of the preparation of the medium is a point of great importance; it seems a pity where accuracy is so essential that a few lines later he refers to peptone or trypsin agar of the "usual reaction." The reviewer feels compelled to admit that he had considerable difficulty in following Crow's method of classification. One sees its value as of a rapid method by which the non-hæmolytic streptococci can be put into certain big groups, but one cannot help feeling that the average bacteriologist's sense of shape and colour are not sufficiently well developed to make this a method of universal adoption.

With its large clear type and the beautiful illustrations the book compares very favourably with many of the valuable limited editions of the private presses.

L. E. N.

DEMONSTRATIONS OF PHYSICAL SIGNS IN CLINICAL SURGERY.—By Hamilton Balloy, F.R.C.S. (Eng.). Bristol: John Wright and Sons, Ltd., 1927. Pp. 217, with 261 illustrations, some in colour. Price, 21s. net.

HOWEVER much laboratory and other auxiliary methods of diagnosis may advance, the history and physical methods of examination must always remain the main roads to a diagnosis. Students are apt to forget this fact until it is brought sharply to their notice by an examiner, who is not content with a written report on a case but insists on watching how the candidate sets about the examination of a patient. A very few minutes will enable the experienced to decide whether a candidate knows his clinical work or not. This book, which is on much the same lines as Legars' more ambitious work, is an epitome of a course of demonstrations on physical signs delivered to students, and it should not only be helpful to them but to junior teachers also. Some general physical signs such as fluctuation, translucency, crepitus, pulsation are first dealt with, after which the regions of the body are systematically surveyed and the methods of examination detailed with brief references to special signs of which quite an amazing number are given, many of them little known. If the information is somewhat disjointed in its arrangement, it is nevertheless very sound and its value is much enhanced by the numerous excellent illustrations of methods of examination, some of the coloured plates indeed are quite works of art. The book is one which we can recommend both to students and teachers, since it collects in one handy volume much that is scattered and difficult to find in large textbooks. We hope that in a future edition which is sure to be needed the author will delete the passage quoted from Shakespeare on page 153; it is not mnemonic and the meanings read into it are in questionable taste.

W. L. H.

GREEN'S MANUAL OF PATHOLOGY AND MORBID ANATOMY, FOURTEENTH EDITION, 1928. REVISED AND ENLARGED.—By A. Piney, M.D., M.R.C.P. London: Baillière, Tindall and Cox. Pp. viii plus 650, with 8 plates and 261 figures. Price, 21s. net.

THIS is a new edition of a very well-known manual of pathology which needs no introduction. The revising author has done a great deal of re-writing, and many additions have been made, as in the sections dealing with shock, protein intoxication, inflammation, parasites, and nephritis. The section on parasites has been considerably improved and constitutes a useful feature of the book for students in medical schools in India. It is noted that no mention is made of the work on the transmission of *Leishmania* infections by sandflies, and that the terms *Tetramitus* and *Lambdia* are retained for *Chilomastix* and *Giardia*. This work, on account of its excellent arrangement, completeness and low price, can be highly recommended as a textbook for students, and as a work of reference for practitioners.

PRACTICAL BIRTH CONTROL.—By E. A. Hornbrook, with Preface by Sir W. Arbuthnot Lane. London: William Heinemann (Medical Books), Ltd., 1927. Pp. 53. Price, 3s. 6d. net.

THIS small book sets out to improve the health, happiness, morality and well-being of the community, and the author, starting with the promise that marriage is the ultimate goal of all, endeavours to show how intelligent contraception, as apart from sexual abstinence, can achieve happiness and diminish vice and misery.

The book commences with anatomical considerations and then goes on to the various methods which are employed at present. The author is an optimist, and just as the surgeon forgets or does not hear of his

failures; so it is to be presumed the author does not hear, as does the gynæcologist of the multiple failures of any particular "control" panacea, for such except the operative one, Nature will never divulge. The problem is one of the most difficult ones one has to meet in the tropics, for we must admit that yearly conceptions in this country among pure Europeans is not a thing to be advised, for in our experience the child or the mother is apt to suffer as a result of often repeated pregnancies. Apart from financial worries it is probable that three children spread over seven years is the ideal for the European mother in the plains of India, and if by the use of any of the means that are mentioned this ideal can be reached, in our opinion after these births it is kindest and best to advise an operation by which the tubes are tied once and for all, for we are in agreement with the author that such means do very materially conduce to greater marital happiness provided the full pros and cons in every aspect have been considered by the parties concerned. The reviewer has never seen any had results from tying of the tubes, but it is only fair to state that others including psycho-analysts have recorded cases of a peculiar mental negativity owing to an idea creeping into the mind of the woman that she is incomplete or a neuter. Therefore it is all-important that the surgeon or general practitioner should explain that nothing is removed and that she is in all respects the same except for the two threads occluding the tubes. In connection with this matter of tying the Fallopian tubes, may it be permitted to the reviewer to state that there is no need whatever to open the abdomen provided the appendix is not to be removed at the same time. Scores of times during the last ten years he has purposely tied the tubes via the vaginal route, a very easy operation to the expert, practically painless, and only demanding a stay in bed of a few days. Given the above provisos of mutual consent after the birth of three children, the reviewer is of the opinion that such an operation makes for greater love and happiness in the family of those who are perforce residents in the East during the best and most passionate days of their lives.

V. B. G.-A.

ADVICE TO THE EXPECTANT MOTHER ON THE CARE OF HER HEALTH.—By Professor F. J. Browne, M.D., D.Sc., F.R.C.S.E. Second Edition. Edinburgh: E. & S. Livingstone, 1928. Pp. 48. Price, 6d. net.

THE author is so well-known that at first one wonders at his writing a popular six-penny booklet on a subject that has been stressed so greatly in recent years; but when one reads the foreword one sees the motif and is repaid. Antenatal care began in 1902 when in response to a popular appeal, Dr. John W. Ballantyne was able to announce that an anonymous donor had endowed a bed for the care of an expectant mother in Edinburgh. This was the first bed in the world to be set apart for this purpose and from that small beginning, inspired by the genius and forethought of Dr. Ballantyne, has sprung the antenatal care movement of every civilised country in the world, for they all have grasped what that meant in the prevention of disease or disaster in the parturient woman. It is not because there is anything new in this cheap little book that the reviewer praises it, but because of that one sentence in the preface—"Antenatal work has spread until it is probably correct to say that there is no civilised country in the world to-day in which the routine care and examination of expectant mothers does not form an important part of obstetric practice." What can India answer to that? What have the popular press and the politicians of the people done for this? Surely the voices of the women and children can be heard in the land: surely the days of *kismet* and *dharma* and *khurma* have passed; surely this little book or its like could reach into every village and town of India. The vernacular press have done nothing to promote *en masse* the physical welfare of the people; can they not make a beginning and aid the village doctor, who has the knowledge but is not permitted to put it into practice because such things savour

of nonsense in the minds of the old ladies who run the *sage femme* panchayets? Can they not see or grasp what has resulted from that one bed founded in 1902 in Edinburgh—a grain of mustard seed that has spread over the whole civilised world—except India. Will the editors and politicians remain silent to the tears and sorrow and suffering agony of millions who have countless doctors at their doors ready to give skill and attention when once the prejudice to their attendance and care is removed by intelligent propaganda!

V. B. G.-A.

BIRTH INJURIES OF THE CENTRAL NERVOUS SYSTEM.—By F. R. Ford. London: Baillière, Tindall and Cox, 1927. Pp. xiii plus 164, with 56 figures in the text. Price, 18s. net.

THIS is one of the excellent monograph series emanating from the Johns Hopkins Hospital which turn topsy-turvy previous conceptions on the subject, for during recent years we have inclined to attribute all spastic diplegias to injuries received at birth. Dr. Ford states that there is convincing evidence that congenital diplegias are not due to cerebral hæmorrhage at birth, but are due to intrauterine pathological processes. He proves that all the diplegias and spastic paraplegias are the result of faults in cerebral development and that it is only about six per cent. of all the infantile paraplegias that can be attributed to bad obstetrics and that all obstetric palsies are monoplegic or asymmetrical pareses, e.g., Lord Byron or the ex-Kaiser William II.

In this monograph there is a very interesting section written by Crothers and Putnam on birth injuries of the spinal cord, and the conclusions of these authors confirm the experience of the reviewer that all such injuries are the result of traction and not in any way due to intrauterine pathological errors. The reviewer has done scores of immediate post-mortems on infants dying shortly after birth in whom there was palsy of one or other extremity, and in every case there was hæmorrhage into the cord or theca or severe naked-eye laceration of the nerves at the site of their emergence from the spinal vertebræ; for the spinal cord, its membranes and its nerves, are the most fragile and least elastic structures imaginable. Therefore it behoves all teachers of obstetrics that traction with undue force, particularly in breech cases or the birth of the shoulders, is a thing which they should warn all students and nurses against, for we now know that such paralyses are permanent stigmata of ignorance or carelessness on the part of the medical attendant.

V. B. G.-A.

THE PRINCIPLES OF INFANT NUTRITION AND THEIR APPLICATION.—By K. H. Tallerman, M.C., M.D. (Cantab.), M.R.C.P. (Lond.) and C. K. J. Hamilton, M.C., B.M. (Oxon.), M.R.C.P. (Lond.). London: William Heinemann (Medical Books), Ltd., 1928. Pp. 103. Price, 10s. net.

The Principles of Infant Nutrition and Their Practical Application is a very useful addition to the books recently published on the subject. The chapter on physiology and bacteriology is excellent with a clear and up-to-date account of the vitamins: the anti-rachitic element is called vitamin D and is a separate entity from fat-soluble A. Nutritional requirements are fully discussed and it is recommended that calculations should be made on a caloric basis instead of on so many ounces per lb. body-weight. From the practical point of view, one is pleased to see the equivalent of calories of milk given in ounces, as well as in cubic centimetres. The example on page 37, illustrating the method of calculating the caloric intake, is, unfortunately confusing and contradictory; four-hourly and three-hourly feeds are confused and consequently five feeds and seven feeds per day are mixed up. Breast-feeding is thoroughly described and it is pointed out that breast milk must not always be assumed to contain an adequate vitamin content. The care of the premature infant is well described in detail, both for the breast-fed and the artificially fed; for the

latter, skimmed lactic acid milk with carbohydrate added up to seven per cent. is recommended.

The thirty pages devoted to the artificial feeding of normal infants are clear, concise and up-to-date, and will repay the general practitioner's time spent in reading them. They contain an excellent account of the various modifications of cow's milk. The authors (as well as Paterson and Smith in their *Modern Methods of Feeding in Infancy and Childhood*) recommend dried milks as being, (a) cleaner than cow's milk, (b) more easily digested, (c) more constant in composition, (d) having a vitamine content that is very little affected and easily replaced. One hopes that in time the recent prejudice against dried milks will die down in Calcutta, as it has disappeared in London, and that the hospitals in Calcutta will not fear to recommend them any more than does Great Ormonde St. Hospital for sick children: cod-liver oil and fruit juice must, of course, be given. The nutritional disorders of infancy are discussed in Chapter VII. The terms "marasmus" and "wasting" are discarded in favour of "athrepsia" and "hypothrepsia." This chapter is very well written and the examples of dieting given are excellent. One noticed, however, that in the treatment of acute gastro-enteritis, gastric and rectal lavage are only very grudgingly mentioned, almost at the end: surely they deserve a more prominent place. The diet during the period of weaning is thoroughly discussed and precise directions are given.

The appendix, in which the methods of preparing various modifications of cow's milk and also the methods of preparing the feeds in later infancy, is excellent. There is a bibliography at the end of each chapter. The criticisms we have to make are so few and the work is otherwise so excellent that we can strongly recommend the book alike to the specialist and the general practitioner.

S. A. McS.

OUTLINES OF SCIENTIFIC ANATOMY FOR STUDENTS OF BIOLOGY AND MEDICINE.—By Dr. W. Lubosch. Translated from the German, by H. H. Woollard, M.D. London: John Bale, Sons and Danielsson, Ltd., 1928. Pp. 392, with 66 illustrations. Price, 21s. net.

THIS book does not purpose to teach human anatomy as such, and its use presupposes such knowledge and study of the facts of anatomy as would be obtained from good textbooks and practical work. In the introduction to the general part, while discussing the position of anatomy in the system of science, the author has rightly said that "Anatomy is to be looked on not only as the foundation but as the principal science of medicine." The general part deals with (i) life, its appreciation and objectivation; (ii) general morphology and aetiology. The special part deals with the special (i) morphology and (ii) morphogenesis of man; (iii) the morphology of the tissues, and (iv) cytomorphology and leptonomorphology. The author has made the conception of life quite clear, and has dealt with the objective features of all living things under three heads, viz., organisation, individuality, and suitability to purpose. The special morphology of man has been dealt under three heads, viz., (i) man as an individual, (ii) man as member of the race, and (iii) man as a member of a higher category. In the promorphology of man the segmental anatomy of man has been thoroughly dealt with, especially from a comparative standpoint. The divisions of the human body have been dealt under (a) trunk and tail, (b) head, (c) neck, (d) extremities, and (e) cavities of the human body. In the morphogenesis of man the general embryology of man has been described in detail. The chapter on morphology of the tissues contains a reasonable classification of the tissues. The last chapter on cytomorphology and leptonomorphology deals exhaustively with cells and the structure of protoplasm. The subject-matter has been dealt with in a masterly way and in minutest detail with special reference to comparative anatomy, and the reader will derive much useful knowledge from this book. We recommend this book to every student of both biology and anatomy.

CARE OF THE TEETH OR LAYMAN'S HANDBOOK OF DENTISTRY.—By Minoo C. Bilpodwala, M.B., B.S., Dental Surgeon, Bombay. Pp. 134, with 18 illustrations. Published by the author, Empiro Building, Hornby Road, Bombay, 1927. Price, Rs. 2.

THE care of the mouth and teeth is the one great duty that we owe to ourselves. At the present time public bodies in India are not aware of the duty they owe to those for whose welfare they are responsible in the shape of oral hygiene. This little book is meant for just those people in India. It has a great message to everybody in the realm of personal hygiene. With the passage of time and with our increasing knowledge of the relationship of oral sepsis to systemic diseases, the mouth hygiene movement is taking on greater importance. It is essentially necessary to teach the man in the street the salient points about oral cleanliness for his own sake, as well as for the sake of the community. Dr. Bilpodwala's book has not come a day too soon, and we hope it will deliver the message that it is intended to deliver to the lay people. The book deals with all the facts about mouth hygiene which everyone should know, and it should be an excellent book for teaching in the hygiene courses in our high schools. The book is printed on antique paper. The printing is not very good and there are several printing mistakes. We hope they will be corrected in subsequent editions.

R. A.

Annual Reports.

THE FIFTY-THIRD ANNUAL REPORT OF THE MISSION TO LEPERS IN INDIA, 1926-27.

THIS report records a year of steady progress. In Bengal, the chief event of the year was the opening in February 1927 of the Kisori Lal Jatia Homes at Bankura. These are intended for the special treatment of early cases of leprosy and comprise six two-roomed cottages with verandahs and outhouses, and accommodation for 36 patients; a doctor's house, dispensary, crafts school and bathing platforms. In declaring the new Homes open, Lord Lytton spoke of the cheerful and optimistic atmosphere of the Bankura Leper Hospital. At Purulia in Bihar there were 760 inmates, and this is the largest institution in India under the Mission. During the year the healthy girls' home and two new hospital wards were finished, and the old hospital converted into nurses' rooms, stores, and an operating theatre. The new healthy girls' home is a model institution, with the whole of the upper floor constituting one big airy dormitory well raised above any possibility of dampness during the rains. During 1927 fifteen patients were discharged symptom-free.

At Cuttack a much needed laboratory has been provided by the Local Government, whilst a further improvement is a hospital ward for female patients. At Champa in the Central Provinces four new wards are under construction; at Jahargaon new wards, a doctor's house, and dispensary are being added to the existing buildings; at Chandkuri improvements in the sanitation and water-supply are being carried out. At Naini, Allahabad, plans have been approved for considerable extensions—an additional female ward, extensions to the healthy girls' home; here there are 100 untainted boys and girls who are being educated and trained for useful careers in life; indeed this is one of the most important aspects of the work of the Mission. At Tarn Taran a new home for healthy boys was opened during the year, whilst it is noted that at all three hospitals in the Madras Presidency the accommodation is quite inadequate to meet the demands upon it.

With regard to treatment Dr. R. G. Cochran reports good results. The numbers discharged as symptom-free may not be large, but the number much improved is very

considerable, and many such patients will undoubtedly become free from infection in the course of time. Other patients are being closely watched before being finally discharged. Reports by visitors to the different hospitals of the Mission all tell the same tale; that the outlook in leprosy is now a hopeful one, and not the pessimistic affair that it used to be.

The total number of lepers resident in the different hospitals of the Mission in India during the year was 6,231, together with 815 untainted children. The total expenditure for the year was Rs. 8,38,297, of which Rs. 4,75,306 was contributed by the Mission to Lepers, Rs. 3,28,604 came from Government and Local grants, and Rs. 34,387 from contributions made direct to the Mission's institutions.

The report is one which records steady progress. A special feature of the report is the admirable series of photographs which it includes, showing the different aspects of the work, and the types of buildings.

ANNUAL REPORT ON THE ADMINISTRATION OF JAILS IN THE BENGAL PRESIDENCY, 1926. BY LIEUT.-COL. W. G. HAMILTON, I.M.S. CALCUTTA, BENGAL SECRETARIAT BOOK DEPOT. PRICE, RS. 4.

COLONEL HAMILTON'S reports, as Inspector-General of Prisons, Bengal, are always of special interest since they deal with the fundamental and most difficult problems of jail administration.

The principal items of interest during the year were: (i) the opening of the Reformatory School at Alipore; (ii) the bringing into force of certain sections of the Bengal Children's Act; (iii) the transfer of the quinine tablet industry from the Jail Department to the Cinchona Factory at Mungpoo; and (iv) the starting of a silk industry in the Women's Jail, Calcutta. From July 1926, the Juvenile Jail at Alipore has been run in two sections, one a juvenile jail, as previously; the other a reformatory school under a committee of management, with a Superintendent with technical knowledge in charge of both sections. The juvenile jail section, however, will shortly be closed down, whilst the reformatory school will be transferred to the Education Department, certain sections of the central jails and the jail at Bankura being set aside for young offenders over 16 years of age. Whilst the Children's Act at present only applies to Calcutta, and young children still continue to be sent to jails in the mofussil, it is hoped that the Act will soon be extended to all-Bengal; the only question is one of accommodation. And in this connection Colonel Hamilton gives an account of how juvenile offenders are now tried in London—the result of a personal visit of inspection. The stipendiary magistrate is assisted by two honorary justices, one of whom must be a woman; the courts are held in a public hall and not in the ordinary police court, and there is no dock; the general public are excluded, and a special female police probation officer carefully enquires into the home surroundings of each offender. The system of probation and of reformatory schools is very largely made use of. Everything possible is done to help the juvenile offender and to prevent him becoming a criminal.

Female prisoners constitute a special difficulty. Their total number is very small, and they are mostly very ignorant and slow at learning any new work. At the Presidency Jail a beginning has been made of teaching them silk-spinning, also weaving and stocking-making. A special note of praise is paid to the lady visitors to this jail, who have been regular in their visits and have made several helpful suggestions and have taken great interest in the welfare of the women prisoners.

Simple imprisonment Colonel Hamilton unqualifiedly condemns as a sentence; there can be nothing more demoralising than for a man to be committed to jail for six months or a year to idle away his time and do nothing. The majority of these prisoners so condemned are illiterate, and have not even the resource of reading. Imprisonment without labour is also against all modern ideas of penal reforms.

The State prisoners and detenus continued to be a cause of great anxiety, for separate and special arrangements have to be made in each jail where this class of prisoner is confined, which were never contemplated when the jails were built. A special committee was appointed during the year to report on discipline and conditions generally in the Bengal jails. Funds were voted to start a Borstal institution in Bengal, and this will be started in the Bankura District Jail, and will admit prisoners of from 16 to 21 years of age. The great success attained by the Borstal system in England is due to the Borstal Association which provides work and help for released Borstal lads, and unless some similar association comes into being in Bengal, the Borstal system is not likely to prove a success.

The problem of the short term prisoner remains unsolved; no less than 2,117 prisoners were committed during the year with sentences of less than one month. In England the alternative of probation and time given for the payment of fines has so greatly lessened the number of prisoners committed for petty offences that no less than 27 local prisons have been closed in England and Wales since 1900. The probation system could well be introduced in Calcutta, but everything depends on getting the right type of probation officer.

Advisory boards for the premature release of prisoners were held at five central jails during the year and recommended that 86 out of 176 prisoners examined should be prematurely released, of whom Government eventually released 77 before their time was up.

Turning to the various statistical statements in the report, there was a definite but slight increase in the number of prisoners under confinement in the Province throughout the year, the daily average being 10,341 as against 10,193 for the previous year. Illiterates constituted 87 per cent. of prisoners admitted. There was a great increase in the number of juvenile prisoners under 16 years of age sent to jail during the year, and Government has again drawn the attention of magistrates to this evil. No corporal punishment for indiscipline was inflicted during the year. Some 36 per cent. of prisoners admitted were habituals or those who had served a previous sentence. Under-trial prisoners were kept on an average for 19 days in non-sessions cases and for an average period of 48 days in sessions cases. There were 12 State prisoners and 53 detenus under incarceration during the year; and they received special treatment under the rules. Head warders and warders are still discontented and have submitted a memorial to Government for the fourth time. Certain improvements were introduced during the year; rewards were given to warders for proficiency in musketry practice, and grants of free railway passes to those proceeding home or returning from leave on the same conditions as apply to police constables. There were 15 escapes among convicts—of whom 11 were recaptured; and 21 escapes among under-trial prisoners. Many convict officers were released under the recommendations of the Advisory Board; this led to a shortage of convict overseers, and prisoners who were not eligible for these appointments had to be utilised in spite of the rules. The total abolition of the convict overseer system is desirable, but cannot at present be effected on grounds of economy. The cost of the entire department during the year was Rs. 23,82,569—a definite decrease on the figure for the previous year.

Turning to the different industries in the jails concerned, the jute mill in the Presidency Jail was closed in November 1926. The Bengal jails and other Bengal institutions receive their supply of metal and wood articles largely from this jail. Mustard oil is also manufactured, and there is an active durrie industry. The Printing Press was transferred to this jail from the Juvenile Jail during the year. The manufacture of quinine tablets from quinine supplied from the Mungpoo Factory was closed down during the year. At Alipore Central Jail the principal industry is the printing of official government forms. At Midnapore Jail the manufacture of police and prison and chaulkidari uniforms is the chief industry, with cane and bamboo work, mat

work and coir industry. The same applies to Rajshahi Central Jail, and also Dacca.

Morbidity and mortality are at minimal figures for the year. The daily average sick were 31.4 per mille, and the death-rate only 13.4 per mille—a figure well below the average for the civil population. Very high in the list of mortality comes pulmonary tuberculosis, responsible for 25 out of 185 deaths, secondly pneumonia with 17 deaths, and third dysentery—always a specially important feature in jails—with 14 deaths. Malaria comes next with 10 deaths, and diarrhoea—(frequently due to infection with the dysentery bacillus of Flexner)—next with no less than 9 deaths. Dysentery and diarrhoea incidence has however shown a very marked falling off in the mortality statistics in the Bengal jails during recent years. Pulmonary tuberculosis is usually present among the patients before their admission to jail. The total earnings of the Jail Department during the year were Rs. 6,03,300. Dacca Central Jail is singled out in the covering Government resolution for its now flourishing industry in the manufacture of woollen blankets.

ANNUAL VACCINATION REPORT, BIHAR AND ORISSA, 1926-1927. BY LIEUT.-COL. J. A. S. PHILLIPS, D.P.H., I.M.S. PATNA, SUPDT., GOVT. PRINTING, B. & O. PRICE, RE. 0-14-0.

THIS report follows much on the usual lines. Lieut.-Col. W. C. Ross, I.M.S., held charge until April 1926, and Lieut.-Col. J. A. S. Phillips for the rest of the year. Capt. S. L. Mitra, I.M.S., was in charge of the South Bihar Circle, Dr. J. L. Das of the North Bihar Circle, and Dr. T. Sebastian of the Chota Nagpur and Orissa Circle and of the Vaccine Depot at Namkum. The inspecting staff consisted of 20 district inspectors, 69 sub-inspectors, whilst 1,111 licensed and 278 paid vaccinators were employed during the year.

The total number of vaccinations during the year was 1,351,084, and represented a definite increase on the previous year. This was largely due to the widespread epidemic of small-pox in the Province during the year, and Col. Phillips notes that the opposition of parents shows no signs of diminishing. Of these vaccinations 1,130,934 were primary vaccinations, and 201,378 re-vaccinations. The success rates were 97.64 per cent. for primary vaccinations, and 48.80 per cent. for re-vaccinations. Most of the individual districts reported a definite increase of vaccination, but there was a marked decrease in Puri and Singhbhum.

A special feature of the report is that in the Orissa Feudatory States where vaccination and re-vaccination are practically compulsory in the majority of the States, results are eminently satisfactory and the population well protected; on the other hand in non-compulsory areas and especially towns some 50 per cent. of the children may not be protected. More than half the total operations are carried out on children over one year of age; in fact it is increasingly clear that Indian parents have the greatest objection to the vaccination of infants of less than one year of age, but much less objection to the vaccination of infants over that age.

Small-pox is endemic in the Province and will continue to be so until and unless vaccination and re-vaccination are made compulsory. During the last ten years the incidence of small-pox in the Province has steadily increased, and the year saw the culmination of one of the regular five to six years increases in epidemicity. The provincial mortality from small-pox during the five years ending with the present report, per mille, was respectively 0.07, 0.11, 0.24, 0.67 and 1.05, and the last figure suggests that the epidemic peak had about been reached.

In a few trenchant sentences Colonel Phillips discusses the difficult question of compulsory vaccination and re-vaccination. Nothing less will control epidemic small-pox in India. Free and compulsory vaccination and re-vaccination, he considers, alone will protect the population; nothing less is any use. On the other hand, "democratic" India—following the lead of Great

Britain—is gradually becoming less and less protected against small-pox.

The supply of lymph for the Province came from the Namkum Depot throughout the year. A very large reserve is always held in hand against sudden epidemic outbreaks; the average cost of the lymph works out at 1.14 pies per dose, and the average cost per successful vaccination at 2 annas 1 pie. The net profit made at the Namkum Depot during the year was Rs. 3,454, chiefly derived from the sale of vaccine lymph to Bengal. The Depot worked very satisfactorily during the year, and with the recent duplication of the cold storage plant the troubles of previous years have disappeared. Research work was carried on with regard to maintaining a low temperature in the bamboo reeds in which the vaccine lymph tubes are supplied during the hot weather, and on methods of destroying extraneous germs in the vaccine without affecting its potency.

A report which, on the whole, is typical of present-day conditions in India. As has often been remarked "fear is the greatest single stimulus towards hygienic reform." A thorough-going small-pox epidemic throughout India might go far towards deleting the non-co-operators, and encouraging the introduction of compulsory and necessary legislation with regard to vaccination.

REPORT ON MEDICAL AND HEALTH WORK DONE IN THE SUDAN FOR THE YEAR 1926.

THIS report covers a large and interesting field of work. The population and the conditions of life vary from the most primitive to the modern. The province of Khartoum has a special health staff; the Sudan in general is under the Sudan Medical Staff Service, while the Principal Medical Officer of the Sudan Defence Force submits a special report on sleeping-sickness.

In Khartoum, dysenteries and typhoid fever appear to be the main causes of morbidity; malaria is comparatively low, while sandfly fever was common. Omdurman on the other side of the river has been improved by being provided with a pure water supply and electric light. The water supply is taken from the Nile and purified by a Paterson Filter and chlorination.

The British Sanitary Inspector is the mainstay of the sanitary administration, and the staff is doing excellent sanitary work. The death-rate was 14.45 and the birth-rate 25 per 1,000. In the Sudan province one is struck by the number of diseases present, relapsing fever, typhoid, influenza, measles, whooping cough, rabies, malaria, syphilis, bilharziasis, yaws, kala-azar, tuberculosis, dysentery, leprosy, goitre, endemic hydrocele, ankylostomiasis, trachoma and Malta fever and sleeping-sickness are all present in a more or less high degree—and the report has something interesting to say about each.

Malaria is the most serious of the endemic diseases. In the North it is connected with irrigation gardens, in the South during the rains, it is endemic all over. Bilharziasis is dealt with by prohibiting bilharzial infected people entering into snail-infested areas (unless such cases undergo treatment at a quarantine centre), by using copper sulphate for killing snails in the fresh water canals, and the prevention of contamination of water channels with excreta. There are some interesting problems—the lakes are dry from the end of March until the rains—yet they are constantly infected with bilharzial snails despite the fact that snails die after 24 hours drying and the dry beds of the lakes show no snails. Yaws is a serious problem in many parts. Kala-azar is endemic in the Blue Nile valley.

Most of the dysentery is recorded as "amœbic." The bacillary type is more commonly of the "Flexner" variety. Endemic hydrocele is an affection common in the Abyssinian border. Here 20 to 25 per cent. of the male population are affected; it is probably filarial in origin.

The report on sleeping-sickness is of special interest. Since 1911 the Sudan has had two epidemics of this disease. One epidemic has come and gone—the second

is declining. The population are a primitive people living in isolated families—the result of old Arab slave raids. They are now being taught communal life and the result of this is a rapid fall in sleeping-sickness incidence. This measure has also allowed cleared fly-free watering places to be established. Bi-monthly inspections of the whole district affected are carried out and measures adopted in infected places. £17,000 is being spent annually in the Sudan on measures against sleeping-sickness. Measures are successful in the Sudan, but the surrounding infected areas are not doing the same—the Uganda, Belgian Congo and the French Congo are infected and remain a danger to the Sudan. It is up to these other areas to adopt similar measures. This report is of great interest and records a great amount of general and special work carried out by the service and public health staff of the province.

A. D. S.

THE SCHOOL OF SANITATION AND PUBLIC HEALTH OF THE UNIVERSITY OF THE PHILIPPINES, 1927-28.

It is now recognised that for the furthering of an enlightened health policy in any country, the most important single factor is a competent health officer. Opportunities for the training of such a health staff until lately were wanting in the Philippine Islands, but the University of the Philippines has lately established an up-to-date training school for health officers where medical men already in or intending to join the State Health Service can receive an adequate training to fit them for their work. The formation of the school is due to the activities of Dr. Calderon, the Director of the School, who was able to convince the authorities of the necessity for such an institution. The school is staffed by the present personnel in the staffs of the College of Medicine, University of the Philippines, the Health Service, the International Health Division of the Rockefeller Foundation, the United Service and the Medical Corps of the U. S. Army. It is housed temporarily in the College of Medicine. The library of the Bureau of Science is available.

The number of students is limited to 15. The syllabus of instruction is very complete and lasts for 9 months; the course being divided into three periods of three months each. After the completion of the course, students proceed to an examination for the Certificate of Public Health.

We wish the University of the Philippines every success, and congratulate them in their forward step in public health education.

A. D. S.

ANNUAL REPORT, CIVIL HOSPITALS AND DISPENSARIES IN THE MADRAS PRESIDENCY FOR THE YEAR 1926. BY MAJOR-GENERAL F. H. G. HUTCHINSON, C.I.E., K.H.S., I.M.S. MADRAS. SUPDT., GOVT. PRESS. PRICE, RS. 2-6.

DURING the year under review the total number of medical institutions in the Presidency increased from 959 to 1,006, and it is of interest to study the distribution of these. Of the total, 63 were Government institutions, 22 were State-aided, 773 were municipal, local fund or rural, 29 private aided, 67 private non-aided, and 52 railway dispensaries.

The total number of in-patients treated rose from 149,988 in the previous year to 159,043 in 1926, whilst the death-rate among them fell from 5.23 to 5.06. In the out-patient departments of the various institutions a total of no less than 10,059,359 patients were treated. (Government is often taken to task for neglecting the extension of medical relief in rural areas; but figures on so colossal a scale show how enormous has been the extension of facilities for medical aid in India during recent decades.) Prominent in the list of the chief diseases responsible come malaria, respiratory diseases,

dysentery and syphilis. Some idea of how prevalent venereal diseases are in India may be gained from the fact that 49,233 out-patients attended for treatment of gonorrhoea, and 76,674 for treatment of syphilis. Pulmonary tuberculosis is represented by an out-patient attendance of 21,695. An infection which ranks very high is that with *Ascaris lumbricoides*, for which 263,765 persons were treated. The figures for malignant growths are 1,298 in-patients and 6,044 out-patients. The relative attendance of different castes at hospital is of interest; taking the census figures the attendance of Hindus was 208 per mille, of Mahomedans 433, and of Anglo-Indians and Europeans 413.

Surgical operations totalled 453,346, of which 29,419 are returned as "major operations" with 842 deaths—case-mortality 2.86 per cent. The total income of institutions of Classes I, III and IV during the year was Rs. 58,92,977, out of which the Government contribution amounted to Rs. 34,00,666. The cost of salaries came to Rs. 31,46,167 as against a figure of Rs. 8,45,294 for medicines and Rs. 8,57,072 for diets.

During the year the hookworm survey was completed in the Tamil, Malayalam and Kanarese districts. Egg-counts indicate that by far the heaviest infections are encountered on the West Coast, especially in the Malabar district. The number of persons treated for this infection was 76,587, whilst 978 lantern lectures or cinema demonstrations were given by way of propaganda.

Turning to the question of medical relief in rural areas, up to the end of 1926 Government had sanctioned the opening of 297 rural dispensaries, of which number 225 were open and running during the year. The scheme aims at encouraging private practitioners to settle in rural areas, with the help of a small State subsidy; and it is reported that "the scheme is of enormous potential value to the population of Madras, and has worked satisfactorily on the whole. The unevenness in working the scheme has been very largely a question of the personalities of the medical officers."

Side by side with this scheme has gone a retrenchment in the cadre of Government sub-assistant surgeons; and district boards are now permitted to appoint their own medical officers to local fund institutions other than those at taluk headquarters up to a maximum of one-fourth of the number of sub-assistant surgeons' posts at present held by Government medical officers in the district. The duly approved scheme for training country *dais* has so far been introduced by only 19 local bodies, and only 44 such *dais* were trained during the year. The scheme is at present in its infancy, and it is too soon to pronounce an opinion as regards its success.

Correspondence.

HELMINTHIC FEVER.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—In his interesting article on "Difficulties in the Diagnosis of Fevers in the Tropics" in the *Indian Medical Gazette* for April, Major J. C. De does not emphasise the frequency of "helminthic" fever.

I give herewith three charts of different types, all apparently due to *Ascaris* infection.

I saw the first case in 1911, since when many cases have come to my notice of fever seemingly due entirely to the presence of some form of intestinal parasite. Such cases are readily cured by an anthelmintic, administered if its exhibition is not obviously contra-indicated.

All these cases were young Mahomedan males.

Case 1 came under my care on the 15th day of his illness.

No malarial parasites were found in his blood.

The tongue was very dirty; spleen not enlarged; no rash.

The action of the bowels was irregular and the pulse relatively slow. He had been classified as a probable

"enteric," but the Widal test on the 16th day was negative. Two days later he passed two ascarides and the following day one. On the 20th day treatment with santonin was begun, but he passed no more worms and thereafter had no further symptoms.

Case 2 gave a history of constipation, fever, and "pains all over." On the evening of his admission to hospital he had headache, burning sensation in the eyes and nose and also on passing urine.

A second course of santonin was given and his symptoms ceased.

No more ascarides were found, but I think it probable that some were passed unobserved.

Case 3 complained of headache, constipation and pain in the small of the back.

There had been a rash (? urticaria) on the abdomen and chest.

The spleen was palpable.

Later there was itching of the skin of the body and he was restless and sleepless.

Blood examination was repeatedly negative for malaria and also for relapsing fever parasites.

On the 16th day of his illness he was given santonin treatment and on the 18th day he passed an Ascaris.

Recurrences of sharp rise of temperature occurred, but blood tests remained negative.

No malaria parasites were found in the blood. While under observation the bowels were irregular in action.

The pulse as in Case 1 was relatively slow.

No facilities existed for a Widal test but the patient was treated as a possible atypical enteric.

On the 16th day of his illness he passed four roundworms, which apparently solved the problem of diagnosis and cure as he had no further symptoms.

No anthelmintic treatment was given in this case.—
Yours, etc.,

L. H. MACKENZIE,
MAJOR, I.M.S.

ABBOTTABAD,
2nd May, 1928.

A CASE OF MULTIPLE ARTHRITIS FOLLOWING SMALL-POX.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—In the correspondence columns of your issues for May 1927 and January 1928, I find physicians reporting on arthritis as a sequel of small-pox. From my own personal experience of a case now on my hands, I can safely state that multiple arthritis is not an uncommon complication—or rather sequel—of small-pox, especially where sepsis has occurred in the course of the disease. In this particular case encountered in my private practice, the father of the patient (a girl of seven years of age) consulted me because his daughter was suffering from stiffness and swelling of both the knees and elbow joints. The history given was that the patient had had an attack of small-pox a month previously, from which she recovered in about a fortnight, when gradually as a sequel the joints began to swell, movements became painful, and suppuration was present in some. On close examination of the patient I found about the joints the marks of punctures which had been made to evacuate pus. The ends of the long bones were found to be hypertrophied, and ankylosis had already set in in all four joints.

At the time when I was consulted suppuration appeared to have ceased in all the joints, and ankylosis was setting in, the appearance of the affected limbs being typical of that condition.

Unfortunately a photograph of the patient could not be taken for want of facilities in this rural district, otherwise I would have enclosed one.—Yours, etc.,

BRAJALAL GANGOPADHYAY, L.M.F.,
Medical Officer.

CHOIBARI TEA ESTATE,
P. O. BASUGAON, ASSAM.

Service Notes.

APPOINTMENTS AND TRANSFERS.

Lieutenant-Colonel G. D. Franklin, O.B.E., I.M.S., an Agency Surgeon, is posted as Civil Surgeon, Ajmer, and Chief Medical Officer in Rajputana, with effect from the 23rd April, 1928.

Lieutenant-Colonel J. R. J. Tyrrell, I.M.S., an Agency Surgeon, is posted as Chief Medical Officer in Central India and Agency Surgeon, Indore, with effect from the 22nd April, 1928.

The services of Lieutenant-Colonel C. H. Reinhold, M.C., I.M.S., are placed at the disposal of the Chief Commissioner, Delhi, with effect from the 22nd April, 1928.

Lieutenant-Colonel W. L. Harnett, M.B., F.R.C.S., I.M.S., officiating Professor of Clinical and Operative Surgery, Medical College, Calcutta, is appointed to do the duties of Principal, Medical College, Calcutta, in addition to his own duties, with effect from the afternoon of the 12th April, 1928.

The services of Lieutenant-Colonel J. M. A. MacMillan, M.D., I.M.S., Civil Surgeon, Simla East, are replaced at the disposal of the Government of the Central Provinces, with effect from the 1st May, 1928.

Major R. L. Vance, I.M.S., is appointed to officiate as an Agency Surgeon and is posted as Chief Medical Officer, Western India States Agency and Residency Surgeon, Rajkot, with effect from the 3rd May, 1928, and until further orders.

Major H. Hingston, M.D., I.M.S., Surgeon to His Excellency the Governor of Bengal, is appointed to hold Medical Charge of the Civil Station of Darjeeling temporarily, in addition to his own duties, with effect from the afternoon of the 7th April, 1928, until further orders.

Major J. C. De, I.M.S., officiating Professor of Clinical Medicine, Medical College, Calcutta, is appointed temporarily to do the duties of Superintendent of the Medical College Hospitals, Calcutta, in addition to his own duties, with effect from the afternoon of the 11th April, 1928.

The services of Major G. B. Hanna, I.M.S., are placed permanently at the disposal of the Government of Bengal, with effect from the 24th October, 1927, for employment in the Jail Department.

Major W. E. R. Dimond, I.M.S., officiating Assistant Director of Public Health, North-West Frontier Province, is confirmed.

Major H. K. Rowntree, M.C., M.B., B.S., I.M.S., is appointed to be Civil Surgeon, Simla East, with effect from the date on which he assumes charge of his duties.

On reversion from foreign service under the Governing Body of the School of Tropical Medicine and Hygiene, Calcutta, Captain G. C. Maitra, I.M.S., of the Medical Research Department, is appointed to officiate as Assistant Director at the Central Research Institute, Kasauli, with effect from the date on which he assumes charge of his duties.

LEAVE.

In modification of previous orders, Major-General G. Tate, M.B., K.H.S., I.M.S., Surgeon-General with the Government of Bengal, is granted leave on average pay

for 5 months and 22 days, with effect from the 26th April, 1928, with permission to affix the Puja Holidays to the leave.

Lieutenant-Colonel D. Heron, I.M.S., an Agency Surgeon, is granted leave on average pay for 6 months and 5 days combined with leave on half average pay for 21 months and 25 days, with effect from the 3rd April, 1928.

Lieutenant-Colonel R. McCarrison, C.I.E., M.D., F.R.C.P., I.M.S., an officer of the Medical Research Department on foreign service under the Indian Research Fund Association, is granted leave on average pay for 8 months, with effect from the date on which he avails himself of the leave. His services are replaced at the disposal of the Director-General, Indian Medical Service, with effect from the date on which he proceeds on leave.

Lieutenant-Colonel J. W. Watson, C.I.E., I.M.S., an Agency Surgeon, is granted leave on average pay for 1 month and 16 days combined with leave on half average pay for 1 month and 14 days, with effect from the 23rd April, 1928.

Lieutenant-Colonel W. J. Simpson, I.M.S., an Agency Surgeon, is granted leave on average pay for 3 months and 15 days, with effect from the 27th April, 1928.

Lieutenant-Colonel W. R. Battye, D.S.O., I.M.S., an Agency Surgeon, is granted leave on average pay for 1 month and 4 days combined with leave on half average pay for 7 months and 25 days, with effect from the 22nd April, 1928.

In modification of previous orders, Captain L. K. Ledger, I.M.S., an officiating Agency Surgeon, is granted leave on average pay for 2 months combined with study leave for 7 months and 7 days and furlough under Military Rules for 2 months and 24 days, with effect from the 16th February, 1928.

PROMOTIONS.

Major to be Lieutenant-Colonel.

Major H. R. B. Gibson, M.D., I.M.S., whose retirement was notified in the London Gazette of 31st December, 1926, is granted the rank of Lieutenant-Colonel, 22nd December, 1926.

Captains to be Majors.

M. T. Khandwalla, M.B. Dated 11th March, 1928.

J. Rodger, M.C. Dated 18th March, 1928.

G. A. Khan, M.B. Dated 23rd March, 1928.

David Clyde. Dated 16th April, 1928.

Lieutenant to be Captain (Provisional).

T. A. Malone. Dated 2nd March, 1928.

RESIGNATIONS.

The undermentioned officer is permitted to resign his commission subject to His Majesty's approval.

Lieutenant J. H. Clapp. Dated 15th June, 1928.

NOTES.

PRIESTLEY, SEER OF AIR.

EVERY physician who administers oxygen, every dentist who gives a whiff of laughing gas, every layman who takes a sip of soda water in midsummer, owe something to Joseph Priestley, scientist and odd genius.

In 1774 he discovered oxygen, and 1928 A. D. marks the 154th anniversary of that epoch-making.

Priestley was most happy when he was in a fight. His temper was ever a fiery one. If it had not been, the world might have missed many things which he gave it. He tried to be a preacher, but his theology was so radical that he could not enter any formal church and started an independent congregation in Birmingham.

His views on politics and social matters were just as pronounced. He brought on himself the rage of his fellow citizens by his expression of his frank opinion

of them in a little book called "Familiar Letters on the Inhabitants of Birmingham," and followed that up with an attack on kings and their ways. He was leading all competitors for the unpopularity contest, when on July 14th, 1791, the anniversary of the French Revolution and the fall of the Bastille, he had a real housewarming party. A mob burned down his little church, and also his home, in which were his library, his apparatus, and the records of his researches.

Then he sailed for America, where he arrived after a stormy voyage of two months, and found peace for a time in Philadelphia. Priestley knew Benjamin Franklin whom he had met through their common interest in electricity, and through him came in close touch with the American Philosophical Society which "Old Ben" had founded. Through that learned organisation he communicated some of his most important discoveries.

Declining the presidency of the University of Pennsylvania, Priestley retired to the little town of Northumberland, Pa. It was in Northumberland that Priestley died and there he was buried in an old churchyard. A movement was recently started to move his house to the campus of the Pennsylvania State College.

It will be remembered that in 1776 Priestley discovered nitrous oxide, or laughing gas, which soon was used as a mild anæsthetic. He made hydrochloric acid and ammonia known to the world and told it, for the first time, what carburetted hydrogen was. To him also goes the credit for the discovery of carbon monoxide. His researches indicated that nitric acid is formed by the passing of electric sparks through the air, and thus he was the pioneer of "airmining," for he made possible the fixation of atmospheric nitrogen.

To this great leader in the realm of pneumatics, we owe the beginnings of many industries which depend upon the use of gases. His analyses of the air started the investigations which resulted in others finding rare elements, such as helium, which, almost as light as the inflammable hydrogen, but as flame-proof as nitrogen, enables airships to be proof against lightning and fire. He pointed the way to the use of the so-called poison gases in chemical warfare and for medicine and industry. Year by year, Priestley, is getting more and more up to date—not only in his chemistry, but in his politics and theology.

His discovery of oxygen, by which he is best known, demolished a time-honoured theory over which scientists puzzled so many years. In order to account for the burning of things, Stahl, the noted chemist and physician, assumed that there was a subtle fluid which combined with ash in inflammable bodies, and escaped when combustion occurs. The flame and the heat was according to this view, the effort of the phlogistin, as Stahl called it to free itself from an affinity. In fact, Priestley called oxygen "dephlogisticated air" at first. The investigations of Scheele, the Swedish chemist, and of Lavoisier, the French scientist, who were also working on the theory of combustion, swept aside the picturesque, but unsound ideas of Stahl, and showed that burning was due to the effect of the oxygen in the air. Of course, their views were bitterly opposed by prejudiced followers of the old idea. The controversy of the "pros" and the "antis" over phlogistin was in fact one of the bitterest which marked science in the eighteenth century. The upholders of the Stahl theory were called phlogistians; the opponents anti-phlogistians, and both names are in modern lexicons.

The name phlogistin, is derived from the Greek word, meaning to burn, or to be inflamed. In these days there has come into the dictionary, Antiphlogistine, the designation of a mineral poultice a inflammation. The remedy in itself is a protest against an unsound practice which research has proved harmful—blood letting. At one time, even learned men maintained that phlebotomy was justified. Modern science has shown that the congestion due to too much fluid can be relieved without recourse to the lancet—and out of

that discovery a new term has come into the vocabularies of many nations.

SPHYGMOMANOMETERS.

WE have received from the Calcutta Pure Drug Co., 41-A, Waterloo Street, Calcutta, specifications of two reliable sphygmomanometers which they stock.

The first is the "Anæroid pattern," No. 5540, which costs Rs. 55. This is of German make, and the special feature of the apparatus is that the index may be adjusted by turning over the cover of the apparatus—a device which we understand is not applicable to any other form of sphygmomanometer on the market. This instrument is of the usual pneumatic pattern, and the case containing it is only some 2 by 5 cms. in size, and its weight 115 gms.

The second, Riva-Rocci pattern, No. 5618, is in a wooden case, and is a mercury manometer. Its price is Rs. 45. It is especially designed to stand transport, and to be safe and reliable. The apparatus is at once ready for use on removing the rubber stopper from the mercury vessel and substituting the ground glass tap. The mercury is contained in a separate bottle in order to minimise risk of breakage and loss in transport. Reports quoted speak very well of the easiness and reliability of this apparatus.

EATAN.

"EATAN" is a dark brown liquid similar in taste to slightly salted meat extract; and stated to consist of a complex of amino-acids and hydrolysates of blood, bones, connective tissue and secretory glands of oxen. It is given in doses of a teaspoonful or less, mixed with soup, milk, or other liquid food, and should never be taken undiluted. This preparation, it is claimed, is of special value in all wasting diseases and in diseases of malnutrition, and especially in chronic tuberculosis of any type. German writers, such as Haff, Basch, Moewes, Bernoulli, Bickel, Braun and Crohen speak of its special value in pulmonary and other forms of tuberculosis, and in chronic osteomyelitis.

According to *The Practitioner*, August 1927, p. 136, "it is indicated and should prove of use in anemia, malnutrition, marasmic disorders, digestive disorders, exhaustion, and in convalescence some physicians have testified to its value in tuberculosis." *The Guy's Hospital Gazette* speaks of it as of value in cases of malnutrition, tuberculosis, osteomyelitis, and inoperable malignant tumours. *The Lancet* states that "it seems worth trial in cases of debility of varied origin."

A very striking series of before-and after-Eatan treatment is published by Dr. Haff of Munich, who claims that the administration of these hydrolysed protein extracts may bring about an almost complete restoration of the normal condition in patients who are reduced to "skin and bone." His paper is illustrated with some remarkable photographs. Dr. W. Braun, a well known gynecologist of Berlin, also speaks of it in the highest terms.

In brief, in this preparation we would seem to have an easily assimilable source of the proteins resulting from normal intestinal digestion, and a source of potential strength to the body in all conditions of severe malnutrition and debility. All reports concur in reporting that its assimilation is not attended by any digestive disturbances, and several of them especially emphasise its value in pulmonary tuberculosis.

The agent for the United Kingdom and the British Empire is Alfred Dehez, 28, Bond Street, Surbiton, Surrey, England; and the price is 4s. for a full size bottle, and 2s. 6d. for a half sized bottle.

"CLINICAL EXCERPTS."

Clinical Excerpts is a bi-monthly journal issued by the Havero Trading Co., 15, Clive Street and P. O.

Box No. 2122, Calcutta, the Indian agents for Plasmoquine, Antimosan, Stibosan and other new German synthetic drugs. A recent issue commences with an interesting review by Professor P. Mühlens of Hamburg on chemotherapy in tropical diseases. With regard to plasmoquine he summarises the literature by claiming that it is as efficacious in benign tertian and quartan malaria as quinine, whilst in malignant tertian it has a special gametocidal effect, preventing the production of crescents, but has to be combined with quinine in order to destroy the growing forms. It is stated to be well tolerated by children. Neosalvarsan, in addition to its well known action in syphilis and frambæsia, is stated to be almost a specific for venereal granuloma, also for rat-bite fever, a fever which is not at all uncommon in India. An interesting account is given of the recent work on the anti-rachitic vitamine; this has now been prepared in a state of great purity and very high potency by irradiation of ergosterin, and results with it are stated to be extremely good. "Spirocid," which is stated to be 4-oxy-3-amino-phenyl-arsenic acid, is claimed to be an effective prophylactic agent against frambæsia when taken by the mouth; and of value in the treatment of that disease, as well as of relapsing fever, amœbiasis, and infections with *Giardia intestinalis*.

A series of abstracts from recent literature deal with plasmoquine, where Sliwensky claims that five days' administration will almost always clear the patient's blood-stream of gametocytes; with the value of rectal administration of "Rivanol" in amœbiasis and in chronic tropical colitis of different types; with "Myo-salvarsan", a salvarsan derivative for intramuscular and subcutaneous administration; and with gold salts—"Triphal"—in the treatment of urogenital tuberculosis. An account is given of "Omnadin", which is stated to be a "non-specific immunising vaccine" for the treatment of very varied conditions; it has apparently given good results in typhoid fever—though Maeyama in his account of its use in 31 cases seems to have used the preparation at a late phase of the fever—usually about 30 days after its onset; in general sepsis of varied types in doses of from 0.5 to 2 c.c.; in pneumonia, where the results in children are claimed to have been especially good; and in surgical conditions such as cellulitis and empyema.

The whole number is well got up, and is of interest in its general account of the progress of the German synthetic drug industry.

Publishers' Notice.

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles will receive 25 reprints *gratis*, if asked for at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions, Advertisements, and Reprints should be addressed to THE PUBLISHERS, Messrs. Thacker, Spink & Co., P. O. Box No. 54, Calcutta.

Annual Subscription to *The Indian Medical Gazette*. Rs. 16 including postage, in India. Rs. 18 including postage, abroad.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

ADDRESS: HEAD OFFICE.

The 7th January, 1928.

Messrs. Bengal Immunity Co., Ltd.,
153, Dharamtollah Street, CALCUTTA.

Dear Sir,

On behalf of our Local Committee, I beg to thank your firm for their assistance during the Far Eastern Association of Tropical Medicine 7th Congress just concluded. The demonstrations at your laboratories were very much appreciated by the members who attended, who had an opportunity of seeing what local enterprise could do in biological research and production.

Yours faithfully,

(Sd.) G. TATE,

Major-General, I.M.S.,
Surgeon-General with the Government of Bengal.

For Ill Conditions of the Gastric Tract

ALOCOL

Colloidal Hydroxide of Aluminium

"Alocol" is the practitioner's safeguard when alkaline medication is indicated. Its clearly defined antacid properties exceed those of bicarbonate of soda, magnesia and subnitrate of bismuth; furthermore, "Alocol" eliminates all the unpleasant drawbacks which are particularly feared with the usual alkalis and oxides.

When "Alocol" reaches the stomach adsorption takes place; a colloidal jelly is formed, which adhering to the walls of the stomach, diminishes their sensibility. The excess of hydrochloric acid is absorbed, but the acid reaction necessary for peptic digestion remains normal.

The advantages of "Alocol" are therefore manifest. It neither hinders proteolysis nor causes destruction of any food element or factor.

Prolonged exhibition interferes in no way with the normal putrefactive function of the gastric juices or with the regular processes of nutrition.

"Alocol" is regarded as a specific in the treatment of hyperchlorhydria, whilst for all forms of fermentative dyspepsias with gastro-intestinal flatulence, acid eructations and other symptoms, common to gastric disease, its influence is beneficial to the highest degree.

Complete chemical history of "Alocol" with convincing clinical reports, and supply for trial, sent free to physicians on request.

FURTHER OBSERVATIONS ON THE EPIDEMIC DROPSY FORM OF BERIBERI.

By J. W. D. MEGAW, C.I.E., B.A., M.B.,
COLONEL, I.M.S.,

Formerly Director, Calcutta School of Tropical
Medicine,

S. P. BHATTACHARJI, M.D.,

Assistant Professor of Tropical Medicine, Calcutta
School of Tropical Medicine

and

B. K. PAUL, B.Sc., M.B., D.T.M. (Bengal),

Formerly Research Worker on Beriberi,
Calcutta School of Tropical Medicine.

THE senior writer has been interested in the subject of epidemic dropsy for more than twenty years and during the past seven years he has had exceptional opportunities for a detailed study of the clinical and epidemiological aspects of the disease. Most of the field work described in this report has been carried out by Dr. Bhattacharji and Dr. Paul under the direction of the senior writer.

For those who are not familiar with the literature of the subject it is necessary to give a very brief summary of the important problems connected with epidemic dropsy and its relationship to beriberi; those who have read the previous papers on the subject can pass on directly to Part II, which deals with the recent clinical and epidemiological observations in connection with the disease.

PART I.

BRIEF SUMMARY OF THE EPIDEMIC DROPSY PROBLEM.

(a) *The Relationship between Epidemic Dropsy and Beriberi.*

Epidemic dropsy is regarded by most workers as one of the forms of beriberi, but we cannot yet dogmatize as to the exact relationship which exists between the two diseases. We believe that it is not yet possible to give a definition of beriberi, as we do not know its cause; our view is that there may be two or more diseases which are included under the old name beriberi. There is one form of the disease with peripheral neuritic manifestations which may well be due to a deficiency of vitamin B in the diet and the majority of modern authors regard it as the only disease to which the name beriberi should be given. If this were the only true beriberi, the study of the disease would be very simple as avitaminosis B is capable of being reproduced with great ease in birds, but most of the cases to which the name beriberi has been given in the

past show cardiac enlargement and cedema of the body, whereas avian avitaminosis is characterised by cardiac atrophy and a drying up of the tissues. We might ignore even these remarkable differences if human beriberi were always associated with deficiency of vitamin B in the diet, but this is far from being the case, as will be seen from the following list of writers, some of whom assert that there was no evidence of vitamin deficiency in connection with the outbreaks observed by them, while others hold that vitamin deficiency cannot account for all the disease manifestations which have been observed.

Horda finds the post-mortem changes to be those resulting from a toxin. McCarrison believes that avitaminosis is one of the factors, but he regards infection as a necessary factor in some cases, and an unknown toxin as a factor in most. Sprawson saw cases in persons whose diet was satisfactory in every observable respect. Boyd, Jauveau Dubreuil, Hofmeister, Mouriquand, Lebrede, Barbe, Mauriac, Wydhoghe, Leporini, Miura, Nagayo, Acton, Chopra, Hoffman, Bernard, de Langen, Conto, Fraga Shimazono, etc., all bring forward evidence which convinces them that avitaminosis does not completely explain beriberi. On the other hand Vedder, Shiga, Stanton, Frazer and others regard avitaminosis as the only essential factor, and almost all the writers of modern text-books accept their views without hesitation; many go so far as to regard the deficiency view as being soundly established on an experimental basis. The unanimity of writers of the text-books on the vitamin deficiency view is in remarkable contrast to the difference of opinion which exists among those who have had actual experience of beriberi.

In considering the evidence for and against the vitamin deficiency view it is necessary to remember that beriberi is a *name* and not an entity, also that the same name may be applied to two or more very different things. It is abundantly clear that many of the outbreaks to which the name beriberi has been applied do not correspond with avian avitaminosis and are not caused by a deficiency of vitamin B in the diet. It would be possible to adopt the drastic course of "disqualifying" all such outbreaks on the grounds that they do not conform to our preconceived ideas regarding beriberi, but such a procedure is thoroughly unjustified as the very outbreaks which cannot be explained on the deficiency view are those which conform most closely with the old descriptions of beriberi.

Using the word beriberi as a name for cases of disease which show certain manifestations, we are faced with the fact that there are various kinds of beriberi and that no satisfactory classification of these has yet been arrived at. One great cause of confusion is that many of those who have discussed outbreaks of beriberi have contented themselves with saying that they saw so many "cases of beriberi"; they give no details of the clinical manifestations of the disease which they observed, and so we have no means of

judging whether the various writers are describing the same disease or different diseases.

But if we use the word beriberi in the only way that is yet justifiable, viz., as a name for disease manifestations which correspond with those described by the old writers on beriberi, and if we admit that two or more diseases may have been included under this name it will not be permissible to state as a simple dogma that beriberi is caused by deficiency of vitamin B in the diet.

These preliminary remarks are intended to show that there is still a beriberi problem in spite of the fact that the modern text-books are almost unanimous in asserting that the final decision has already been reached on the question.

Does Epidemic Dropsy fall within the Beriberi Disease group?

If we divest ourselves of preconceived ideas as to the causation of beriberi and approach the subject of epidemic dropsy with open minds, the first striking feature of this disease is that all the chief hypotheses which have been advanced with regard to beriberi have also been put forward as explanations of epidemic dropsy. Infection, food-poisoning, and vitamin deficiency are the most prominent of these.

The other chief points of resemblance are:—

(1) Both are essentially diseases of rice eaters; exceptional cases or outbreaks of both diseases

have been described as occurring in persons who had not eaten rice, but these are remarkably few.

In these exceptional outbreaks there is no evidence on record to show that the surreptitious eating of rice has been excluded or that rice had not been used to adulterate the flour which was in use.

Even if there were complete proof of the rare occurrence of a disease resembling beriberi among people who have not eaten rice, it would still be permissible to state as a broad general truth that beriberi and epidemic dropsy are essentially diseases of rice eaters.

(2) The geographical distributions of the two diseases dovetail into each other in India so exactly that if a map of the distribution of beriberi is made a gap will be found in and around Calcutta; this will be filled in when the distribution of epidemic dropsy is inserted in the map (*see* Map I).

(3) The seasonal distribution of the two diseases although capricious in certain cases is remarkably similar on the whole (*see* Chart 4) Beriberi in Japan and in Burma is most common at the same season as epidemic dropsy in Bengal.

(4) Both diseases tend to occur as family, institutional or place outbreaks, often in the absence of any obvious change in the diets of the persons concerned.

(5) The age distribution of both diseases is very similar if we leave out of account infantile beriberi which will be discussed later.

Speculative Classification of Beriberi and Diseases which Simulate Beriberi.

I. Diseases associated with errors and deficiencies of diet.			II. Diseases which are probably due to rice-intoxication or toxi-infection.		
Probable Causes.	(a) Due to deficiency of calories, vitamins, etc.	(b) Due to deficiency of vitamin B in the diet.	(a) Intoxication by poisoned over milled rice.	(b) Intoxication by poisoned over milled rice.	(c) Intoxication by parboiled and under-milled rice.
Name of Disease.	Famine œdema.	Avitaminosis B.* (When this disease occurs it is probably called beriberi.)	Dry beriberi.	Wet beriberi.	Epidemic dropsy form of beriberi.
Clinical Features.	œdema. Cardiac depression. Polyneuritis not noted.	No œdema. Cardiac excitation absent. Polyneuritis.	No œdema. Cardiac excitation. Polyneuritis.	œdema. Cardiac excitation. Polyneuritis usual.	œdema. Cardiac excitation. Polyneuritis in 10–50 per cent.
Remarks.		* This name is proposed for those beriberi-like diseases in which there is polyneuritis without cardiac manifestations or œdema, and in which the diet is known to have been deficient in vitamin B.	May follow or precede wet beriberi.	May follow or precede dry beriberi.	Cannot be differentiated with certainty from wet beriberi but fever and gastrointestinal symptoms are more pronounced. Glaucoma is common. Polyneuritis is not so pronounced as a rule.

It is obvious that combinations of the above causes may be at work, for example, vitamin B deficiency and rice-intoxication may co-exist and it may be difficult to assign to each factor its relative importance.

(6) There is no reliable clinical criterion which justifies us in separating the two diseases; both frequently show initial gastro-intestinal disturbances, oedema, cardiac excitation, liability to heart failure and prolonged convalescence.

The chief points of difference are:—

(1) Beriberi occurs chiefly among persons who have eaten overmilled rice, while epidemic dropsy usually affects people who have eaten parboiled and undermilled rice.

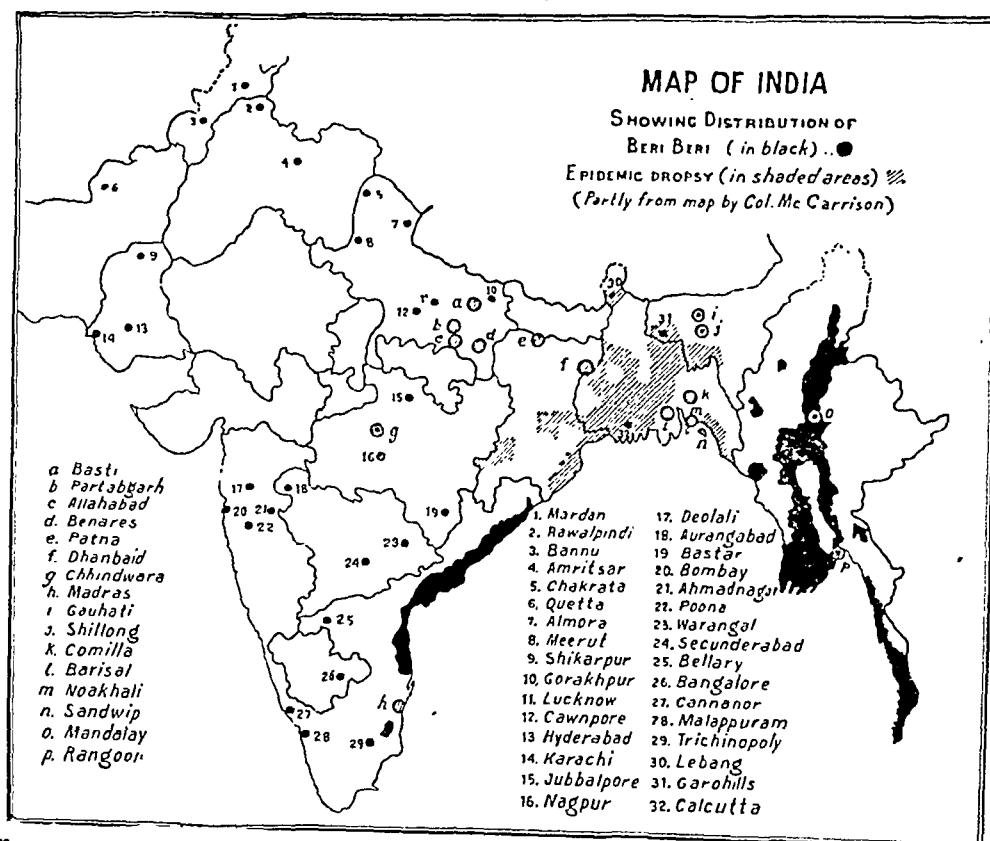

(2) Gastro-intestinal disturbances, fever, with a diffuse vaso-motor rash are much more frequent in epidemic dropsy than in beriberi, while loss of the knee-jerks, muscular wasting and foot drop are more frequent in beriberi than in epidemic dropsy.

Dr. Mozumdar, the Health Officer of Calcutta, has seen a few cases which he believes to have been examples of infantile epidemic dropsy, but the disease must be extremely rare, if it occurs at all.

We have not yet found any clinician or research worker who has been able to supply a criterion by which the average case of moist beriberi can be distinguished from a typical case of epidemic dropsy: it is pretty certain that a case which would be called moist beriberi in the Far East would be called epidemic dropsy in Calcutta and vice versa.

Broad clinical differences do exist between the two disease groups and it is necessary to try to discover the reasons for these: they may be due

MAP I.

These differences are of degree rather than of kind, and the only two points in which real differences exist between the diseases are the frequent occurrence of glaucoma in the later states of epidemic dropsy and the complete absence of infantile forms of the disease, whereas infantile beriberi is well known in some parts of the Far East.

It would be interesting to know if the ophthalmic surgeons of the East do not come across more cases of glaucoma after outbreaks of beriberi. Le Dantec describes dimness of vision and scintillation as a symptom of some cases of beriberi.

With regard to infantile beriberi this has not been reported from India or Burma so far as we are aware, so that the absence of infantile epidemic dropsy does not form satisfactory evidence by which to differentiate between the diseases.

to variations in the composition of the poison which we believe to be the cause of both diseases. Such variations may result from the action of different micro-organisms, or more probably from the action of the same organisms on different types of culture media—polished rice in one case and parboiled rice in the other. Until there is some satisfactory means of distinguishing between the two diseases it is better to class them together provisionally in one disease group. The following speculative classification of the beriberi-like diseases is modified from that given in a paper submitted to the 1923 meeting of the Far Eastern Association of Tropical Medicine.

It is very interesting to note the great variety of opinions which have been expressed on the causation of epidemic dropsy.

Most of these are based on the observation of single outbreaks of the disease.

THE SYMPTOMS OF EPIDEMIC DROPSY.

The following table shows the percentage frequency of some of the chief symptoms of epidemic dropsy as recorded by various observers.

	Cobb (Barisal Jail, 1903).	Ball (Sylhet Jail, 1906).	Greig (Basti Jail, 1907).	Anderson (Comilla Jail, 1908).	Daley (Alipore Refrac- tory, 1908).	Campbell (Dacca Asylum, 1908).	Greig (Calcutta outbreak, 1910).	Megaw and others (Cal- cutta and Allahabad) including the reports of Banerji, Bhattacharji and Paul (1909-1927).
Fever	87	26	40	51	30-50
Gastro-intestinal dis- turbance.	87	100	18	20	60	26-81

Infection and rice-intoxication are the most popular views and Lt.-Col. Greig is the only writer who favours the dietetic deficiency to the exclusion of other theories.

Various Theories as to the Ætiology of Epidemic Dropsy.

1. *Place Infection:* Remarks.
Dr. C. Barry, *I.M.G.*, 1900-01. Also nitrogen deficiency.
Major Hall, *I.M.G.*, 1906. Organisms in floor of infected building.
2. *Infection spread from person to person (by contact of food).*
Col. McLeod, *I.M.G.*, 1877-80.
1893-94.
Capt. Rogers, *I.M.G.*, 1902.
Col. Cobb, *I.M.G.*, 1903. "Intestinal infection."
Daley, *I.M.G.*, 1908. "More or less communicable."
Anderson, *I.M.G.*, 1908. Controlled by segregation.
Dr. H. N. Ghosh, *Cal. Med. Jour.*, 1910. Infection of rice.
Lyngdoh, *I.M.G.*, 1912.
Capt. McCombie Young, *I.M.G.*, 1912. Food contamination.
Drs. B. K. Bhowmik and S. L. Sarkar, *Ind. Journ. of Med. Res.*, 1921 and 1922.
Dr. B. B. Brahmacharji, *Cal. Med. Jour.*, 1927.
Anderson, *I.M.G.*, 1927. Evidence of person-to-person communication.

3. *Insect-borne Hypothesis (infection by a microbe through an intermediate host).*

Heaney, *I.M.G.*, 1905. Insect-borne protozoon.
Dr. A. Pal, *I.M.G.*, 1907. Mosquito-borne.
Capt. Delany, *I.M.G.*, 1908. Bacterial infection transmitted by bed-bug.

4. *Deficiency in Food (nitrogen, phosphorus, etc.).*

C. Barry, *I.M.G.*, 1900-01. Also infection.
Major Greig, *Scientific Memoirs*, 1910. One-sided dietary.
Major Greig and Major Kennedy, *I.M.G.*, 1916. Inferior diet.

5. *Mustard Oil Poisoning Theory.*

Dr. S. N. Sen, *Cal. Med. Jour.*, 1909 and 1911. Adulteration with mineral oil.
Dr. Sagayam, *I.M.G.*, 1927.

6. *Due to Intoxication by Rice.*

Campbell, *I.M.G.*, 1908. Rice or fish poisoning; most probably rice.
Munro, *I.M.G.*, 1908. Food-poisoning; possibly diseased rice.
Capt. Megaw, *I.M.G.*, 1910. Poison in stored rice.
Major Acton, *I.M.G.*, 1921.
Lt.-Col. Megaw and Dr. Banerji, *I.M.G.*, 1923.
Lt.-Col. Megaw and Dr. Bhattacharji, *I.M.G.*, 1924.
Maj. Acton and Maj. Chopra, *I.M.G.*, 1925.
Maj. Hingston, *I.M.G.*, 1926.

Lt.-Col. Acton and Maj. Chopra, *I.M.G.*, 1927.
Drs. S. L. Sarkar and B. M. Gupta, *I.M.G.*, 1927.

7. Toxi-Infection.

Capt. Rost, *I.M.G.*, 1910. Found a diplobacillus.

8. Intestinal Sepsis.

Col. Lukis, *I.M.G.*, 1908. Of the nature of urticaria, erythema nodosum, etc.

9. No cause ascertained.

Capt. Campbell, *I.M.G.*, 1904.
Rev. Crozier, *I.M.G.*, 1905.

It will be noted that the disease manifestations are very variable in their frequency with the exception of œdema which is almost always present. In spite of the variability of the symptoms there are few diseases which are so easy of recognition by an observer who is familiar with the essential features of the disease. The figures in the last column represent my own personal experience combined with that of the various colleagues who co-operated with me in studying the outbreaks which we have encountered. The figures for small and exceptional groups of cases are not included as they would give a misleading idea of the disease.

It is necessary to emphasize the great variations which occur in the severity of the disease; some outbreaks and cases are so mild that it may be difficult to tell whether the patients really have the disease at all.

In other outbreaks the disease may be of such severity that the mortality is 50 to 75%. The remarkable outbreak, recorded by Major Hingston in the *Indian Medical Gazette* of August 1926, is an example of the excessively severe form of the disease. Out of a household of 22 persons no less than 15 died and 3 of the survivors suffered from a severe pernicious type of anæmia with retinal hæmorrhages from which they recovered. The Allahabad family outbreak, recorded by Dr. R. N. Banerji and myself in the *Indian Medical Gazette* in 1923, was the most severe of which I have had personal experience; in it several of the affected persons also had hæmorrhagic retinitis, but the mortality was low because treatment was started early.

It may be mentioned that there was no possibility of dietary deficiency in either of the above severe outbreaks; in both there was a strong presumption that the disease originated from a special sample of highly toxic rice.

A striking fact is that when the disease is recognized early and proper treatment instituted the patients make a rapid recovery. The essential points in the treatment are to cut rice out of the diet and to supply suitable food rich in easily assimilable animal proteins, fresh milk being the most valuable source of these. The supply of vitamins is also important, but not more so than in the case of other diseases in which damage to the nerves has occurred.

PART II.

RECENT OUTBREAKS OF EPIDEMIC DROPSY IN BENGAL.

This part of the paper deals with a number of small outbreaks observed in Bengal in 1925 to 1927, including the great outbreak of 1926. Most of the observations were made by the two junior authors under the general direction of the senior. The chief features of these outbreaks are shown in the tables and charts, but a few explanatory remarks are necessary.

OUTBREAKS IN BALLYGUNGE (CALCUTTA) IN JULY AND AUGUST 1925.

(a). United Mission Girls' School.

This outbreak occurred in a school for Indian girls: 14 out of 50 girls were attacked, all were eating the same food which was the usual Bengal diet. At an early stage rice was excluded from the diet and rapid improvement followed: then the Lady Superintendent, believing that mustard oil was the cause of the disease, allowed the girls to return to a rice diet for a week but excluded mustard oil. After a few days the symptoms became aggravated and rice was stopped; rapid convalescence then followed.

It is interesting to note that a boy from the neighbouring Bishop's College was attacked at the same time as the girls: it was found that his food had been supplied by his sister from the girls' school. He was the only person in the college who had the disease. The cases were mild, there was no diarrhœa and no fever, all had palpitation and œdema, the knee-jerks were lost in 4 out of 14, increased in 7 out of 14, and normal in 3.

Enquiries into the diet brought to light the fact that eight maunds (640 lbs.) of rice had been bought in the middle of June: the first case occurred a month later. About 3 maunds of rice remained when the disease appeared, and an attempt was made by us to secure this rice for examination; the mistress of the school entrusted it to the dealer from whom it had been bought for the purpose of having it weighed; but the dealer evidently feared that he might get into trouble and disposed of the rice so that we failed to get possession of it. This outbreak is of considerable importance as all the statements made by the Superintendent of the school can be relied on implicitly.

(b). Ahiripukur Outbreak (Map II).

This occurred almost entirely among persons of the labouring classes who lived near the United Mission Girls' School. There were 56 cases and the affected families with only two exceptions bought rice which came from the same store from which rice was supplied to the girls' school. One man who lived at a distance, bought his rice from this store and got the disease. No other cases were discovered in this immediate locality.

Forty-one cases were personally investigated by the junior writers, of these 2 had fever, 3 had diarrhœa, 36 had palpitation, the knee-jerks were

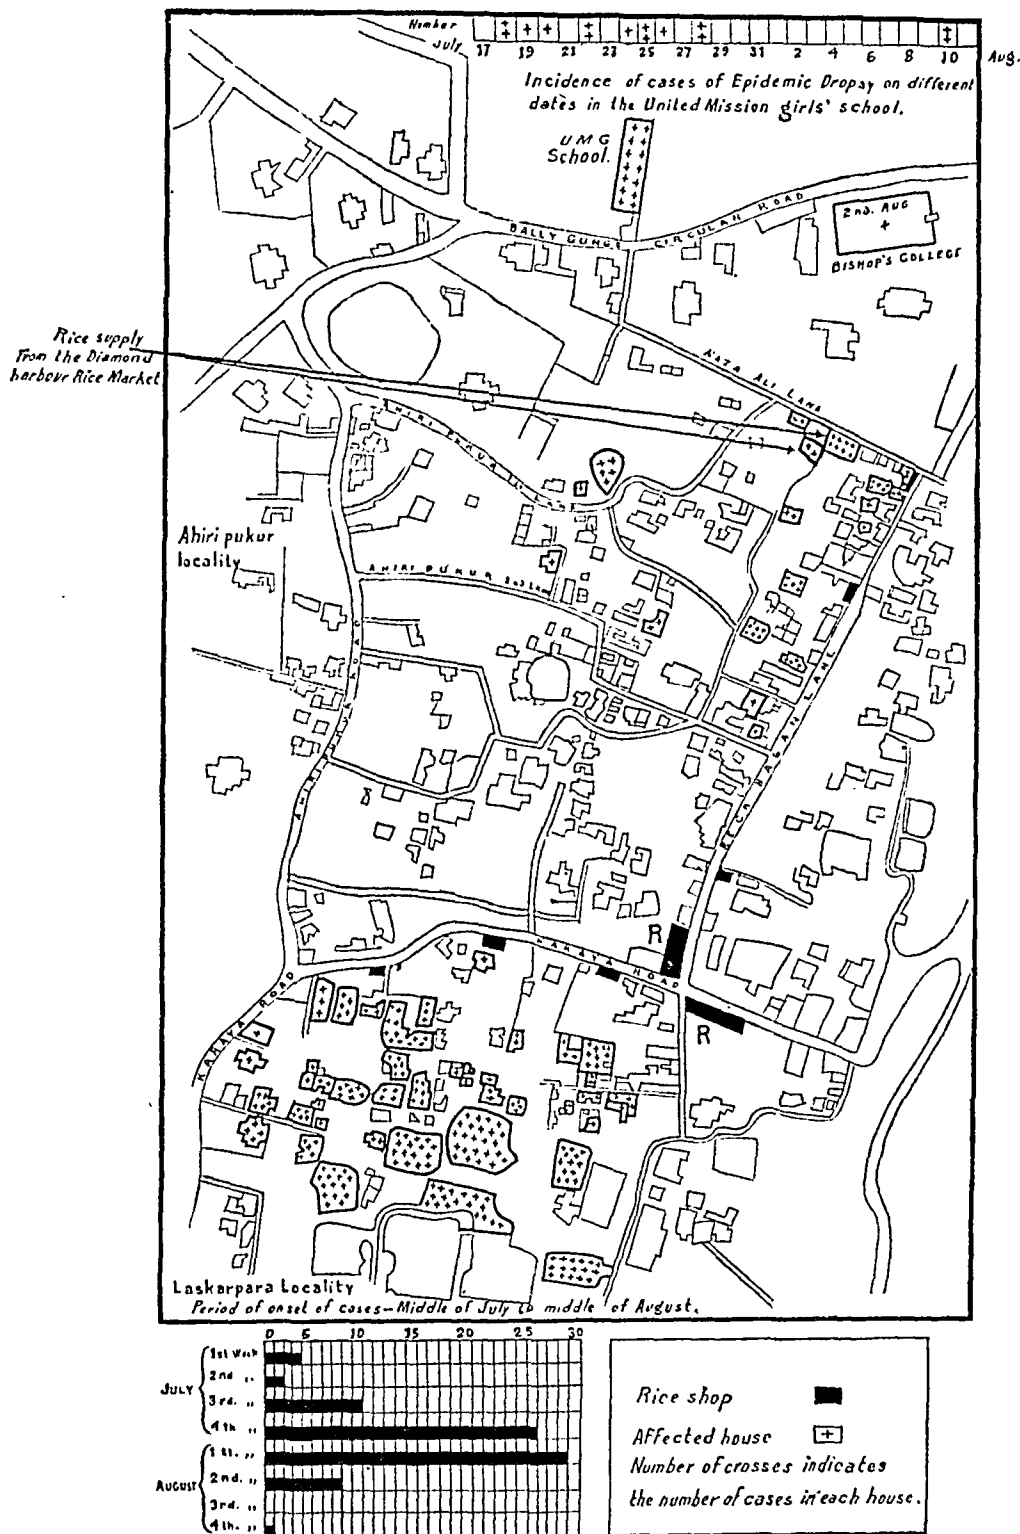

lost in 15, exaggerated in 18, and normal or diminished in the rest. During the investigations we had reports of 4 deaths.

(c). *Laskarpara Outbreak (Map II).*

This was a large outbreak occurring in a locality near the above two. The patients

MAP II.

Epidemic Dropsy in Calcutta, 1925.

Incidence of Cases in the Ahiripukur Locality.

The rice supply to all the affected families came from the Tollygunge Rice Mills being originally stocked in the two big rice godowns marked R, from which the smaller rice shops got their supply, with the exception of two families who got their rice from a different place.

belonged to the working classes, and about 500 persons were attacked; these made up about 75 per cent. of the population of the locality. Rice was bought from six small shops, all of which obtained their supply from the same two stores from which rice was supplied to the persons affected in outbreaks (a) and (b). The rice was originally obtained from rice mills in Tollygunge. There were at least six deaths. These cases could not be investigated in detail as we did not visit the locality till the epidemic had nearly subsided. The rice had been stored in the shops for one or two months as a rule after receipt from the mills, but some had been kept for 10 months after manufacture, this being the residue of a consignment which was not fully sold out. It was not possible to trace the source of the rice which was presumably responsible; it was likely to have come from the same original stock as the rice in use by the persons affected in outbreaks (a) and (b) as these stores were close to the affected locality and the disease occurred at the same time.

OTHER SMALL OUTBREAKS IN 1925.

From the whole of the rest of Calcutta only three small family outbreaks were reported for 1925, but it is probable that others may have occurred. In one family two of seven persons were attacked, in another two out of three, and in the third all three members had the disease.

In each of these attacks, the symptoms appeared about three weeks to a month after a particular supply of rice had been taken into use.

OUTBREAKS OUTSIDE CALCUTTA IN 1925.

1. Bosepukur Outbreak.

In July and August 1925, there was an outbreak affecting 7 persons in a small village called Bosepukur; this is of special interest, as it was one of the very rare examples of occurrence of the disease among villagers who store their own rice in the form of paddy and prepare it for themselves in quantities sufficient for 10 to 14 days' requirements. The paddy had been stored for six months in a granary with mud-covered bamboo walls, and a thatched roof. The floor was raised two feet from the ground on posts. The granary was situated in a damp place and the conditions of storage were exceptionally unsatisfactory.

2. Jessore Outbreak.—September and October 1925 (Map III).

This also is an example of the rare outbreaks in which rice made from home-stored paddy was being used. There were 46 cases, of which 16 were in middle class persons who were eating old rice and 30 were in cultivators who were eating rice which had been recently prepared from their own paddy which had been harvested in July. The outbreak ceased suddenly after the harvesting of the new crop in the second week of October. The chief symptoms in these 46 patients were—fever in 35, palpitation in 34, diarrhoea in 24, loss of the knee-jerks in 17, exaggeration of the knee-jerks in 19. A diffuse

patchy redness of the skin was seen in 9, cedema of varying degree was present in all.

The Bosepukur and Jessore outbreaks are the first in which there has been satisfactory evidence that the disease can occur among persons who store their own paddy and prepare the rice in small quantities. When we consider the large number of cases of epidemic dropsy which have been reported among the eaters of parboiled rice which has been stored for several weeks or months, and the extreme rarity of its occurrence among the millions of rice-eating cultivators of Bengal, it is evident that the time-honoured village methods of storage and manufacture of rice constitute a valuable protection against the disease. Until these two outbreaks were discovered, it seemed likely that paddy was entirely exempt from the changes which are associated with the occurrence of the disease. As a practical working rule we may still regard the risk of eating freshly prepared rice as almost negligible, but it is obviously desirable to recommend care in the storage of paddy as well as in the case of manufactured rice.

It is quite possible that a few unreported cases of epidemic dropsy may occur from time to time among cultivators who store their supplies of rice in the form of paddy but the disease is now so well known in Bengal that it is impossible to believe that it occurs to any appreciable extent without being reported.

THE CALCUTTA OUTBREAK OF 1926.

This is the largest outbreak on record, it caused many deaths (*see* Charts 1, 3 and 4).

In a previous article the senior writer expressed the hope that the establishment of large numbers of rice mills near Calcutta would result in a shortening of the dangerous period of storage of manufactured rice and so protect the city from the disease.

Till 1926, there were good grounds for believing that this hope was justified as the disease rarely attacked the people of Calcutta who used rice from the local rice mills, and the only considerable outbreak since 1909, was that which occurred in 1918-19, in Howrah* where rice from the country districts was used to a great extent: this rice had been manufactured at distant places and was imported by rail, road or country boats and so was exposed to damp during transit or storage.

It was, therefore, disappointing to find that the new conditions of storage and manufacture of the rice in Calcutta failed in 1926 to protect the population from the disease. In previous outbreaks it had invariably been found that the rice which was in use had been stored under conditions in which it was exposed to damp, heat, and lack of ventilation, so that it was natural to seek for similar conditions in this case.

The meteorological reports show that May and June were exceptionally hot in 1926. On the

* Howrah is really the part of Calcutta which is separated from the rest of the city by the river Hooghly.

18th of May at 4 p.m. there was a sudden and unexpected storm with 1.3 inches of rain; this thoroughly wetted large quantities of rice which was being dried in the sun after parboiling. On the 17th of June there was another heavy shower of rain (3.3 inches) which soaked large quantities of rice. Then there followed a period of very sultry weather till the 22nd of July, when very heavy though belated rain came and caused extensive flooding so that the people in many places had to move about on boats or rafts (*see* Chart 1).

The outbreak appeared rather suddenly towards the end of June: it was shorter and sharper than the previous great outbreak of 1909-1910, but

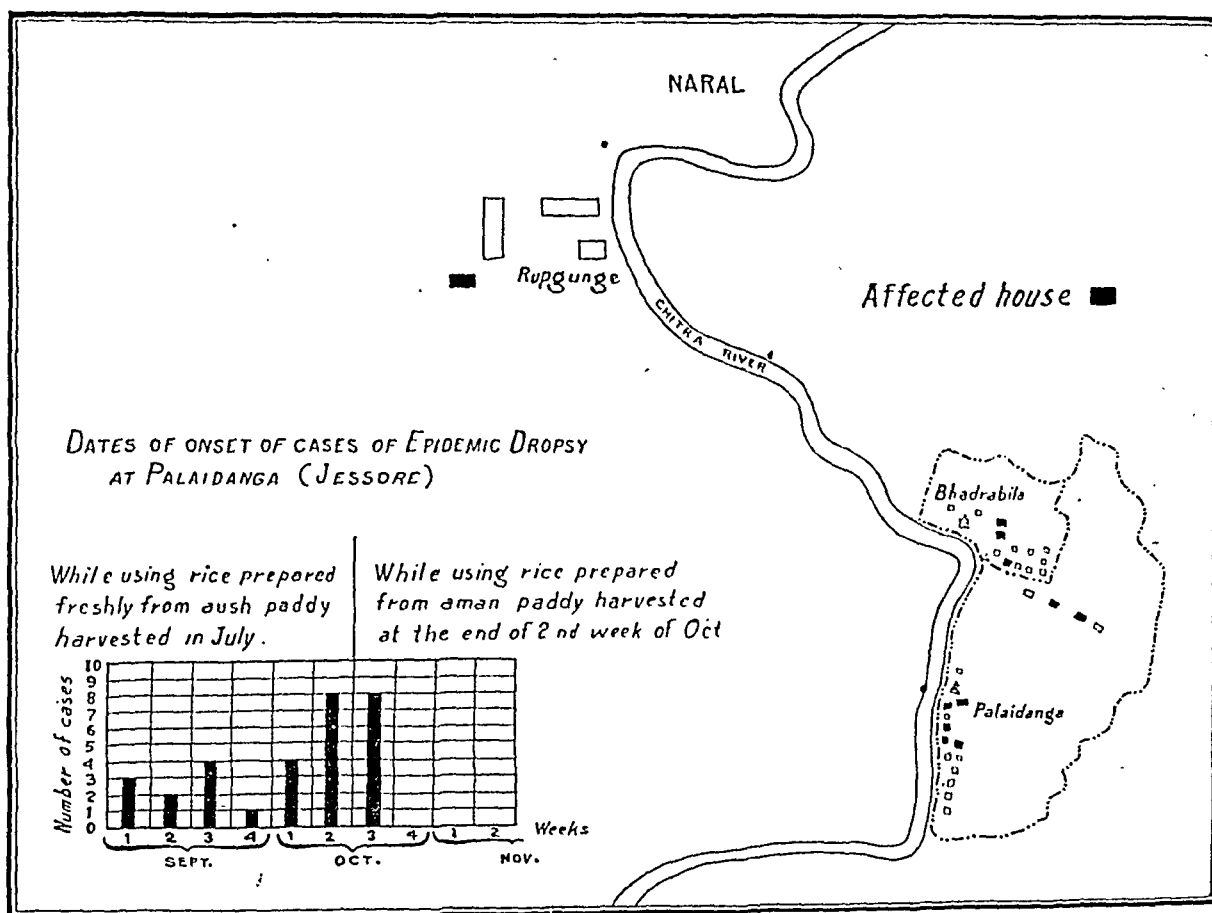

which the causal factors were at work. It is impossible to form any accurate estimate of the number of cases, but there must have been at least 6,000. More than 1,500 cases were investigated by the junior writers, Dr. S. P. Bhattacharji and Dr. B. K. Paul; these cases are believed to form an accurate index of the whole outbreak.

It is probable that large numbers of other persons suffered from mild and unrecognized forms of the disease. The chief features of the outbreak were as follows.

Only rice eaters were affected, no Europeans were attacked, Sikhs (who eat a little rice, brought from up-country) also escaped entirely, Marwaris were attacked rarely and only when they

MAP III.

Outbreak of Epidemic Dropsy in Jessore in 1925.

occurred at the same season (Charts 1, 2, 3, 4 and 5). The explosiveness of the outbreak is more evident if the separate localities are considered, as in each place the great majority of the attacks began within a period of about a fortnight.

The whole outbreak may be regarded as a prolonged storm of widespread distribution, made up of a large number of local outbursts most of which occurred rather suddenly and explosively. It is to the date of onset that attention should be specially directed, as the illness may be prolonged and death may result several weeks after the first appearance of symptoms; hence the dates of deaths are of little value in showing the time at

had adopted the habit of rice eating. The age distribution was the same as usual, infants and very young children being almost immune. There were 94 cases in children under the age of 10 years out of a total of 1,055 investigated. Of 447 cases which were examined clinically there was cedema in all, diarrhoea at the onset in 361, fever at the onset in 68, palpitation in 424, pains in the calf muscles in 282. The knee-jerks were lost in 58, diminished in 15, normal in 50 and increased in 324, at the time of examination.

A mottled red flush of the skin of the legs was seen in 95. Dimness of vision was complained of by only 8 persons, but there were many

cases of glaucoma in the later stages of the disease and after the symptoms had subsided. The recorded deaths for the whole of Calcutta were 1,165, the probable mortality was about 25 per cent. In some localities the death-rate was much higher than in others.

Many relapses were reported, in a few cases relapses were said to have taken place in persons who continued to abstain from rice. Such an occurrence has never been noticed among patients who were under proper control in hospitals and it is a well-known fact that Bengali

tract when rice of any kind constitutes part of the diet, and not otherwise.

The average diet of the victims consisted of, rice 12 to 16 oz., *dal* (leguminous grains) 1 to 2 oz., *ata* (wheat flour) 2 to 4 oz., fresh fish 1 to 2 oz.; green vegetables 6 to 8 oz., mustard oil was used by all. Many of the well-to-do patients also took eggs, fresh milk, meat and fresh fruit, and it was quite impossible to detect any association between a dietary defect and the occurrence of the disease. All classes of the rice eating communities were equally affected. The diets of the

CHART 1.

Incidence of Cases and Mortality in Epidemic Dropsy, 1926-27.

patients regard abstinence from rice as an intolerable hardship. It is quite common for them to continue to eat rice even when they assure their medical man that they are not doing so.

An interesting point is that a return to a rice diet may be followed by a return of the symptoms even when a different kind of rice is eaten. The senior writer has no personal experience of this as he invariably prohibits rice of any kind, but several cases have been reported which appear to be well authenticated in which this has happened. The occurrence of cases suggests the possibility that the causal agency sometimes continues to be formed in the gastro-intestinal

affected persons were of the same kind as they had been eating before the disease appeared, and those who were living on a liberal and varied diet were attacked just as frequently as the poorer people whose diet was less satisfactory. The year 1926 was not one of any special scarcity of food or of economic depression, and there was no association with increased cost of rice such as was reported by Colonel Greig in 1909 (Chart 6). The rice was the usual parboiled variety, most of it came from the rice mills in the outskirts of Calcutta. Some details of the diet scales of the affected persons are given later in this paper.

As reported already by Col. Acton it was observed by Dr. Bhattacharji and Dr. Paul that a good deal of rice was badly wetted by unexpected downpours of rain during the normally dry season in May. It would obviously be difficult to get the rice properly dried after this wetting, and, during the days following on the heavy rain, the air was hot and moist, so that the conditions were exceptionally favourable for microbic and fermentative changes to occur in the stored manufactured rice. Samples of rice which were being eaten at the time were found to be affected by the "white disease," which Col. Acton regards

(a) In one diabetic patient the knee-jerks were found to be absent and there was slight œdema over the tibiæ. On these grounds the diagnosis of epidemic dropsy was made. The absence of the knee-jerks is very common in diabetics and in this case it was found that œdema had previously occurred from time to time.

(b) Two persons who were convalescent from typhoid fever were suspected of suffering from the disease; in both of these there was only a slight œdema of the feet and ankles such as would often be found in convalescents from a severe disease.

CHART 2.

Showing the Relationship between the Rainfall and the Incidence of Epidemic Dropsy in Calcutta, 1926.

On the 18th May a violent rainstorm occurred about 4 p.m. There was practically no warning of this and much of the rice in the factories was being dried when the storm came and thoroughly wetted all the rice which was exposed.

On the 22nd July there was a very heavy shower and all Calcutta was flooded, the water entering inside many rice-godowns.

as being associated with the occurrence of epidemic dropsy.

I am not convinced that this association is constant, but it is quite certain that the "white disease" is a clear indication that microbic action has taken place and therefore rice which shows signs of this disease should always be regarded with suspicion, as the grain must have been exposed to conditions under which toxic substances are likely to be formed.

Reports were received from time to time of the occurrence of the disease in persons who had not eaten rice. Every available case of this kind was investigated. The cases fell into three groups—

(c) One dyspeptic patient had slight œdema of the feet, but no other symptoms: there was no evidence that he had epidemic dropsy.

When epidemic dropsy is common, everybody is on the lookout for swelling of the feet and legs, so that puffiness of the feet and ankles is often discovered for the first time in persons who have had the condition for months without paying attention to it.

Quite recently a patient came to the hospital with swelling over the tibiæ; he had been diagnosed as a case of epidemic dropsy but the swelling was fully accounted for by the chronic parenchymatous nephritis from which he was found to be suffering.

AN OUTBREAK IN HOWRAH, 1926 (MAP V.)

This remarkable group of cases was investigated by the junior authors with the valuable help of the Health Officer of Howrah. The map is self explanatory: it shows a wonderfully close

association of the disease with the rice supply. The two places shown on the map were situated at a short distance from each other and it will be seen that the disease was present in nearly all the houses which were supplied from two shops, while the houses supplied from other shops entirely escaped.

CHART 3.
Average Monthly Variations in the Prices of Rice (*commoner varieties*) in Rupees per Maund.

Average Dieteries of the Different Classes of People (*males*) affected with Epidemic Dropsy.

Class or Creed.	of Article Food.	Rice.	Ala.	Dal.	Fish.	Mutton or Beef	Potatoes.	Green Vege- tables.	Ghee or Butter.	Oil.	Fruits: Man- goes, etc.	Sweets, Pud- dings, etc.	Milk.	Eggs.	Bread, Bis- cuits, etc.	Muri (Fried Rice).	Soup.	Total Pro- teins in gramme.	Total Calo- ries.
Hindu Bengalis— Rich ..	Quantity in ozs.	4	6	1	4	4	2	4	3	2	4	2	12	115.2	3,289
Middle-class ..	"	16	..	2	2	..	2	6	1	1	4	1	6	72.4	2,837
Poor ..	"	22	..	2	1	..	1	6	..	1	2	1½	..	66.1	3,066
Muhammadans— (Poorer classes)	"	8	8	1	1	2	2	4	..	1	2	2	76.2	2,425
Indian Christians	"	16	..	1	2	2	2	4	½	1	2	1	2	67.2	2,780
Anglo-Indians ..	"	1½	12	4	4	1	..	5	2	2	2	12	..	6	116.4	3,039

This suggests that while the disease is associated with the eating of rice, there is no strict proportion between the quantity of rice eaten and the incidence of the disease. The richer classes eat old rice while the poorer classes eat fresh rice to a preponderating extent, owing to its cheapness.

The Diets of the Persons Affected.

Dr. Bhattacharji and Dr. Paul made exhaustive enquiries into the diets which were in use by the persons who had epidemic dropsy with a view to finding whether there was any observable difference between the diets of the affected and the non-affected who belonged to the same classes of the community.

They were unable to discover any association between diet and the disease except that rice was eaten in considerable amounts by all those who were attacked. There are remarkable variations in the total quantity of rice which was

The general composition of the diets gives no support to the vitamin B deficiency view. The rice in use was parboiled undermilled rice which had been stored for varying periods after manufacture.

The table shows the average composition of the diets of the class of persons suffering from epidemic dropsy; the diets of those who escaped did not differ in any observable respect from the diets of those who were attacked.

Blood Pressure.

The junior author made careful estimates of the blood pressure at various stages of the disease

CHART 4.
Onset of Cases of Epidemic Dropsy in Calcutta.
During 1909.....
" 1924-----
" 1925-----
" 1926-.-.-

consumed; for example the Muhammadans who were heavily affected eat only 8 oz. of rice daily, whereas the poorer Hindus who did not suffer any more severely consumed about 22 oz. of rice. There are reasons for believing that some samples of rice become highly toxic, hence the frequency with which the disease appears soon after the offending rice has been taken into use.

in 218 patients. The results do not justify us in making any generalization on the subject, further than that in the majority of cases there is a slight increase in the systolic pressure in the early stages of the disease while in the severe cases there is a fall in the pressure. The blood-pressure, on the whole, is not of any special significance.

Variations in the Knee-jerks.

Many observations were made on the knee-jerks at various stages of the disease. Taking all degrees of severity of the disease the findings stated in percentages were:

	In-creased.	Normal.	Feeble.	Absent.	Total number examined.
During first fortnight.	60	21	3	16	117
From 15 till 30 days.	52	17	8	23	113
From 1 to 2 months.	48	12	5	35	57
Over 2 months.	38	24	..	38	13

In a few cases knee-jerks which were absent at an early stage were found to be increased in the later stages.

SANDWIP CASES IN SEPTEMBER 1926.

(These were investigated by Dr. Paul.)

Sandwip is an island in the Bay of Bengal about 40 miles by steamer from Chittagong: it is 150 square miles in area and has a population of 1,15,000. The Civil Surgeon, Dr. S. L. Sarkar, and the Health Officer, Dr. B. Gupta, kindly associated themselves with the enquiry into these cases and gave valuable assistance to Dr. Paul.

Forty people were attacked in the largest village, Harishpur (population about 400), only seven families were affected. The onset of the

CHART 5.

Comparative Study of the Monthly Incidence of Cases of Beriberi in Japan and Epidemic Dropsy in Calcutta.

----- Beriberi in Tokio (Mense).
 Epidemic Dropsy in Calcutta (1926).
 _____ " (1909).

In the later stages of the disease there is a tendency to an increase in the number of cases of loss of the knee-jerks and to a diminution in the number of cases of increase of the jerks.

In a group of 55 patients whose knee-jerks were found to be increased in the early stages of the disease, the knee-jerks were absent at some later period in no less than 25, and were diminished in 9 others.

disease was on the 26th September in the first case and on the 20th October in the last, more than half of the cases were attacked within a period of a week from the 10th till the 16th October. In this outbreak rice from several sources was used, no common source of supply could be traced; if rice-intoxication were the cause it must be assumed that several stocks of rice kept at a short distance from each other were

infected with an air-borne micro-organism which had a local distribution.

In every case the rice had been stored for a considerable time after manufacture. In Kalapania village (300 inhabitants) 2 persons in a family of 22 were attacked. The chief supply of rice in this case was home-grown, but for 15 days in July and August, Rangoon rice bought in the market at Harishpur had been used. The disease appeared 5 weeks after they had ceased to use the rice from the market. In Charani Hat village (200 inhabitants) 2 families were affected, all of the members of the 2 families used Rangoon rice from the market of Harishpur. One family consisted of 4 members; all were attacked within 2 days; another family of 6 members had 4 cases, the onset being within a period of 4 days.

The Harishpur outbreak is unusual in that no association could be traced between the use of one sample of rice and the occurrence of the disease, the other two small outbreaks were quite typical in their explosiveness, and in the apparent association with certain samples of rice which had been stored. There were no deaths.

The Sandwip inhabitants live for the most part on home-grown rice, and as usual the disease attacked only those persons who lived on rice which had been stored in the manufactured condition. Mustard oil can be excluded with reasonable certainty as no mustard oil is produced in the island, all the inhabitants use imported mustard oil from the same sources and yet the disease picked out certain families among those who consumed rice from the bazar, the other inhabitants of the island remaining free from the disease.

BOSEPUKUR CASES.

(Observed by Dr. Paul.)

In the early part of the year 1927, several cases were reported from this village (population—118).

The onset was in the first week of December 1926, and cases continued to occur till the end of January 1927. There were altogether 47 cases in a population of about 118 persons. The youngest patient was only 4 years old. There was fever at the onset in 4 cases, diarrhoea at the onset in 27 patients and later on in 5 others, the knee-jerks were lost in 4 cases, slight in 3 and increased in 35 cases.

Precordial pain was complained of by 8 and there was actual dilatation of the heart with systolic bruit in 8 patients. Pain in the calf muscles was complained of by 31, and vascular mottling of the skin of the legs was found in 16 cases. There were 3 deaths. In this locality we found very interesting evidence pointing to the fact that the cases were exclusively confined to the 12 families which used bazar rice from one shop in the village. An apparent exception was in the case of one family of 7 persons in which

3 cases occurred, this family used home-grown rice but they frequently took meals with the affected families. The shop-keeper and his family who were using the same bazar rice but living at a place nearly $1\frac{1}{2}$ miles distant from this place were affected, whereas the other people who lived in his neighbourhood escaped entirely. The members of 5 families in the same village who used rice prepared from their home-grown paddy or rice from other sources all escaped, with the exception of the three persons referred to above; and these had also eaten the rice which is presumed to have been responsible for the outbreak.

Cases of Epidemic Dropsy in Calcutta in 1927.

In Akhil Mistry lane and Kanai Dhar lane in the vicinity of Mirzapore Street—the houses were from 10 to 50 yards apart.

Four households were affected; there were 26 cases; the onset was during the last three weeks of February. The rice used by three of the families was from three different shops; in the fourth family the source could not be traced as the family had left Calcutta. The patients were middle-class Bengalis living in masonry houses and there was no evidence of any intercourse between any two of the families which were affected. In one house all the 11 members of the family were attacked; in another 4 out of 6; in another 6 out of 8; and in the fourth 5 out of 7. There was one death. Most of the cases were of moderate severity.

CASES OF RELAPSE IN 1927.

No cases of epidemic dropsy were reported during the months of March and April 1927, but from May till August, 21 cases of relapse were brought to our notice. Three members of one family relapsed in July 1927 after being free from symptoms for 9 months but in all of the other 18 cases only one person in each of the previously affected families was attacked, the other members of these 18 families remained free from symptoms. Contrary to what usually happens in outbreaks of the disease, there was no evidence whatever of a common supply of rice being responsible for these relapse cases.

The interval of freedom from symptoms since the original attack varied from 7 to 13 months. The symptoms of the disease were the same as usual, e.g., fever in 7, diarrhoea in 12, oedema in all the 21, palpitation in 19, pain in the calf muscles in 18, knee-jerks absent in 3, diminished in 3, normal in 5, and increased in 10. There was one death.

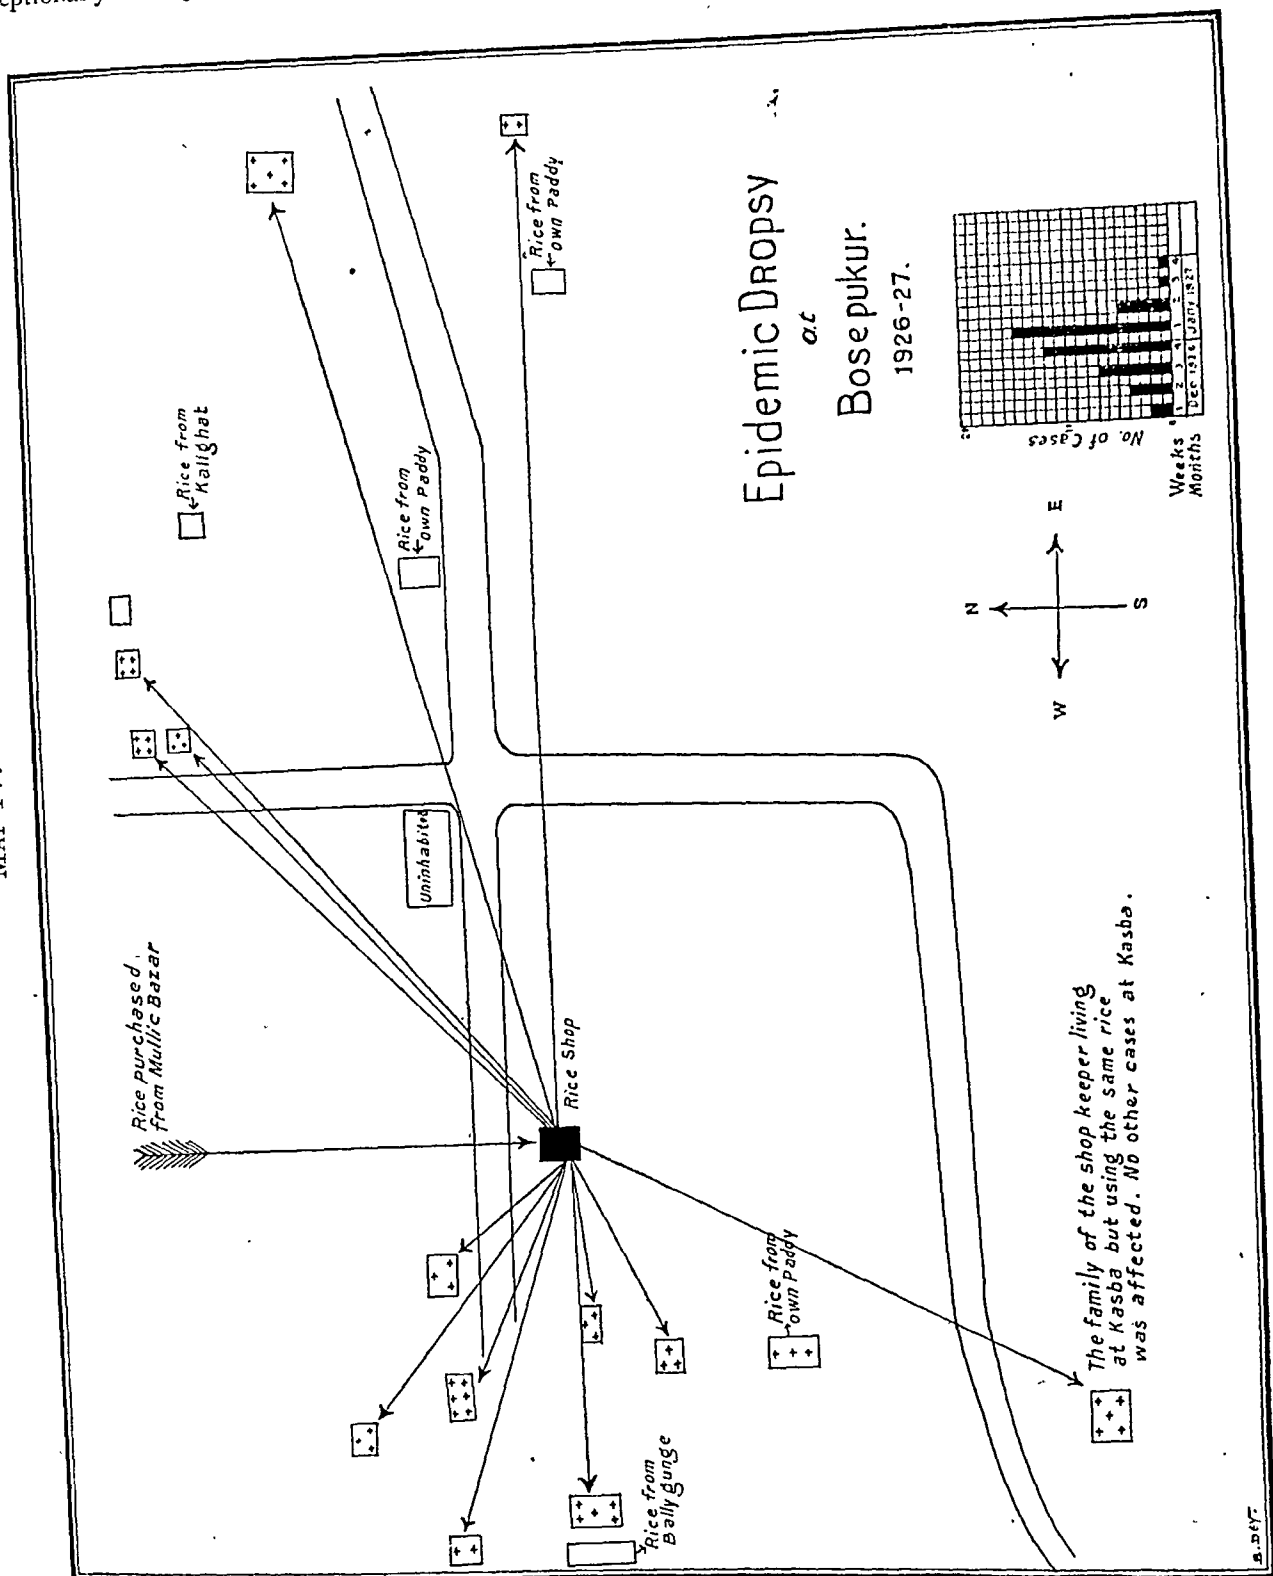

The cause of the relapses is not clear. The circumstances under which these relapses occurred rather tend to support the view that a toxi-infection existed in these cases, whereas the great majority of outbreaks are best explained as being caused by a poison which had been previously formed in the rice.

It is possible, as has been stated in previous papers, that both intoxication and toxi-infection may occur; the data as a whole support the view

that intoxication is the usual factor, toxi-infection being exceptional if it really occurs. It is also possible that the persons who relapsed were exceptionally susceptible to a poison which may

But for the fact that the disease shows so complete a failure to spread by person-to-person communication in places outside the endemic zone it would be natural to assume that these

MAP IV.

commonly be present in small quantities in stored rice, these small amounts being insufficient to cause symptoms in persons whose nervous systems have not been damaged by previous doses of the poison.

persons were "carriers" in whom the symptoms had lighted up again.

The number of observed cases of relapse suggests that such relapses occur in less than 1 per cent. of all cases.

FRESH OUTBREAK IN 1927.

A family outbreak occurred in Garden Reach (Calcutta), in July 1927. All five members of a middle-class Hindu family were attacked within five days. This family had escaped the disease during the 1926 outbreak, although they got their rice from the same shop as their neighbours, about 80 per cent. of whom were attacked. The rice supply was from a neighbouring shop. The diet was in no way different from that which is in common use in middle-class Bengali families. This small family outbreak might be regarded as indicating that the persons who were attacked had escaped the "infection" in the previous year and so had not acquired immunity, but this hypothesis would be directly opposed to the great mass of evidence which is derived from a study of the numerous outbreaks.

HOWRAH CASES IN AUGUST 1927.

(Investigated by Dr. Paul in association with the Health Officer of Howrah, Dr. S. N. Mullick.)

These are of interest as they lend support to the hypothesis of mustard oil intoxication, though they can also be accounted for by rice-intoxication.

(1) A patient who came from a locality in which no other cases occurred was found to have taken his meals at a mess in a mustard oil factory. Five out of eleven persons who fed at this mess were said to be attacked, and it was found that several members of the family of the owner of the oil mill had gone to Calcutta to be treated for dropsy. Further details could not be secured.

(2) Seven families in a lane in the north quarter of Howrah were attacked during the third and fourth weeks of August. They suffered from the usually observed symptoms of epidemic dropsy. 21 cases occurred in 7 families living on the usual diet of middle-class Bengalis. Various kinds of rice were in use, coming from three separate shops; many other persons getting rice from the same shops escaped. All the victims were said to have obtained their mustard oil from one oil factory, and several of the affected persons stated that 5 to 6 days after using a certain sample of oil they suffered from diarrhoea and œdema and later on palpitation occurred. An equal number of other persons using oil from the same source escaped. No evidence could be obtained as to the existence of any adulterants of the oil. The owner of the mill asserted that the other seeds which are suspected of being used as adulterants are quite as expensive as mustard seeds, and that therefore there could be no motive for adulteration of this kind.

The possibility of some accidental and undetected adulteration of the mustard oil with poisonous seeds has to be considered, and if these two outbreaks were the only ones on record there would be good reason for thinking that accidental poisoning by contaminated mustard oil was the cause of epidemic dropsy. The question of mustard oil poisoning will be discussed later.

ENTALLY OUTBREAK IN 1927 (MAP VI.)

This outbreak began on the 2nd of August and lasted till the third week of September.

It was possible to obtain detailed information of the behaviour of the outbreak so that it is reported more fully than most of the others.

The persons affected were (1) middle-class Hindu Bengalis living in good masonry houses, (2) working-class Hindu and Muhammadan Bengalis living in huts, (3) Indian Christians.

Two infants were attacked, one was 7 months old, the other 9 months old; both lived in the same house, both had been given rice occasionally. No infant which was entirely breast-fed was attacked, although several mothers who were suckling their babies were badly affected. The rice supply of all the affected persons came from two rice shops, both of which obtained their rice from Beliaghata rice market. About 90 per cent. of all the persons who used rice from these shops were attacked. None of the twelve persons in two families living in this locality who obtained their rice from other sources was attacked. Several varieties of country (parboiled) rice were used by the affected families. The shops kept small stocks enough for two or three weeks' consumption, the supplies came chiefly from the Beliaghata rice market.

Although several varieties of rice were used it is quite possible and even likely that a certain amount of rice from one common source may have been used in making the "blends" of rice which are sold at varying prices to suit the pockets of the consumers.

It is also conceivable that several samples of rice in the shop may have become infected accidentally at the same time by micro-organisms distributed by the air, and that the conditions of storage were specially favourable to the activity of the chance infection. Mustard oil cannot be excluded with certainty as it is likely that the people bought their mustard oil from the same shops as their rice.

Some of the chief features of this outbreak are as follows:—The houses investigated were 59 with a total population of 332: of these 297 were attacked, males and females in about equal proportion.

The age distribution was—

Under 10	years	51
11 to 20	"	58
21 to 30	"	70
31 to 40	"	73
41 years and over		45

There was thus an exceptionally high incidence in young children. The clinical features of the disease were those usually seen. Out of 297 patients all suffered from œdema, 96 per cent. from palpitation, 81 per cent. from diarrhoea at the onset while only 25 per cent. had diarrhoea at the later stages. At the onset 25 per cent. had fever, while at the later stages about 46 per cent. had fever. The knee-jerks at the time of examination were—absent in 17 per cent., diminished

EPIDEMIC DROPSY IN HOWRAH.

Onset during 3rd. & 4th. weeks of July 1926
all cases broke out within 10 to 12 days.

About 150 people living in the same area
bought their rice from this shop at Dharmatola
None of these were affected

About 100 people bought their
rice from this shop,
of these only Six escaped
all the others were
affected

The only unaffected house in this lane
got its rice-supply from Dharmatola

Affected houses in thick borders
Number of crosses in each house
indicates the number of cases.

This shop supplied rice
to the affected houses
in these two localities.
71/93 attacked.

in 9 per cent., increased in 67 per cent., and normal in 7 per cent. Calf-pain was present in 84 per cent. Precordial pain was complained of by 24 per cent. There was a vascular mottling of the skin in 60 per cent., anæmia in 26 per cent., piles in 11 per cent., and dimness of vision in 4 per cent.

OTHER RECENT EVIDENCE.

Dr. G. Ghosh of Allahabad has kindly shown me a paper which he is contributing to the *Indian Medical Gazette*. The paper deals with the Allahabad outbreak of 1927, which has already been described in the *Indian Medical Gazette* of April 1928 by another former student of the senior writer Dr. R. N. Banerji. Dr. Ghosh's paper throws new light on the outbreak and is one of the most important recent contributions to the subject of the ætiology of epidemic dropsy. When Dr. Banerji sent us his report on the outbreak it occurred to us that rice from Bengal might have been responsible, as the disease was almost confined to Bengali residents of Allahabad and its occurrence after the subsidence of the Calcutta outbreak suggested that some dealers might have disposed of their stocks of rice to a distant market.

Dr. Banerji was unable to obtain any information regarding the importation of rice from Bengal, but Dr. Ghosh now supplies categorical evidence that large consignments of rice were received from Bengal by those Allahabad merchants who supplied the dealers from whom the Bengalis of Allahabad bought their supplies. These consignments arrived early in January 1927, and the disease broke out about a month later.

The other facts reported by Dr. Ghosh can hardly be explained on any other hypothesis than that of rice-intoxication. Allahabad is a place in which epidemic dropsy is uncommon, though a very interesting family outbreak occurred there about ten years ago which was described by Dr. R. N. Banerji and myself in the *Indian Medical Gazette* of February 1923.

LT.-COL. TAYLOR'S MEMOIR ON BERIBERI IN BURMA.

After the present paper had been written a very interesting number of the *Indian Scientific Memoirs* by Taylor, Martin and Thant appeared (March 1928). This has a very important bearing on the relationship between epidemic dropsy and beriberi and it may be stated at once that there is not a single statement in the memoir which would not apply with equal relevance to the discussion on epidemic dropsy in Bengal.

While we do not agree in every detail with the views of the authors our differences relate merely to the interpretation of their observations and not in the slightest degree to the observations themselves. Incidentally the same remark applies to the valuable reports on beriberi in India by Lt.-Col. McCarrison. Every observation which has been made by him on the beriberi of India

appears to us to be equally applicable to epidemic dropsy, and the differences which exist between Lt.-Col. McCarrison and ourselves relate entirely to our interpretations of the facts.

Col. Taylor and his colleagues do not deal with the clinical manifestations of the outbreaks of beriberi which they discuss, unfortunately they had little opportunity of observing patients and so were compelled to deal with the records which were available. But it is certain that their observations relate to the commoner forms of beriberi of the Far East.

The authors suggest that some of the school outbreaks which they deal with may have been of epidemic dropsy rather than beriberi, the reasons given being their greater explosiveness and the large percentage of the attacks. These are hardly sufficient grounds for differentiating between the two diseases as beriberi is often explosive and may attack most of the inmates of an institution.

The question of diets is very carefully studied, but in most cases the authors have to rely on diet scales and the usual dietaries of the classes of the community which are affected; the actual foodstuffs which were consumed before the onset were, of course, not available.

Some important generalizations could be made such as:—

1. The disease is essentially one of persons in the larger coastal towns and of small communities like labour camps, schools, jails, light houses, etc.

2. The disease attacks persons whose diet consists largely of rice which had usually been stored for considerable periods either in the husked or unhusked condition.

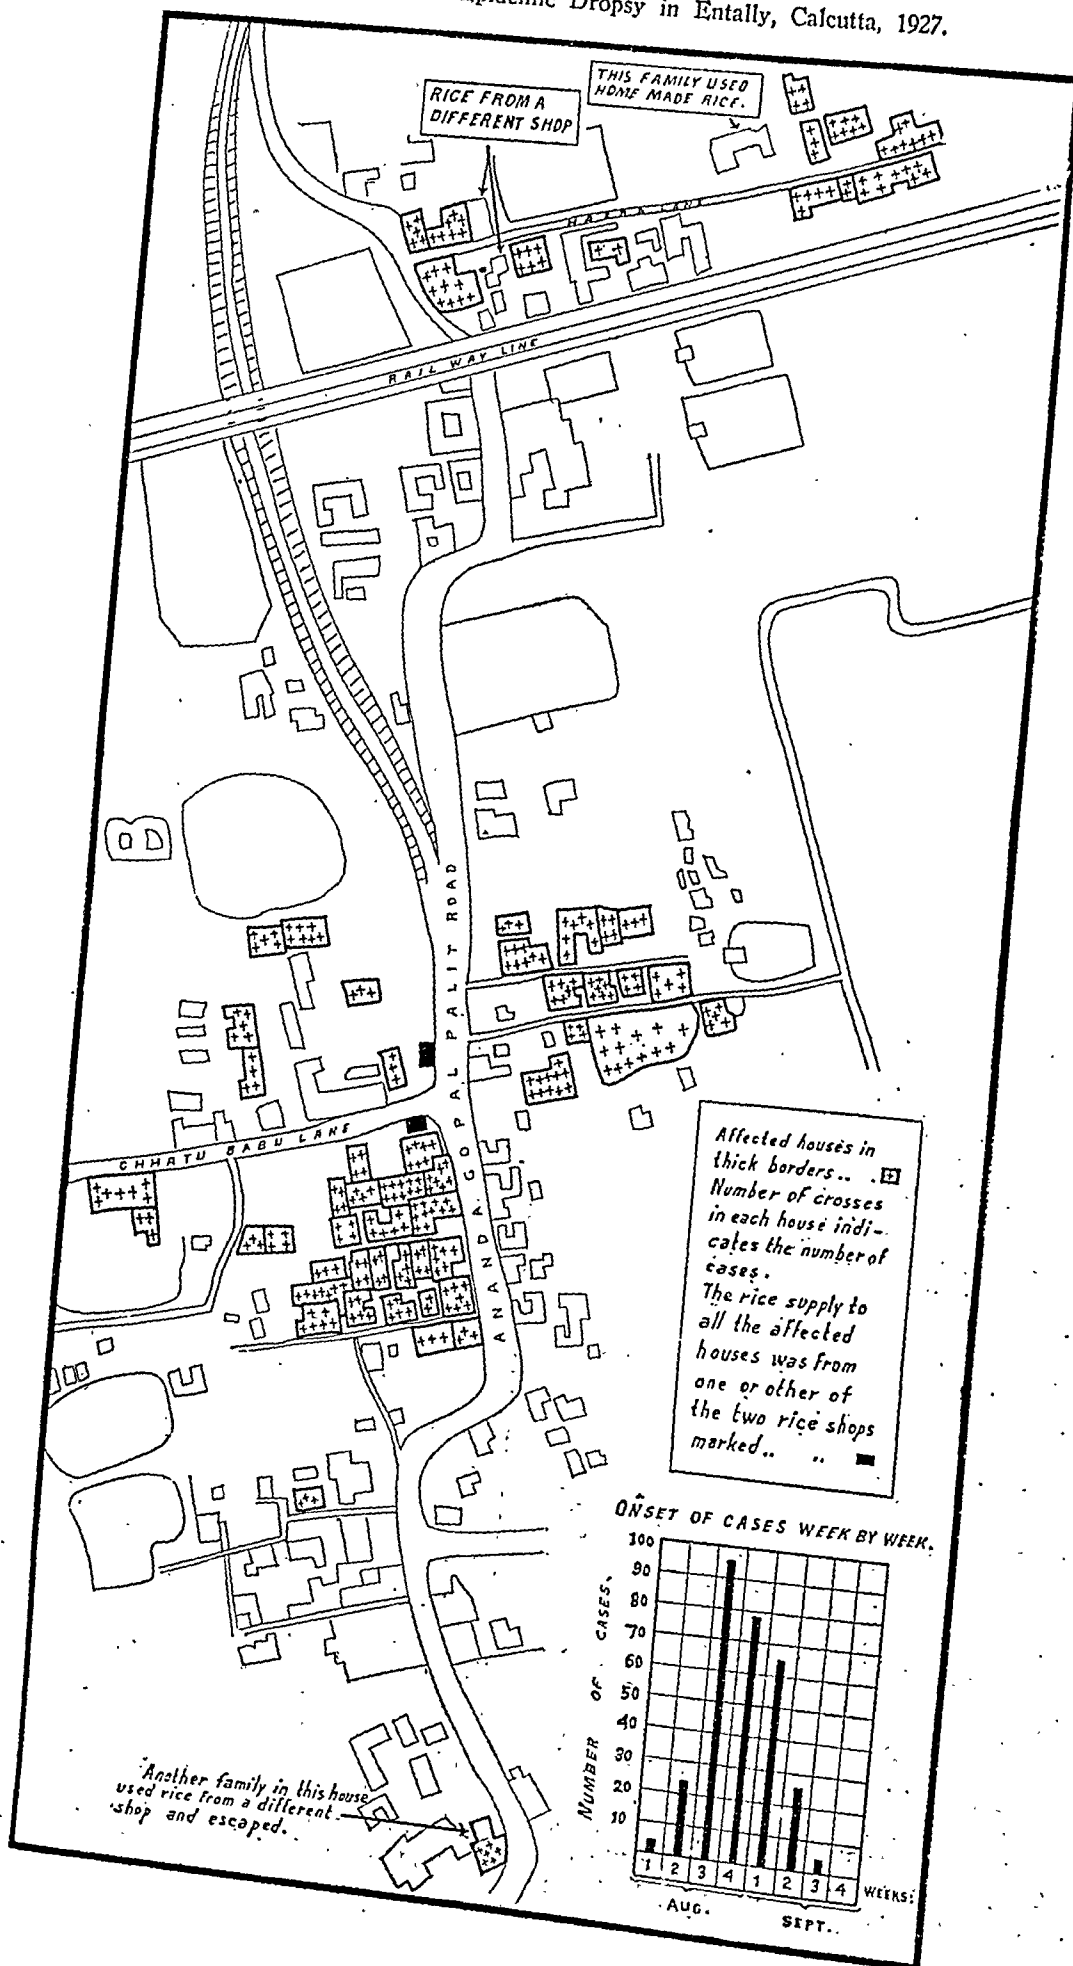

3. Deterioration of rice from damp and moulds appeared to the authors to be a very important factor in the outbreaks which they investigated; they are unable to decide whether a toxic substance is produced or whether the necessary washing of the mouldy rice causes a loss of vitamin content in the rice.

4. There is a definite seasonal prevalence commencing about two months after the breaking of the monsoon with a diminution during the cold weather months.

The authors evidently attach considerable importance to the vitamin content of the diet, but the numerous diet scales which are given do not suggest a deficiency in vitamin B; most of them contain a good proportion of *ata*, *dal* and fresh vegetables. In a school at Mowlaik in which an outbreak was observed in 1927, the diet was rice 1 to 1½ lbs. daily (hand-pounded but liable to deterioration from storage), *dal* 2 to 3 oz. a week, beans 2 to 3 oz. a week, fresh vegetables 4 to 12 oz. a week, meat 20 to 24 oz. a week, fresh fish 3 to 4 oz. a week, milk 7 to 14 oz. a week, fruit 14 to 21 oz. a week.

It is difficult to believe that severe avitaminosis could result from such a diet, or from most of the other diets which were in use by the persons who had the disease. A perusal of the memoir

MAP VI.
Outbreak of Epidemic Dropsy in Entally, Calcutta, 1927.

creates a strong impression that storage of the rice under unfavourable conditions and the formation of a poison in the rice is far more likely to be the universal causal factor rather than vitamin B deficiency.

In some of the outbreaks the diet was seriously defective in several respects, but in others the diets were less open to criticism than those of many millions of people in India in places where beriberi is entirely unknown.

The vitamin deficiency view has to be stretched to incredible limits before it can be made to embrace all the outbreaks which have been described.

In the forest camps the association of the disease with storage was exceptionally definite, the disease occurred among users of both hand-pounded and milled rice, but only when it had been stored for some time under unfavourable conditions; no cases were seen among the people who used either milled or hand-pounded rice which had been protected from adverse conditions during transport and storage.

The greater incidence of the disease among the persons whose diet consisted chiefly of large quantities of rice is not inconsistent with the rice-intoxication view, as the person who eats one pound of poisoned rice will ingest twice as much poison as the person who eats half a pound; besides, the person who eats larger amounts of wheat, beans, etc., will have better nourished and more resistant tissues than the one who eats little else than rice.

The important point is that Col. Taylor and his collaborators are firmly convinced of the necessity for attending to the proper storage of rice: if this fundamental principle is agreed to, it does not matter much whether the disease is an intoxication or whether it is caused by vitamin deficiency resulting from damage to the rice during storage.

The conditions under which beriberi occurs in Burma are remarkably similar to those in which epidemic dropsy breaks out in Bengal, the two diseases cause similar effects on health, and their prevention can be secured by exactly the same methods.

The memoir greatly strengthens our belief that epidemic dropsy belongs to the same disease group as beriberi and that both diseases are caused by rice-intoxication.

DISCUSSION OF THE OUTBREAKS DESCRIBED IN THIS PAPER.

Most of the outbreaks which have been described in this paper can only be explained on the hypothesis that the rice in use by the patients had in some way become poisoned during the period of storage, yet there are some observations which if taken by themselves would point to other possibilities, notably mustard oil poisoning and infection.

The Howrah (1927) outbreak, on the facts as stated by our informants, cannot readily be explained on the rice poisoning hypothesis and it

was obvious that the victims themselves firmly believed that one sample of mustard oil was to blame: it is just possible that their belief may have been due to a suggestion which gave rise to a mental bias and that the evidence which they gave may have been affected by that bias.

The Garden Reach outbreak of 1927 might be regarded as showing that immunity is established by a previous attack, while the relapses seen in Calcutta in 1927 are somewhat suggestive of the existence of carriers of infection.

These are concrete examples of the conflicting nature of the evidence which is obtained when we investigate the conditions of occurrence of a number of outbreaks of the disease, and it is obvious that a medical man who has only seen a single group of cases is liable to be strongly influenced by his own personal experience. In our discussion we take into account not only the numerous outbreaks observed by ourselves but also those recorded by others, as we believe that it is only in this way that the problem can be viewed in its true perspective.

It is impossible to reconcile every reported circumstance with any one hypothesis. The maps and the statements of the evidence which has been obtained, indicate that epidemic dropsy in Bengal has the following features:—

Epidemic Dropsy in Bengal.

1. It resembles other diseases of the beriberi group so closely that it cannot be separated from "beriberi," and therefore it may be classed provisionally as the "epidemic dropsy form of beriberi." At the meeting of the Far Eastern Congress of Tropical Medicine in Calcutta in December 1927, Lt.-Col. Vedder and Lt.-Col. McCarrison were shown the data which had been collected by us during the past few years; neither of them was able off-hand to suggest any criterion by which it is possible to form a separate disease group for epidemic dropsy as distinguished from beriberi. For these reasons it must be emphasized that when we use the name "epidemic dropsy," we do not imply that we are dealing with a special disease which is peculiar to Bengal.

2. It is a disease, essentially of rice eaters, the rice in use being usually parboiled undermilled rice.

3. The outbreaks of the disease are usually explosive.

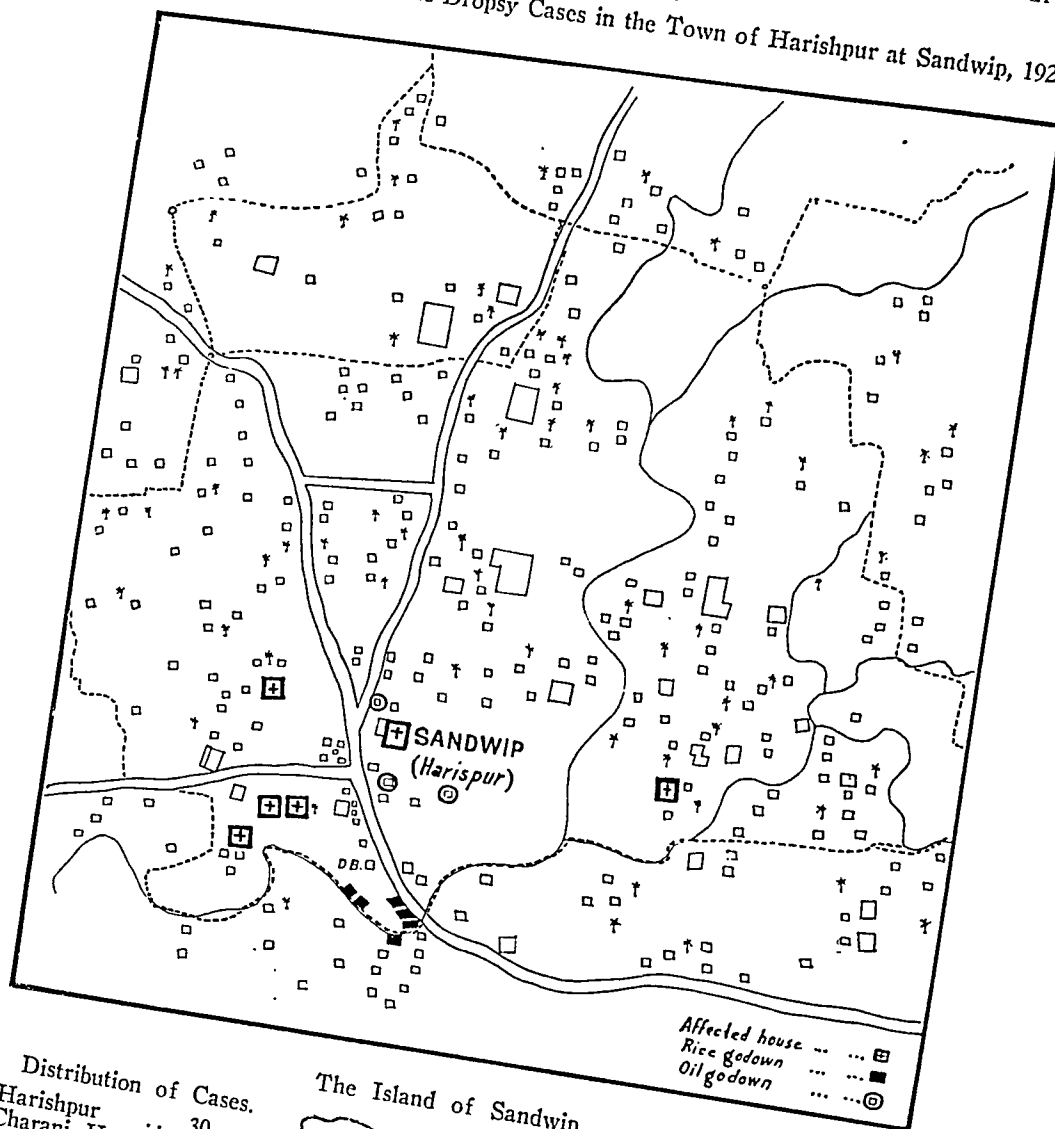

4. The disease almost always selects persons who have been using a stock of rice from a common source, though in a few outbreaks it has attacked several families living in the same locality in such a way as to suggest the possible presence of an air-borne organism which attacks the rice supplies of the neighbourhood.

5. The rice has almost invariably been stored in a hot and damp place for a considerable time after manufacture. Users of home-grown rice stored as paddy and prepared in small quantities for use are so rarely affected that the storage of paddy can be regarded as being almost without

risk, though it is desirable that paddy also should be stored under good conditions.
6. The only other foodstuff which is under suspicion is mustard oil. There have been a few outbreaks which, on the available evidence, are

ing can be completely excluded, in no case can rice poisoning be ruled out.
The distribution of the disease rarely fits in with the distribution of any common supplies of mustard oil, and as epidemic dropsy is so similar

MAP VII.
Distribution of Epidemic Dropsy Cases in the Town of Harishpur at Sandwip, 1926.

Distribution of Cases.

Harishpur	.. 30 cases.
Charani Hat	.. 8 "
Kalapania	.. 2 "

Cases occurred only among those who used imported rice, no cases among those using the locally produced rice.

The Island of Sandwip.

The supply of mustard oil came from Calcutta through three intermediate dealers who had their shops in Harishpur. The people all over the island used this oil.

most readily explained as being caused by a poison contained in mustard oil. The evidence which is opposed to the mustard oil view is so strong that we cannot accept these exceptional occurrences as having any important bearing on the problem. In many cases mustard oil poison-

to beriberi, it is inherently probable that the two diseases should also resemble each other in aetiology.
It is very unlikely that the Far East should have two very similar diseases which affect rice eaters, and that one of these should be associated

with rice while the other is associated with a very different substance.

Lt.-Col. Greig has already investigated and ruled out the mustard oil theory, and our own observations are in complete agreement with his.

7. The incidence of the disease does not suggest that the poison is usually present in rice, but rather that certain samples which may be sharply restricted contain the poison.

8. No association with any diet deficiency can be detected; the diets of the affected persons did not differ in any observable manner from those of their unaffected neighbours, nor did they differ from the diets in use by the affected persons before the disease appeared and after it had disappeared. In other words the diets were "the same," using the word "same" in the usual accurate manner in which it is usually employed by writers on beriberi. Of course, we regard the offending diet as being quite different from the normal diet though the difference is not one which is apparent if we deal merely with lists of articles of food or even with a casual inspection of the food. In food poisoning of various kinds, the foodstuff often looks and tastes exactly like wholesome food even in the case of such deadly intoxications as botulism.

It is impossible to believe that the disease could be caused by a deficiency of vitamin B; the explosiveness and the nature of the symptoms in themselves are enough to exclude this theory.

9. The evidence is very strongly opposed to the view of a person-to-person infection. There are one or two outbreaks in which at first sight the disease appears to have spread by infection, but these occurred in places where the disease was endemic at the time. Questionnaires were sent to more than a hundred doctors in Madhupore, Benares, Deoghur, Giridih and other places to which large number of patients went for a change while they were still suffering from the disease. In no case did we obtain evidence that the disease was communicated to other persons in these places. This point, also, has already been carefully investigated by Lt.-Col. Greig and our experience is entirely in keeping with his findings.

We have invariably found that persons who are suffering from the disease made a prompt recovery in every case in which they are put on a rice-free diet at an early stage of the disease; whereas if we had been dealing with an infection, the disease would be expected to run a course uninfluenced by diet. In severe and advanced cases in which irreparable damage has already been done to the tissues, improvement does not occur, nor can it be expected to do so.

10. In most cases the evidence points strongly to the existence of a preformed toxin in the rice, but there are some carefully observed cases in which it appears that the poison may continue to be formed in the intestine if a rice diet is allowed.

We do not exclude the possibility that a "toxi-infection" may occur as well as an intoxication. In this respect, also, the disease may be analogous to some other kinds of food poisoning.

11. We do not express an opinion as to the micro-organisms which are concerned in producing the poison. These may be the bacteria which were isolated by Lebrede, Acton and others. We do not know whether the bacteria are normally present in stored rice or whether they are accidental contaminations as is the case with other food poisons. The place distribution of the disease suggests that an air-borne infection of the rice may occur in some outbreaks, and the manner in which certain ships and jails are affected year after year suggests that the store rooms in which the rice is kept may become infected with organisms which attack each fresh stock of rice.

The Prevention of Epidemic Dropsy and Beriberi.

We have already admitted that there are still many points with regard to which further investigation is needed.

The whole problem of the beriberi group of diseases still bristles with difficulties, but the more we investigate epidemic dropsy, the more firmly convinced are we that it is possible to lay down certain rules for the prevention and cure of the disease. These rules are not based on debatable opinions, but on extensive observations by ourselves and others. We have never encountered a case of the disease in a person who has lived on rice freshly prepared from paddy which has been stored under favourable conditions, nor in a person who has eaten carefully stored rice made from properly stored paddy.

RULE I.

We therefore insist on the rule that epidemic dropsy can be controlled by the use of rice which has been properly stored at every stage after harvesting.

We believe that the same will be found to be the case with the most important other forms of beriberi.

This rule can be accepted all the more readily because it is based on the dictates of economy and common-sense, apart altogether from its bearing on the causation of epidemic dropsy. The foodstuff of many millions of the human race ought to be properly stored, especially after it has been killed and mutilated in the process of manufacture.

When we include all forms of "beriberi" in our survey we admit that vitamin B deficiency and other dietetic deficiencies may play important parts in the causation of beriberi and other diseases, so that we willingly add a second rule.

RULE II.

The diets of all persons should contain sufficient quantities of all the nutritional elements, including the necessary vitamins.

We cannot conceive that any rational person will take exception to either of these rules, whatever may be his views on the relationship between epidemic dropsy and beriberi, or on the causation of these diseases.

If both of these rules are accepted and acted on, we believe that the beriberi-epidemic dropsy problem will cease to be urgent; it will become an interesting academic study for curious and ingenious investigators.

Incidentally, we believe also that the problem of pellagra ought to be studied on the same lines; vitamin deficiency is now being emphasized to the exclusion of other aspects of the disease; storage of maize may be the clue to pellagra, and even if this is not the case, there should be no hesitation in adopting rational measures for the preservation of maize and maize products at every stage from the harvesting of the grain.

Our attitude towards vitamin B has never been of the nihilistic kind that has been attributed to the senior writer by some authorities. Vitamin B deficiency ought to receive its fair share of attention, but it should not be allowed to obsess our minds to such an extent that we refuse to admit the possible existence of other factors in beriberi-epidemic dropsy, pellagra and other diseases associated with diets.

"EMERGENT SURGERY" IN HEAD INJURIES.

By K. M. NAYAK, L.M. & S.,
Assistant District Medical Officer, Vellore, North Arcot.

"A SCALP wound properly cleansed, antiseptised and drained, represents in a highest degree the possibilities of good surgery," writes Donald J. Armour; "a scalp wound improperly cared for, covered with hair and matted blood, and its extent undetermined, represents one of the worst forms of surgical neglect." This statement is so true that it requires no further elaboration. Although, in my fifteen years of service, I have not seen very numerous cases of head injuries, yet in 1927, a particularly large number of such cases presented themselves at this hospital, and an account of them may raise points of considerable interest.

Lejars, in his "Urgent Surgery," states that the medical practitioner should always be ready for emergency surgery, but how many men keep their equipment for such work in good condition? Only too often are important instruments allowed to get rusty, or jumbled up in a bag with dressings, chloroform, stethoscope, and thermometer. When the emergency arises, the instruments are not fit to use, are rusty and may break. One would state that the following instruments at least

are essential, and that they should be kept separately, and frequently examined to see that they are in good condition.

Cutting Instruments.—Two or three scalpels, two pairs of scissors—straight and curved, and a pair of Liston's bone forceps, angled on the flat. Alcohol, chloroform or petrol may be used to ensure their absolute cleanliness after use; their edges should be perfect, and they should be kept lightly smeared with vaseline. Two grooved directors—one grooved to the tip and the other probe-pointed; one pair of dissecting forceps, another pair with teeth; two double-ended retractors are also essential. An emergent surgeon's safety lies in the number of artery forceps which he possesses, and for work on the head one can hardly have too many; whilst it is as well to complete the series with six pairs of Kocher's artery forceps. Two hand trephines, one of half an inch diameter, and one three-quarters of an inch diameter are also essential.

An aneurysm needle, one or two pairs of volsellum forceps, a curved periosteal elevator, a raspator, a gouge forceps, a chisel and mallet, are all necessary.

Ligatures and Sutures.—Here it is absolutely essential to use only the very best and most reliable material. It is as well to have catgut, silk, linen thread, and silkworm gut. If catgut properly prepared and sterilised beforehand is not available, it is better to dispense with it.

Needles.—Ordinary straight and curved needles of different sizes are all that are needed. Half curved ones are sometimes useful, but often give more trouble than real help. Fixed needles mounted in handles, such as Doyen's, are extremely useful in suturing the scalp. Michel's clips are even better, and give great precision and exactness in apposing the cut edges.

No wound of the scalp should be regarded as unimportant, and it is essential thoroughly to clean, disinfect and explore the wound. "Excluding some cases where there has been considerable loss of tissue, hernia cerebri is almost invariably due to inflammatory causes, and asepsis is the best means of preventing it," writes Lejars. Anaesthesia should be resorted to freely, and especially in the case of children, in whom it is frequently impossible to explore a scalp wound properly without a general anaesthetic. Continuous irrigation of the wound with normal saline at a temperature of 110° to 115°F. is often very helpful. The use of a tourniquet, fixed tightly round the head across the forehead, just above the ears, and beneath the occiput, is useful in controlling hæmorrhage, and is too often neglected. The importance of shaving and disinfecting a wide area of the scalp surrounding the wound, lies in the fact that it facilitates the thorough and satisfactory examination of the wound in all its depth. Provision should always be made for drainage. In cases of general oozing from the scalp edges and from the pericranium at the bottom of the wound I have always found hydrogen peroxide very useful, for it is a hæmostatic

as well as an antiseptic. The supposed danger of air embolism from the use of this drug is a myth, and I have often used it freely.

Every attempt should be made to save as much of the scalp tissue as possible, for the great vitality of the scalp tissues is a powerful factor in repair. In one of my cases almost two-thirds of the skull was completely denuded of scalp tissue, but luckily for the patient the scalp was hanging by a pedicle half an inch wide. I simply cleaned the whole flap and skull with nothing but warm sterile water, and then carefully sutured the whole flap back into position, with four gutter drains at the corners. On the sixth day, when the stitches were removed, the union between the edges was perfect. Cases are even recorded where the completely torn-off scalp has been thoroughly cleansed and replaced in position with a few sutures, leaving very free drainage, and where the implantation has succeeded.

Compound Fractures of the Skull.—In this connection, certain points are important. A linear fracture should be thoroughly opened up. Sometimes a sharp, clean cut edge of the epicranial aponeurosis, or even the cut edge of the pericranium itself, may give the impression that the bone underneath it is fissured, but careful examination will show that it is not. I have myself been misled in this way on two or three occasions. Acute infective osteomyelitis is a rare, but dangerous complication of such cases, leading to the appearance of "Pott's puffy tumour," with high fever and rigors. The bacterial infection in these cases is not always necessarily from the external wound, but may occur by auto-infection, just as a hæmatoma may sometimes suppurate in a much-debilitated patient. In some rare cases, infection may occur from the middle ear.

Where there is a fissured fracture of the outer table, always suspect the presence of more extensive damage to the inner table. To examine the fracture with a probe is a dangerous and ineffectual proceeding; it gives one but very little information, and may spread infection. It is usually necessary to open up with the chisel and mallet and lay bare the *diploë*. If a gaping fissure is present, with the margins at different levels and blood continuously flowing from it, or if a star-shaped depression or a localised crushing of the vault is present, then the best line of treatment is by means of an osteoplastic flap, or, failing this, a trephine hole should be made and the extent of damage to the inner table explored. All irregular fragments must be carefully removed. Do not simply raise them and leave them in place. Never try to tear them out or lever them out from one edge; the dura may be torn or the brain compressed or lacerated by such manœuvres. Seize the fragment transversely about the middle, and raising it gently, separate the underlying dura with a curved elevator or dissector.

If the dura is torn, the cavity should be very gently cleansed with small gauze or wool swabs

on the end of a pair of forceps. Bleeding cortical vessels should be ligatured by passing a ligature on a fine curved needle underneath them. The dura should not be completely closed, and drainage should be provided for. In cases of compound fracture of the skull with depressed bone, operation should be undertaken at once, whether focal cerebral symptoms are present or not. In cases of comminuted fracture, or where a large segment of the skull has been driven in, when the fragments—usually triangular or star-shaped—remain locked together, the attempt should be made to raise by one of its edges that fragment which appears to be the most detached and most moveable. After the first fragment is removed, the others can usually be dealt with easily. Below the layer of superficial splinters will be found the layer of deeper fragments. These should be raised gently, separating the underlying dura mater with a curved elevator or a director; they should never be torn out. Wherever necessary, make more room by the gouge forceps, as the extraction of endocranial scales is of the utmost importance for future recovery.

Trephining should not be regarded as a highly specialised operation and dangerous proceeding, which only specialists should carry out; for it is often called for in emergent surgery. The specialist may make use of the electric burr, or the brace and burr, either Hudson's or Doyen's, or even Albee's saw method, but the ordinary practitioner must be able to deal with the ordinary case. The trephine which I have always successfully used is the ordinary hand—or so-called "crown" or "circular"—one. It is inexpensive, slow in operation—perhaps—but always obtainable, steady, and sure. In trephining, safety perhaps counts for more than any other factor, and the hand trephine is safer in the hands of the novice than the more complicated instruments. The instrument, however, should be of the best possible description and of small diameter, half or three-quarters of an inch, sharp edged, and fitted with a heavy handle. On striking the inner table of the skull special care is required, as rough or unequal trephining may lead to injury to the dura mater, meningeal arteries, etc. It is very debatable whether the brace and burr pattern presents any real advantage over the ordinary hand trephine, with the possible exception that it may afford some additional safeguard against damage to the dura mater. Experience alone will decide which method appeals best to the operator.

Cranicectomy.—Before applying the craniectomy or enlarging forceps, the dura mater must be separated from the bone. The action of the forceps should be a nibbling one, and no attempt should be made forcibly to avulse fragments. The fragments removed by the trephine and the enlarging forceps are useless for purposes of bone regeneration, and are actually dangerous in the event of sepsis. Where a fragment of bone is completely detached all round, simple elevation of it is unsatisfactory, as it may subsequently

cause either sepsis or compression symptoms, and it should be removed. On the other hand, it is necessary to guard against any greater denudation over the surface of the brain than is absolutely essential.

Hæmorrhage is a constant source of trouble in these operations. In hæmorrhage from the *diploë*, the use of Horsley's "bone wax" may be useful. Its composition is as follows:—

Vaseline	50 parts.
Paraffin	50 parts.
Acid carbolic	50 parts.

A meningeal artery is best dealt with by passing beneath it a ligature on a fine curved needle, and the same procedure may be applied to a cortical vessel. For general oozing, hydrogen peroxide is very valuable. Every endeavour must be made to ascertain the source of the hæmorrhage; for bleeding from a sinus immediate occlusion with a finger is indicated, then a prompt attempt should be made to underpin it with a ligature in a curved needle, though the pressure in tightening the ligature must be very gradually applied; or, finally, plugging may have to be resorted to. On two or three occasions, I have had to resort to plugging; once, when operating for mastoid abscess, I opened the sigmoid sinus, on which occasion I removed the plug on the third day, found the wound quite dry, and the patient made an uneventful recovery. Where the source of the bleeding cannot be ascertained, irrigation with hot saline at 115°F. is often a useful measure, followed by plugging.

No operation for compound depressed fracture of the skull should be considered complete until the depressed fragments have been elevated or removed, the hæmorrhage checked, and the entire exposed area cleansed and disinfected.

The respiratory centre is very nicely balanced, and it may fail in the early stages of administration of the anæsthetic. If so, trephining must be carried out rapidly, and artificial respiration commenced. The use of x-rays is often helpful in estimating the thickness of the skull; in the temporal and cerebellar regions in adults, and in the skulls of children, the bone may be unusually thin, and in such cases the pin of the trephine should be discarded earlier than usual. In bandaging, even pressure over the whole area should be aimed at, and it is often not necessary to bring the bandage over the chin. On returning the patient to bed, he should be placed in the semi-recumbent position with the head thrown slightly backwards, reclining on pillows. The administration of morphia previous to operation is often helpful in preventing restlessness, pain, and excitement after operation. It is often helpful to keep the patient under the influence of morphia for 24 to 48 hours after the operation, or bromides or chloral may be given. Stitches should be removed on the sixth or eighth day (since wounds of the scalp heal very rapidly, and more so than wounds elsewhere in the body), but

the patient should ordinarily be confined to bed for three weeks, and special care should be paid to the avoidance of post-operative constipation.

With regard to the question of when to operate, it is clear that a patient in a condition of profound shock is not a suitable subject for instant operation. Morphia should be given, and he should be allowed to pass into the stage of reaction before operation is carried out. On the other hand, too much delay is fatal. The period of immediate shock does not usually last more than twelve hours, and the onset of symptoms of compression is marked by a slow pulse, low blood-pressure, Cheyne-Stokes' respiration, and profound unconsciousness. Attention should be directed, not so much to ascertaining the presence or absence of a fracture of the skull and its location, as to the degree and extent of the damage to the brain.

In selected cases, lumbar puncture should always be carried out. It is a most useful aid to diagnosis in doubtful cases, as the presence of blood in the cerebro-spinal fluid may confirm the diagnosis of fracture of the skull. On the other hand, the presence of blood in the cerebro-spinal fluid merely denotes bleeding from an intradural vessel, with or without a fracture of the skull, and the absence of blood does not exclude an intracranial hæmorrhage. Where initial stupor persists and the patient remains unconscious, with laboured respiration and slackening pulse, 15 to 20 c.c. (5 to 6 drachms) of cerebro-spinal fluid should be withdrawn as a therapeutic measure. This may be repeated the next day, whilst daily removal of 15 to 20 c.c. of fluid often gives great relief to cases characterised by headache, nausea, dizziness, stupor, and restlessness. Lumbar puncture, however, can never take the place of a decompression operation.

With regard to the complications arising after operation, but little can be done for cases of meningitis, encephalitis, and ventriculitis. Acute abscess of the brain after operation is usually due to the retention of some foreign body, whether fragments of bone or some piece of stone driven into the wound from a fall. Removal of the foreign body and free drainage are essential. *Hernia cerebri* is a difficult condition to deal with; often lumbar puncture is useful in such cases, or a fresh decompression operation may have to be undertaken. The formation of scar tissue in the cerebrum may lead to insomnia, fits, paralysis or spasticity. It should always be borne in mind that the surgeon is responsible, not only for the immediate future of the patient, but for his later working capacity, and a depressed fracture which has not been properly treated, or a blood clot which has not been removed, may lead to irreparable injury in future years.

In general, one may say that these cases should be operated on at the earliest possible moment (after shock has been alleviated). Unless the surgeon is fully convinced either that the injury is an undoubtedly fatal one, or so trivial that it

can be ignored, it is his duty to explore the nature of the injury very fully; to administer a general anæsthetic whenever necessary and to remove all sources of irritation. These cases are not—as is so often supposed—minor ones; they may be amongst the most important ones in the general practice of surgery.

APPENDIX: ILLUSTRATIVE CASES.

Case 1.—Male patient, aged 40, a criminal lunatic. He was drying his clothes after washing them when a second criminal lunatic in the same asylum suddenly seized an iron bar from the smithy, and commenced to attack all and sundry whom he met. Three persons escaped with trivial injuries, and two had their heads smashed and converted into a pulp, and died on the spot. The sixth was the patient referred to. He had a compound depressed fracture in the right temporal region, was completely unconscious, and had complete paralysis of the left side of the body. The pulse was full and bounding, and the respiration laboured, deep, stertorous, and of Cheyne-Stokes type. At operation, a piece of the right temporal bone about the size of a quarter-anna piece was found depressed, and jammed down on to the brain beneath. The middle meningeal artery had to be ligatured, the depressed piece of bone removed, and a large extradural clot turned out. The dura mater was fortunately intact. Continuous irrigation with hot saline was applied during the operation, and free drainage provided.

The patient was conscious the day after operation, and the paralysis had disappeared. The wound healed by first intention. I saw the patient six months after operation, when he was perfectly fit and had developed no untoward symptoms and showed no signs of hernia cerebri.

Case 2.—A male coolie, aged 35, was gored by a bull. This injury is a common one in these parts, and is usually to the abdomen, but in this instance it was to the head. On an average we get some six to nine such cases a year,—often with the viscera protruding and wrapped in filthy clothing,—yet such is the resistance of the peritoneum that very few of them die.

In this instance nearly two-thirds of the scalp had been removed, and was hanging by a pedicle half an inch wide in the occipital region. The almost torn-off scalp was thoroughly cleansed, replaced in position, a few sutures inserted, and free drainage provided. The wound healed by first intention, and the patient made a sound recovery.

Case 3.—Male coolie, aged 38, was digging at the bottom of a well when a piece of wood from the well head fell and struck him. On admission there was a lacerated wound some 3 inches long over the vertex, with a gutter-shaped fracture at its bottom. He was fully conscious. On operation, it was found that both parietal bones were involved in the depressed fracture, and the sagittal suture lay in its floor. The inner tables of both bones were found to be intact on trephining, but blood was oozing from the superior longitudinal sinus. This was controlled by pressure, and the patient made an uneventful recovery. He left hospital fifteen days later, but whether he developed a hernia cerebri or not, I do not know. It seems improbable.

Case 4.—A boy of 10 years of age who was stated to have fallen about 10 feet from the plinth of his house. On admission he was unconscious, with a temperature of 102°F., and a lacerated wound in the right temporal region. At operation, a depressed fracture of the right temporal bone was found. The middle meningeal artery had to be ligatured. The dura mater was intact. The patient made an excellent recovery, and five years later was in good health.

Case 5.—This is a case, which is of interest from the medico-legal point of view. The patient, a wealthy landlord, aged about 50, was attacked with *lathis* in a riot. He had no less than 32 injuries on admission, most of them on the trunk. There were one or two contusions on the head; however. On admission, he was

suffering from shock, but regained consciousness the next morning and was able to talk. The next day he became very irritable and restless and lapsed into a semi-conscious condition. A lumbar puncture was done and 25 c.c. of cerebro-spinal fluid removed. This was slightly blood-tinged. For the next three days the patient was conscious and appeared to be recovering rapidly. On the fifth day after injury, he complained of very severe headache. Lumbar puncture was again carried out, and 20 c.c. of fluid removed; this immediately cured the headache. Unfortunately, he now developed hypostatic pneumonia, and died on the seventh day after injury.

On the second day in hospital, the deceased had what was rather like an epileptic fit. At post-mortem a small blood clot, about the size of a quarter-anna bit, was found in the region of the right middle meningeal vein. The artery was intact. The skull bones were intact and there was no basal fracture. Being a rather obese subject, he had a certain degree of fatty degeneration of the heart.

The case was tried in the lower court, where 14 persons were put on trial as possibly concerned in the riot and in the death. The defence was that the death was due to hypostatic pneumonia and heart failure. The case was referred to the High Court, which finally ruled that death was due to natural causes and hypostatic pneumonia, and discharged the accused. On the other hand, one is convinced that, had the deceased not sustained the cerebral injury discovered at the post-mortem examination, he would have been alive to-day.

Case 6.—This case again was of medico-legal interest. The patient, a male aged 30, was hit on the head by another man with a stout stick, and received a lacerated wound in the left frontal region. He saw a local doctor the next morning, who gave him a medical certificate, and failed to notice that there was a depressed fracture at the bottom of the wound. The patient was both conscious and rational in his speech.

On the fourth night after the injury he began to develop symptoms of cerebral irritation, and was brought into this hospital on the fifth night after injury, with a temperature of 103.2°F. A diamond-shaped depressed fracture of the frontal bone was discovered at operation, about one inch by three-quarters of an inch, with laceration of the dura and injury to the surface of the left frontal lobe of the brain. The patient's temperature rose to 107°F. after operation and he died two hours later.

At post-mortem, a fracture of the anterior fossa was discovered and a condition of acute spreading œdema of the brain. The immediate cause of death was paralysis of the higher centres of the brain. The cerebro-spinal fluid was under pressure, and compression of the medulla was probably present. The case for the defence was that the deceased, when drunk, had fallen and hit his head on a stone, which was produced and appeared to be blood-stained. A test by the Imperial Serologist, however, failed to recognise any trace of blood on the stone. Five of the six accused were acquitted, but a sixth, who was stated to have thrown the stone, was sentenced to one year's rigorous imprisonment.

In this case, lumbar puncture at the moment when pressure symptoms were first recognised, might have saved life. The giving of the first certificate by the local doctor on the day after injury, and the fact that he clearly failed to recognise the severity of the injury, are special features of the case.

Case 7.—This was a female child, aged 7. Whilst her father was lopping off the branch of a tree, she was standing below the tree, about 12 feet below, when the axe fell out of his hands and struck her on the vertex. There was a comminuted fracture of the right parietal bone, with a smaller but similar lesion of the left parietal. All comminuted pieces had to be removed, and the superior longitudinal sinus was found to be badly lacerated and bleeding profusely. Firm plugging was applied, and the patient's condition, from shock and hæmorrhage, was bad. She made a

splendid recovery, however, and was discharged from hospital a month later in sound health.

Case 8.—This was a male child, aged 6 years, kicked on the right side of the forehead by a cow. The brain substance was protruding from the site of injury. There was no sign of paralysis or of cerebral irritation. At operation a small detached piece of bone was removed, which had become detached and buried in the brain substance. A month after his discharge from hospital, the small patient was brought back to hospital with a visibly pulsating mass in the right temple. This was dressed daily with dressings of a copper sulphate lotion. On the fifth morning it suddenly disappeared, and the patient made a complete recovery. What had happened here is quite uncertain. The patient had no hernia cerebri when discharged from hospital. The tumour, when it appeared, showed undoubted pulsation. The favourable termination of the case was at least fortunate.

Case 9.—Male patient, aged 35, who fell over a stone, and sustained a lacerated wound running from the middle of the left eyebrow to the scalp. There was a gutter-shaped fracture of the left frontal bone, and the left frontal sinus was also involved. At operation trephining had to be resorted to, but the patient made an uneventful recovery, and was discharged cured.

Case 10.—A male patient, aged 14, who had sustained a fall. At operation a depressed fracture of the right parietal bone was found. Trephining had to be resorted to, and a branch of the middle meningeal artery tied. The patient made a sound recovery.

Case 11.—A male patient, aged 37, who had received a blow during a scuffle, the result of a stone which had been thrown at him. There was a lacerated wound at the back of the head, and a compound depressed fracture of the left parietal bone. The outer wound was about an inch in diameter, but the lesion to the inner table only five-eighths of an inch by half an inch. He was discharged in good health a fortnight after admission.

Case 12.—A male patient, aged 18, who was stealing mangoes from a tree, and fell immediately he picked the first mango. He had a lacerated wound on the left side of the forehead, with a compound depressed fracture at the bottom of the wound. The left half of the frontal bone was also fractured and depressed inwards into the brain. The scalp wound was slightly oedematous, owing to injury to the left frontal air sinus. The dura mater was badly torn and the brain very badly lacerated. One fragment of bone was actually deeply buried in the brain. Despite this, he was operated on and left hospital 18 days later in good condition.

Case 13.—Boy, aged 15, who fell from a mango tree, and had a compound depressed fracture of the frontal bones running for nearly 4 inches above the superciliary ridges. The dura mater was badly torn and the brain matter literally flowing from the wound. He was discharged from hospital a month after operation in sound health.

Case 14.—The patient, a male aged 50, fell to the bottom of a well nearly 30 feet deep. On admission, he had a badly lacerated wound on the top of the head, running from behind forwards in the middle line. On exploring the wound, it was found that there was a severe diamond-shaped depressed fracture of both parietal bones, with extensive comminution. There were two perforations of the dura mater, and the brain was injured underneath these. The superior longitudinal sinus fortunately escaped. The area of brain denuded of bone was diamond shaped, and measured 4 inches by 2 inches. Unfortunately, the patient died on the fourth day after operation.

Case 15.—The patient, a male aged 35, was working at the bottom of a well when the wooden beam at the top of the well fell a distance of some 20 to 25 feet and hit him directly on the vertex. There was a longitudinal wound about 2 inches long, with a depressed fracture of the right parietal bone. At operation the whole of the right parietal bone was exposed, and a lozenge-shaped piece was found to have been detached and buried in the brain matter underneath. The fracture

fortunately stopped half an inch short of the middle line and the superior longitudinal sinus. No trephining was necessary. On admission he had slight paresis of the left arm, but this was gradually recovered from. He left hospital cured a month after admission.

Case 16.—This patient, a male aged 30, was also injured whilst working at the bottom of a well, a large stone having fallen on to him from above. On admission, there was complete hemiplegia of the left side of the body. There was an irregular depressed poul-like fracture to the right of the middle line. The right parietal bone had to be trephined, and a branch of the middle meningeal artery tied. One fragment which was very loose was removed, but a second was elevated and left in position. The hemiplegia cleared up immediately after operation, and the patient left hospital cured on the 22nd day.

Case 17.—This was a case of medico-legal importance. The patient, a male aged 45, was injured on the right side of the forehead during a riot. He came to hospital at 11 o'clock on the night of the injury, walking, and fully conscious. There was an irregular wound about one inch by half an inch above the outer half of the right eyebrow; also minor injuries to other parts of the body. He refused to stay in hospital and went to his home for the night, but returned to hospital the next morning. For the first six days he appeared to be doing well, but suddenly dropped down dead about 11-30 p.m. on the night of the seventh day after injury.

At post-mortem, a crescentic fracture of the frontal bone was discovered. Starting from the zygomatic process, it passed backwards along the roof of the orbit. During life, there had been no signs or symptoms indicating trephining or the necessity for elevating the bone; it appeared to be a simple fissured fracture. But at post-mortem examination, a condition of acute spreading oedema of the meninges at the base of the brain was discovered, and the immediate cause of death was apparently paralysis of the higher centres of the brain. The cerebro-spinal fluid was under pressure, and there was probably medullary compression as well. A timely lumbar puncture might have saved life in this instance, but the symptoms were not such as to call attention to the necessity for it.

The medical officer who was called into court gave it as his opinion that the injury might have been caused by a stick. The defence said that it was caused by a stone; they said that the deceased was drunk at the time of the occurrence, and that he fell and hit his head on a stone, and proceeded to produce the alleged blood-stained stone. The Imperial Serologist, however, failed to find any trace of blood on the stone. The judge acquitted five of the six accused, and sentenced the other to one year's rigorous imprisonment only.

I have perhaps said sufficient to show the importance in general medical practice of head injuries, and the necessity for the general practitioner to be constantly prepared to deal with them at any hour of the day or night. He requires an armamentarium carefully selected beforehand, and kept in the very finest of working order. Further, he must remember that he may at any time be called in to give medico-legal evidence in connection with such cases. The questions that he may be asked in court, indeed, are sometimes ludicrous. Lately I was asked in court whether an infant four months of age could have committed suicide by leaping down a well. When the facts of the case came to light, it was discovered that the child had been thrown down the well by his mother, since it was a male child and illegitimate, and she did not wish it to grow up and interfere with her clandestine trade. In another case, it was suggested to me that a newly-born baby had committed suicide by swallowing

a handful of ashes. Is the answer to be that death was due to "heart failure," or to "carelessness," or "to an eclipse of the moon"?

TRACHEOTOMY FOR DIPHTHERIA IN CHILDREN.

By P. BANERJEE, *P.R.C.P.S.*,

MAJOR, *I.M.S.*,

Resident Surgeon, Medical College Hospital, Calcutta.

THERE is considerable difference of opinion as to whether a low or high tracheotomy should be performed for the relief of urgent dyspnoea in children suffering from diphtheria. There are objections against either form. But so far as I am aware, there appear to be more objections against the performance of a low tracheotomy than against that of a high one.

In high tracheotomy, especially in children, laryngeal stenosis sometimes occurs, due to oedematous granulations at the seat of operation, which is very close to the larynx. Thus, in a series of 53 cases where high tracheotomy had been performed, in 5 laryngeal stenosis was observed with the result that the little patients could not do without their tracheotomy tubes. On removal of the tube, urgent dyspnoea with cyanosis supervened. In one case for the relief of this symptom the tracheotomy tube was taken out and intubation was attempted without success, owing undoubtedly to the stenosis that had taken place. In every one of these cases low tracheotomy had again to be performed, which made the healing of the high tracheotomy wound possible and led to the disappearance of the oedematous granulations. After 4 or 5 days, the low tracheotomy tube was removed without any trouble. In the 77 cases of low tracheotomy performed by me, there was not a single instance where dyspnoea persisted after removal of the tracheotomy tube in the usual course in 2 to 3 days.

The objections against a low tracheotomy are, (1) that the trachea in the lower part of the neck lies deeply, (2) that there is a danger of injuring the large vessels, which pass into the neck from the thorax, (3) that owing to the depth, which separates the trachea from the skin wound, a large tracheotomy tube is required as otherwise it is coughed up, (4) that there is a danger of producing mediastinal cellulitis, and (5) that there is a likelihood of driving the diphtheria infection into the trachea. Thus, the arguments against a low tracheotomy appear to be quite formidable, but fortunately do not stand examination. When a low tracheotomy is performed in what I consider the proper way, there is no danger of wounding any large vessel, such an accident never having occurred in any of my cases. As for the other objections they appear to me to be purely theoretical, as I have never seen mediastinal cellulitis or extension of the diphtheritic membrane into the trachea when it had not already been there. In children, the depth at which the trachea lies is not great, and does not make the

operation in any way difficult. It is also quite easy to fit a proper sized tracheotomy tube into the trachea.

It will thus be seen that when correctly performed a low tracheotomy, as it does not produce laryngeal stenosis and is also definitely indicated in those cases where the diphtheritic membrane has extended from the larynx to the upper part of the trachea, is the operation of choice.

In all these cases apart from septic bronchopneumonia, which is almost always present, the heart is enfeebled, as is well-known, by the diphtheritic toxin. It is therefore not advisable to use either ether or chloroform as a general anaesthesia in these cases, nor is such anaesthesia necessary, the only pain in the operation being a momentary one caused by the skin incision.

Descriptions of tracheotomy operations in textbooks are frightening, as is the situation where the operation is performed. Thus, a simple operation, which may be performed in 2 or 3 minutes, is regarded with fear by the general practitioner in this country and is not attempted, this resulting in death to many little children.

I will now take the liberty of describing the operation as I perform it. To me it seems that it would be better for beginners to forget the existence of all the vital structures which lie in the neck round about the trachea, because they are far away from the field of operation. The only caution necessary is that one should stick strictly to the middle line. In performing the operation, the structures that will come in the surgeon's way are the two anterior jugular veins, Burns' space, the thymus, the trachea, the inner edge of the sterno-thyroid muscles, and the thin line of deep fascia between them.

After having cleaned and sterilized the neck in the usual way, extend the neck by raising the shoulders on a sand bag and holding down the head at a lower plane. The little patient is rolled up in a sheet to make movement of the limbs impossible. One assistant holds the patient down by the lower limbs and another holds the head with great care, keeping it in the middle line. The surgeon stands to the right side of the patient.

Putting the tip of the index finger of the left hand at the sternal notch, a longitudinal incision about 2 inches long should be made exactly in the middle line down to the investing layer of the deep cervical fascia. This brings into view the thin line of deep cervical fascia between the sterno-thyroids in the middle line, and also resting on the muscles on either side the two anterior jugular veins. There is little or no hæmorrhage at this stage of the operation, and there is no pain felt subsequent to this. With the sharp edge of a small scalpel directed towards the chin pierce the deep cervical fascia at the level of the lowest points reached by the anterior jugular veins before they disappear into Burns' space to communicate with each other, and continue dividing the two layers of the deep cervical fascia which

form the walls of Burns' space. The large vessels, which pass from the thorax into the neck, are situated well below this level behind the pre-tracheal fascia. This incision should be carried upwards, that is towards the chin, for a distance of an inch and a half. The knife should penetrate to a depth of about half an inch and keep strictly to the middle line. There may be a little bleeding due to the division of a few very small veins which are congested. None of these vessels requires any attention. If the soft tissues thus incised are now separated, the thymus comes into view and the outline of the trachea behind the pre-tracheal fascia can be perceived.

To perform the next stage of the operation, the thymus is pulled down with a hook by an assistant. With the tip of the left index finger the trachea is palpated immediately above the thymus, and a half inch longitudinal incision is made into it through the pre-tracheal fascia with a tenotomy knife with its sharp edge directed towards the chin. The edges of the tracheal incision are now separated by the tracheal dilator and a well-fitting silver tracheotomy tube fitted into it.

The retraction of the soft tissues is only necessary for beginners, and for this purpose the self-retaining retractor devised by me will be found useful. It assures not only wide separation of the tissues, but also secures equal separation on either side of the middle line, preventing lateralization of the trachea. It can be steadied by the tip of the left index finger while the knife incises the trachea between its two blades. The old fashioned hook retractors do not bring about equal retraction on either side, whether the retraction is done by an assistant or by the surgeon himself. The result often is that the trachea is pulled more to one side than the other, thus confusing the beginner. An illustration of the

retractor is given below. The operation is now finished by carefully bringing the skin edges together above and below the tracheotomy tube. There is no danger to any vital structure if the operation is performed as described above, and it takes only about 2 minutes to do it.

One helpful suggestion may here be made for the beginner, and that is that before incising the skin the line of incision exactly in the middle line may be traced on the skin with the point of a needle, the knife later following this line. Hooking the trachea to fix it is unnecessary. Retraction of the soft structures by hooks is confusing. Chloroform or ether as a general anaesthesia is positively dangerous.

THE INTENSIVE TREATMENT OF KALA-AZAR BY NEO-STIBOSAN.

By L. EVERARD NAPIER, M.R.C.S., L.R.C.P.,
(Lond.),

*Officiating Director, Kala-Azar Commission, Indian
Research Fund Association,*

and

M. N. MULLICK, M.B. (Cal.)

*House Physician, Carmichael Hospital for Tropical
Diseases, Calcutta.*

THE treatment of kala-azar has now reached a comparatively satisfactory stage; thirteen years ago the death-rate in kala-azar was said to be 95 per cent. (though in our opinion it is doubtful if it was ever as high as this), whereas now, at whatever stage of the disease the patient first comes under treatment, the recovery rate should be at least 95 per cent. Many pentavalent compounds have been used; a number of these have proved satisfactory, but there is still scope for further work on this group of compounds and it is very probable that others, even more satisfactory than those at present in use, will be found. It also seems possible that some advance may be made in the methods of administering these compounds.

It is not known how the antimony acts, but it is almost certain that the action is not directly on the parasite. The largest single dose of any of the antimony compounds that is given does not amount to a 100,000th part of the body-weight of the patient, the antimony is fairly evenly distributed amongst the various organs and tissues of the body, and the concentration in any one organ, except possibly the kidneys, is unlikely to be greater than 1 in 10,000 at any time. As the antimony is very rapidly excreted, especially when given in the pentavalent form, the cumulative effect is probably not very great. On the other hand, we know that solutions of antimony compounds of 1 in 100 have no effect on the flagellate form of the parasite *in vitro*. It has been suggested that, as is the case with arsenic in the salvarsan group of compounds, the parasitotropic action of

Tracheotomy Retractor devised by the author.
A, closed; B, opened.

antimony is increased in the presence of body tissues, but Noguchi (1924) failed to show that this was the case.

It has been shown repeatedly by the senior writer and the observation has been confirmed by others (Greig and Kundu, 1925) that at the end of the comparatively short course of treatment by one of the pentavalent compounds of antimony parasites are still present in the spleen, that they may be demonstrable even at the end of a month, but that they eventually disappear without any further specific treatment.

These observations all suggest that the antimony stimulates certain of the body tissues to react and produce an environment unsuitable for the existence of leishmania, and that this reaction continues even after the antimony is excreted. Now over-stimulation usually produces paralysis, so that if this theory is correct, there is a danger that by increasing our dosage to too great an extent we shall defeat our own ends by producing paralysis where we had hoped only to produce stimulation.

Ehrlich's ideal, his *therapia magna sterilans*, was a drug with the maximum parasitotropic and the minimum organotropic action, of which one dose would have no detrimental effect on the body, but would kill all the parasites (of that species for which the drug was a specific) in the body. This ideal is much more likely to be attained with a drug which has a direct action on the parasite than with one in which the action is indirect, as is almost certainly the case with antimony in the treatment of leishmaniasis. It is much easier to imagine that steady stimulation over a period of a few weeks would produce better results than violent momentary stimulation. Presumably, it is for this reason that the usual practice of dividing the dose of the antimony compound necessary to produce a cure into 30 doses, and giving them over a period of 2 to 3 months in the case of the antimony tartrate salts, or into 10 to 12 doses and giving them over a period of about a month in the case of the pentavalent compounds, has been considered the most satisfactory. It was not, however, for this reason that the practice was adopted; most workers found that it was not satisfactory to increase the dose of sodium antimony tartrate above 0.1 gramme; some patients stood the greater dose, but on the whole signs of intolerance rapidly and frequently appeared directly this maximum was exceeded. In the same way most observers make 0.2 gramme the maximum dose for urea-stibamine.

Contrary to the above theoretical considerations, the senior writer has found in practice that more satisfactory results are obtained by concentrating the treatment as far as possible; that is to say to an extent

short of producing immediate symptoms of overdosage; and he has felt that if a compound of low toxicity could be discovered, a further concentration of the course might be beneficial, more especially in "resistant" cases.

One of the most successful compounds in the treatment of the disease in the senior writer's experience has been Neo-stibosan (No. 693), an amine salt of para-amino-phenyl stibinic acid prepared by Bayer (previously prepared by Hayden). He used this compound first more than 4 years ago, but it is only during the last year or so that he has been able to obtain sufficient supplies to give it an extensive trial. The results of the treatment of the first 61 cases were published about a year ago (Napier, 1927). The results in this series were extremely satisfactory; vomiting was, however, a prominent complication and prevented the maximum dose from being administered in one or two instances. Whilst on leave last year, the senior writer visited the factories of the Bayer-Meister-Lucius Company at Leverkusen and Elberfeld and had an opportunity of discussing this preparation with Professor Schmidt, the originator of the pentavalent compounds of antimony; by a slight modification in the method of preparing this compound without any corresponding modification in its composition Professor Schmidt has now been able to prepare a compound from which the emetic properties have been entirely eliminated. Since his return from leave the senior writer has treated more than a hundred cases, using different batches of this compound, with entirely satisfactory results; in no instance has it caused vomiting, or any other adverse symptoms. Another point of interest is the very low death-rate that has occurred. About 175 unselected patients have been treated by this compound of whom only 3 have died, a death-rate of less than 2 per cent. Most of the cases were very advanced and the condition of some of them was very precarious at the time the injections were commenced. All the adults tolerated the maximum dose of 0.3 gramme without any difficulty.

The writers felt that this compound was so particularly innocuous that it would be a suitable drug with which to attempt a further concentration of the course of treatment. Previous experience had shown that 8 injections produced a very high cure rate, so that this was adopted as the routine course. The initial dose was 0.2 gramme and each subsequent dose 0.3 gramme in the case of adults; in the case of the child weighing 26 lbs., 0.1 gramme was given throughout; other children under 50 lbs. received a maximum dose of 0.2 gramme, and those from 50 to 60 lbs., 0.25 gramme. In every case the injections were given daily, so that if they were given at the same time each day the whole

course could be finished within a period of one week (the actual time expended in giving the injection being negligible). The cases were not in any way selected, but after a certain date all patients admitted to the Carmichael Hospital for Tropical Diseases were given this concentrated course, and in only one instance was it found necessary to abandon the treatment; this was in a case in which dysentery developed after the first injection. Dysentery has not previously been associated with the administration of this compound, and the concentration of the course could not be blamed because the symptoms started after the first injection. In the first 28 cases included in this report, the above-mentioned routine course was given. Of these, 24 had received no previous treatment; details of the previous treatment of the others are given in the table.

No. 29, a patient who had previously had 2 courses of sodium antimony tartrate and two of urea-stibamine and had relapsed after each, was given over a period of 10 days 2.6 grammes in seven injections, including one dose of 0.5 gramme; after this he absconded from hospital, but returned two months later and was readmitted. In the meanwhile he had received no specific treatment, nor did he receive any during his subsequent stay in hospital. Spleen puncture and culture failed to show the presence of parasites; his condition on his final discharge is noted in the table.

No. 30 was a very unusual case. Some time ago he received a course of injections of Stibosan; during his treatment and convalescence he gained nearly 40 lbs. in weight. He remained in good health for at least a year, after which he began to get low irregular fever for some months; he also lost weight, but on admission this time he was still 30 lbs. heavier than when he was first admitted. His spleen was very hard and fibrous, quite unlike an ordinary kala-azar spleen. In the spleen puncture smear there were a very few large unusual shaped leishmania parasites. As the first course of injections made little difference to his condition, after a fortnight's interval a second course was given, in each instance the course consisting of 10 injections on 10 consecutive days. During the second course he complained of a sensation of constriction in his throat shortly after each injection, so the dose was reduced to 0.2 gramme.

RESULTS OF TREATMENT.

The table gives details of the individual cases.

The fever.—In some instances the temperature fell to normal during the course of injections, more frequently immediately they were discontinued, but in a few instances low

fever continued for some days. However, in every instance in which the fever was not already normal, there was a distinct drop at the end of the course of injections which suggested that the treatment itself helped to maintain the temperature. In some instances the fever was kept up by the presence of complications, and in a number of instances the administration of quinine brought the temperature down to normal. Five typical temperature charts are shown.

Weight.—In every instance the patient was gaining weight at the time of discharge. No. 11 shows a net loss of weight; he lost a considerable amount during the first three weeks but gained weight during the last week in hospital.

No. 16 lost $4\frac{1}{2}$ lbs. during the course of treatment, but had regained this weight before discharge. No. 30 lost weight during the first course of injections, but had recovered some of this before discharge. The rest showed a net gain in weight of varying amounts up to 21 lbs. in one instance.

The Spleen.—In every instance there was a very decided decrease in the size of the spleen. In many instances there was little or no decrease by the eighth day—when the course of injections was completed—but the spleens decreased progressively from the time the treatment was discontinued. In only 5 cases was the spleen measurably enlarged at the time of discharge, in 19 cases it was palpable only and in 6 it was not palpable.

The white blood count.—The blood count was not done as a routine measure before treatment. This is frequently as low as 2,000 per c.mm., and fairly constantly below 4,000 per c.mm. in well-developed cases. (the average of 59 cases done in this hospital some time ago was 3,624 per c.mm.). In the majority of instances the blood count done during the third week was very satisfactory, but the average of the counts done during the fourth week was above the average for normal healthy persons. Where more than one count was done, a progressive improvement was demonstrated in every instance but one.

Notes.—Although no specific treatment was given after the eighth day, most of the patients were kept in hospital for about a month in order that their progress might be observed. In most instances the general condition of the patient was distinctly improved by the eighth day; at this point an examination of the patient with reference to splenic enlargement, weight, etc., would show little progress, but in every instance a definite progressive improvement was noticeable from this time onwards.

In most instances the doses were given into the vein in a 5 per cent. solution but in one instance a 25 per cent. solution was used, and in another a 25 per cent. solution was given

into the muscles. Intramuscular injection of a 25 per cent. solution of this drug caused no local reaction, and much less pain than is usually caused by one-fifth the amount of emetin similarly given. Doses as large as 0.35 gramme were given into the deltoid muscle, but as a rule the injections were given in the gluteal region. The response to treatment

appears to be equally satisfactory, whether the injections are given intravenously or intramuscularly. No reaction occurred when a 25 per cent. solution was given intravenously, and the drug is readily soluble to this extent. It is very convenient to administer it in this strength, as a dose of 0.3 gramme requires only 1.2 c.cm. of distilled

water and can therefore be given in a small hypodermic syringe.

This communication is by way of being a preliminary note as it is not possible to say definitely yet whether these patients are completely

behaving as if they were now completely cured and they will be extremely surprised if of the whole series more than, say, two relapse. The patients will be followed up and a report on their subsequent history issued later.

cured or not. The writers can only say that in their opinion all the previously untreated cases are

It is thought that these observations might be of value to those in charge of hospitals

where it is undesirable that patients should occupy beds unnecessarily long. The course of injections could be given and the patient could then be sent home to complete his convalescence.

With regard to the concentrating of the course of treatment it is obvious that it is quite a safe procedure, there is every indication that equally good results are obtained, and it seems possible that in "resistant" cases some definite advantage may be gained.

SUMMARY.

An attempt has been made to concentrate the course of treatment of kala-azar. The drug which has been used is Neo-stibosan, (No. 693), a pentavalent antimony compound of low toxicity and high curative value. Eight injections at intervals of one day have been given, so that the full course is completed within a period of a week. The results of this course of treatment in 28 cases of kala-azar have been very satisfactory and indicate that a high percentage cure-rate can be anticipated.

This drug can be given safely in a 25 per cent. solution; this makes it possible to use a small hypodermic syringe even for the maximum dose.

The drug is equally efficacious when given intramuscularly; 0.3 gramme of a 25 per cent. solution, which is isotonic with the tissues, gives rise to less pain than a similarly given injection of 0.063 gramme (1 grain) of emetin.

Our thanks are due to Dr. S. N. Bhattacharyya, M.B., House Physician to the Carmichael Hospital for Tropical Diseases for assistance in giving the injections and to the Havero Trading Co., 15, Clive Street, Calcutta, for a generous supply of Neostibosan.

A Mirror of Hospital Practice.

AN INTERESTING CASE OF MALARIA.

By S. M. RABBANI, M.B., B.S.,

Kampala, Uganda.

ON 11th March, 1928, I was called to see a patient, a Punjabi, aged 32, occupation—

mason in the P. W. D. At the time of examination the patient had a temperature of 104°, was restless, had a severe headache and marked bilious vomiting, so much so that not even a drop of water could be retained. He told me that the fever came on in the morning at about 10 a.m. with shivering. The spleen was just palpable. A blood film was taken and showed the presence of subtertian parasites.

The patient was a well-developed muscular person, had been for eleven years resident in Uganda and had had three previous attacks of severe malaria, the last one being in 1926. He was living in a well-ventilated newly-built pucca house outside the main town in a comparatively healthy locality. He gave no history of any venereal disease.

Treatment.—An intramuscular injection of 9 grs. of quinine bishydrochloride was given in the gluteal region, and calomel in fractional doses to stop the vomiting followed by magnesium sulphate the next morning.

12th March.—Vomiting abated; patient could take milk and soda, headache still present, had a free motion, temperature 103.8°. He was put on a diaphoretic mixture, but in the afternoon the temperature rose to 105°. Another intramuscular injection of quinine was given, and an ice bag was applied to the head.

13th March.—Headache less, patient felt somewhat better, temperature 102°. He was given 30 grs. of quinine bisulphate in mixture form, but vomited the mixture every time. Temperature in the afternoon was 103°, and another injection of quinine was given.

14th March.—Morning temperature 102.5°, another blood film was taken, but this time no parasite could be detected, nor did I find any other organism. I decided to give quinine intravenously, accordingly 7½ grs. of quinine bishydrochloride diluted with 10 c.c of water was given intravenously. The temperature fell to 100° in the afternoon and the patient felt much better; headache disappeared.

15th March.—Morning temperature 101°, patient feeling better, had a good sleep last night, bowels moved all right. Patient was put on liquor arsenicalis with mist. cinchona co. In the afternoon I was not called to see the patient and so temperature was not taken.

16th March.—Morning temperature 102°, previous day's mixture was again ordered, but temperature in the evening shot up to 104°.

17th March.—Morning temperature 102.4°.

In the *American Journal of Tropical Medicine* 1925, Dr. Brosius had reported excellent results in the treatment of persistent cases of malaria with neosalvarsan. Accordingly, I gave 0.3 gramme of neosalvarsan

intravenously and the temperature fell to normal after 8 hours. The patient made a rapid convalescence and reported himself on duty on the 22nd.

The point about this case is the resistance of malarial fever to quinine and the rapid yielding to neosalvarsan.

A CASE OF ACUTE YELLOW ATROPHY.

By CAROL E. JAMESON, M.D.,
Missionary Medical School Hospital, Vellore, N. Arcot.

THE patient, a widow aged 55 years, entered the hospital with a chronic inflammatory mass of many years' standing and a foul smelling leukorrhœa. She had been treated elsewhere with Sulfarsenol for syphilis and we discovered a slightly positive Wassermann reaction. Cervical smear was positive for gonococci. Hysterectomy with removal of adnexa was advised, but at operation, on separation of coils of bowel from the uterus, free pus was encountered in the pelvic cavity and an extensive yellowish white slough. This was removed as far as possible with very little manipulation or contamination of the abdominal cavity and the wound was closed leaving a rubber tube drain. The patient was in excellent condition for about forty hours when her pulse became feeble and she became semicomatose. There was no distention and very little abdominal pain, but a partial suppression of urine. On treatment with glucose, fluids, and alkalis she improved very much, regained consciousness and took her food well. The urine, which was normal before operation except for a trace of albumen, was full of hyaline and granular casts, bile, acetone, and diacetic acid. The fæces were pale, straw-coloured and curdy. Jaundice and restlessness, which became at times a marked delirium, developed. The temperature went up to 103° every two or three days. Her general condition improved considerably on the ninth and tenth days. Some of the urine was passed in bed and could not be measured, but approximately thirty ounces was passed in the bed-pan during the day and this was normal except for bile and a trace of albumen. The tongue had a thick brown coating and the lips were covered with sordes. She continued after this in a typhoid state, progressively worse with a noisy delirium, alternating with a semicomatose condition until her death, the thirteenth day after operation.

Only a partial autopsy was possible. This showed the liver to be less than one-third its normal size, up against the dome of the diaphragm, and bright yellow in colour with small red spots. The consistency was moderately soft. The spleen was slightly enlarged.

Microscopic examination showed extensive fatty degeneration of the liver with the shape

and outline of the cells lost in most places, and spots of necrosis; also well marked pigmentation.

The chloroform must have been the main factor, and the syphilis possibly a contributing factor in this case of acute yellow atrophy of the liver.

A CASE OF SERIOUS VASO-MOTOR DISTURBANCE AFTER AN INJECTION.

By U. TRAVATHAM, I.M.P. (Mad.),
Physician and Surgeon, Wakema, Burma.

A YOUNG lady, aged about 20, was under my treatment for chronic gonorrhœal rheumatism. My usual treatment for such cases is to give a combined course of mixed gonococcal vaccine (Gonorgin) and contramine intramuscularly. A course of vaccine consists of six injections given twice weekly in graded doses; the contramine is given weekly, intramuscularly, about 3 times.

Contramine is an organic compound of sulphur whose composition is diethyl-ammonium-diethyl-dithio-carbamate. At present it is supplied in the form of solution for ready use, in 1 c.c. and 2 c.c. ampoules. According to the directions, I used to give 1 c.c., which is 0.125 grammes, intramuscularly, as the initial dose. I take the necessary precautions for an intramuscular injection by giving it deeply into the muscle, the needle being always inserted first to see that it is not in the blood-vessels. Then the syringe is attached to the needle with the solution and injection made slowly. The patients usually complain of little pain at the time and nothing afterwards. But the case of interest is that of the young lady above referred to. She had had about two injections of gonococcal vaccine already. I gave her one injection of contramine. I gave her the usual dose of the solution, namely, 1 c.c. intramuscularly, taking all the necessary and usual precautions. The injection was given at about 8 a.m. in my dispensary. She went home afterwards presumably quite all right.

At about 10 a.m. she took her diet as usual. Half an hour after she got suddenly giddy and began to pass three or four watery motions, spitting a lot of saliva, and passed into a state of coma.

The relatives came to me in a great hurry and explained to me what had happened. I hurried to the patient's house at once and examined the patient thoroughly. She was unconscious and her breathing was very hard. Her pulse was very slow and weak, about 50 per minute. She was sweating profusely and saliva was coming out of her mouth profusely. I was much alarmed to see the symptoms of the patient. I have never had any such experience in such a case of contramine injection. I immediately gave her 0.5 c.c. of

adrenalin hypodermically. After 15 minutes she began to improve in her condition. Her pulse improved, respirations came to normal, and consciousness revived. Her eyelids which were enormously swollen, subsided gradually.

Again I gave her 2 grains of caffein citras with a 3-minim dose of tincture of strophanthus in one ounce of water internally, about three doses once every hour.

In the evening she was completely all right except for slight giddiness.

A CASE OF MEDICO-LEGAL INTEREST.

By ATINDRA NATH SEN, M.B.,

Teacher, Medical Jurisprudence, Campbell Hospital,
Calcutta.

A HINDU male, aged about 25 years, was admitted to the cholera ward on the 29th March, 1928, in a collapsed condition. The examination of the stools revealed *Entamoeba histolytica*, but no cholera vibrios. He was transferred to the medical ward on the 30th. On the morning of the 5th April at 1 a.m. he was found lying on his bed groaning from some pain, as the patients nearby reported. At about 1-30 a.m., a white form attracted the nurse's attention and she found the patient hanging by a twisted bed sheet round his neck ligatured on the right side, from the thick wire stretched at the foot of the beds through the whole ward for suspending mosquito curtains. The limbs were all free, except the left hand which was holding the wire. The body was immediately taken down. The duration of the hanging was probably not more than 15 minutes and the drop was not more than a foot; no ligature marks were noticed by the medical officer on duty.

Post-mortem Appearances.—Eyes closed, pupils slightly dilated, tongue inside the mouth, no lividity of nails, slight whitish discharge from the urethra. Rigor mortis present. A faint ligature mark on the upper part of the left side of neck about three-quarters of an inch was noticed. The mark appeared more translucent when the skin was dissected up and seen against the light. The margins did not show any redness. No ligature marks were visible at all on the right side. The muscles and other structures showed no signs of injury. Liver, spleen, lungs and brain were all anæmic. Both the cavities of the heart were empty. The sigmoid flexure was perforated for about $1\frac{1}{2}$ by $1\frac{1}{2}$ inches, and numerous gangrenous ulcers were noticed in both the descending colon and the sigmoid flexure. Death appeared to be due to shock. Evidently this was a case of suicidal hanging at a time when the man was under shock from perforation of intestines. The interesting point is whether a person under shock, when he is about to

take his last gasp, is capable of doing such an act. At least this case shows it is quite possible.

I am greatly indebted to Major S. N. Mukherjee, F.R.C.S., Superintendent of the Campbell Hospital, for allowing me to publish this case.

COMPLETE INVERSION OF THE UTERUS.

By R. A. MURPHY, L.R.C.P. & S.I.,

Medical Officer to Tea Estates, Lusherpore Valley,
S. Sylhet.

A COOLIE woman, aged about 35; was first seen on the morning of May 4th. She had given birth to her sixth child on the early morning of May 1st, and the labour was reported to have been normal, and of short duration. The untrained *dai* insisted that there had been no traction on the cord, and this is probably correct, as the more popular method of aiding the third stage is to stuff a tress of the mother's hair into her mouth, so that the resulting vomiting will cause expulsion of the placenta. As far as the history could be ascertained, a protuberance had appeared shortly after birth, and during the day had gradually increased in size, but the husband forbade the *dai* giving information. Hæmorrhage had been negligible. On examination the whole of the uterus was found inverted, lying between the thighs, wrapped in a dirty cloth. The condition of the patient was excellent, showing no signs of shock, nor collapse. Reduction was effected under chloroform with great difficulty, and only after one and a half hours. The easy replacement as described in textbooks was not possible, and it was necessary gradually to squeeze and knead back the parts, in reverse order of the descent, Sub-assistant Surgeon Mohin C. Datta and myself alternately carrying on the somewhat trying process, while another assistant gave the anæsthetic, which last at no time gave any cause for anxiety. "E.C." lotion was liberally applied during the whole time of operation. After reduction, the vagina was packed with acriflavine gauze, and this was renewed daily until the day of discharge. No douching was done. No shock followed, and most surprisingly there was no rise of temperature later. It is remarkable that such a serious accident as inversion of the uterus could occur, and be followed by neither bleeding, shock, nor pyrexia. To the patient, the occurrence was little more than an inconvenience, and much persuasion was required to prevent her leaving hospital the following day. She eventually left on the seventh day, but has been seen since, and the uterus is normal.

Indian Medical Gazette.

AUGUST.

MYCETOMA INFECTION: AN APPEAL FOR MATERIAL.

A NEW science has arisen of recent years in tropical medicine, and is rapidly coming to the front; that of medical mycology. Many of the skin diseases of the tropics are due to infection with fungi, and recent articles by Lt.-Col. H. W. Acton, I.M.S., and his assistants, Dr. C. McGuire, Dr. Ganapati Panja and Dr. K. P. Bannerji, show how important this infection is in general medical practice in India. Cryptococcus infections are extremely prevalent in birds and animals, and have been reported in man from time to time. *Rhinosporidium seeberi* is essentially an Indian disease. *Sarcocystis* infection is possibly of fungoid origin. It is possible that the mysterious Rickettsia bodies which are responsible for typhus fever, for spotted fever of the Rocky Mountains, and for the seven-day fever of Japan are of fungoid nature. Granuloma inguinale has long been suspected to be of fungoid origin. Fungi—such as *Blastocystis hominis*—frequently parasitise the intestinal tract of man, where they seem to be non-pathogenic, but are especially associated with indigestion due to starchy food-stuffs.

There is one special fungoid infection of man, however, concerning which our ideas as to causation, classification and treatment are still in a state of chaos, viz., mycetoma infection (commonly referred to as "Madura foot," though it may affect the hands also). From time to time, severe cases of this infection are reported in our columns. Yet it is clear that cases are so infrequent that no one observer within his lifetime will see a sufficient number of cases thoroughly to work out the ætiology, pathology, and treatment of this disease. Hence the present appeal.

We have previously commented in these columns on the fine work which has been carried out in the Skin Out-patient Department of the Calcutta School of Tropical Medicine, financed by the generosity of the Indian Research Fund Association. And—in response to a request by Lt.-Col. H. W. Acton, I.M.S.—we now desire to broadcast an appeal for help in studying the problems of mycetoma infection. If workers all over India will collaborate in sending in material, clinical notes, information and photographs of cases, there is very little doubt that within the course of a few years sufficient information can be collected to render a standard account of this rather rare disease possible; and to indicate the best measures of prophylaxis and treatment.

Turning to the history of the disease, Madura foot, as it has hitherto been reported in India, it is stated to be common in the following areas:

Bombay Presidency; Larkana, Sukkur, and East Khandesh.

Madras Presidency; South Kanara, Guntur, South Arcot and Ramnad.

Mysore State; in South Kanara.

Hyderabad State, Deccan; Aurangabad.

Delhi Province.

It is stated to be rare in—

Bengal; where it occurs at Pabna.

Assam; the Garo Hills, Kamrup and Sibsagar are reported to be infected.

Bihar and Orissa; in the Santhal Parganas.

Burma; in Mandalay and Sandoway.

The Punjab; where it has been reported from Karnal, Gujrat and Shahpur.

The Central Provinces; reported from Yeotmal, Bhandara, Bilaspur and Jubbulpore.

The method of classification generally adopted is that of Chalmers and Archibald. This classification is followed by Brumpt, Langeron, Castellani and Chalmers and other workers in their manuals. They subdivide the mycetoma infections into two broad groups, as follows:—

(a) The actinomycoses. These are forms of mycetoma infection in which the grains are composed of fine, non-segmented mycelial filaments, in which the walls are usually not well-defined as apart from the contents, and in which chlamydospores are absent.

(b) The maduramycoses. In this type of infection the grains are composed of large, segmented mycelial filaments possessing well-defined walls and chlamydospores.

The actinomycoses are caused by organisms belonging to a genus which is usually termed the genus *Actinomyces*, though it is termed *Discomyces* by the French workers, and *Nocardia* by many British workers. These are organisms which grow in the form of a much branched mycelium, which may break up into segments that function as conidia. They are sometimes parasitic, and infect animals as well as man, the radiating threads showing prominent clubbed ends. Some are anaerobic. The following species have been isolated from cases of mycetoma infection in man:—

(i) *Actinomyces bovis* harz. Three cases in Brazil. The colour of the granules is not reported.

(ii) *Actinomyces asteroides*. From the Argentine, Europe and Brazil; the colour of the granules is not reported.

(iii) *Actinomyces convolutus*. From Khartoum; granules orange coloured.

(iv) *Actinomyces bahiensis*. From Brazil; granules yellow.

(v) *Actinomyces mexicans*; from Los Angeles; granules yellow.

(vi) *Actinomyces indicus*; from the Sudan; granules yellow.

(vii) *Actinomyces madurae*; from Greece, Algiers, the Argentine and Cuba; granules white.

(viii) *Actinomyces somaliensis*; from Somaliland and the Sudan; granules yellow.

(ix) *Actinomyces yazbebi*; from Brazil; granules white.

(x) *Actinomyces pelleteri*; from Brazil, Egypt and India; granules red.

(xi) *Actinomyces verrucosus*; from Switzerland; granules white.

The above list will be sufficient to show the confusion which at present surrounds the whole subject, and one cannot help wondering whether the white, yellow, black and red strains are not possibly analogous to the different colour strains of *Tinea cruris*, and whether in fact they cannot be reduced to a common denominator on a suitable synthetic medium; whether they are not local varieties or sub-species of one and the same organism. Further, infections with *Sterigmatocystis*, *Aspergillus*, and other species are common. Are these secondary contaminating fungi, or are they pathogenic? The point remains to be worked out. Is Madura foot a clinical entity caused by several different species of fungi; or is it due to a certain genus of fungus which causes localised periostitis?

Castellani divides the actinomycoses into the following genera: (i) *Nocardia*, (ii) *Colni-streptothrix*. The fungi of genus *Nocardia* are stated to grow best under aerobic conditions, are usually cultivated very readily, and produce arthrospores. The genus *Colni-streptothrix* Pinoy, 1911, grows best anaerobically, is difficult to cultivate, and does not produce arthrospores. He recognises black, white or yellow, and red varieties of actinomycosis infection, with granules of corresponding colour, and then differentiates different species within these groups. The white or yellow variety of actinomycosis may thus be caused by an organism of either the *Nocardia* or *Colni-streptothrix* groups. The red variety is due only to *Nocardia indica*.

Turning to the maduramycoses, here the grains show large, segmented mycelial filaments, possessing well-defined walls, and usually chlamydospores. Seventeen different species, belonging to different classes and genera, have been reported as causative agents. They have been classified as follows:—

Fungi imperfecta.

- Genus *Madurella*; 6 species.
- Genus *Indiella*; 3 species.
- Genus *Glenospora*; 2 species.
- Genus *Scedosporium*; 2 species.

Ascomycetes.

- Genus *Allescheria*; 1 species.
- Genus *Aspergillus*; 1 species.
- Genus *Sterigmatocystis*; 1 species.
- Genus *Penicillium*; 1 species.

Castellani again divides the maduramycoses into black, white or yellow, and red varieties, with grains of corresponding colour. According to its geographical distribution, he sub-divides the black variety into European, African, Asian and American strains. This classification seems needlessly complicated; especially since Nicolle and Pinoy have experimentally produced both black and white grains by injecting *Sterigmatocystis nidulans* into pigeons' feet. Castellani also divides the white or yellow maduramycoses into European, African and Asiatic strains.

As far as can be observed from the literature, black maduramycosis may be produced by the

different genera *Aspergillus*, *Madurella*, *Sterigmatocystis* and *Glenospora*.

* * * * *

It is obvious, from the above outline, that the whole subject of mycetoma infection in man (as also in animals) is at present in a state of confusion. Sir Aldo Castellani deserves the utmost credit for his pioneer work on the subject, which now merits fuller attention and study.

The material asked for is (a) cultures, and (b) infected tissues for section.

In cultivating, the greatest care should be taken to take cultures only from sinuses which have not been opened up previously, since open sinuses are very apt to become secondarily contaminated. If the pustule is open, the grains removed should be well washed in saline, then heated in saline at 56°C. for ten minutes to kill secondary, contaminating bacteria, and two grains planted on each tube of culture medium. At least three such cultures should be taken from each case. The media used should be either Sabouraud's Maltose Agar, which has the following composition:—

Maltose 4 per cent.
Peptone (Chassing) 1 per cent.
Agar 2.5 per cent.
Distilled water 100 c.c.

With a pH of 6; or Whey Agar. The method of preparation of this is as follows:—

Whey 250 c.c.
Peptone 5 grms.
Saccharose 7.5 grms.
Urea 3 grms.
Agar 2.5 grms.
Distilled water 250 c.c.
pH. 7.4

Wherever possible, grains should be taken from unopened pustules. The skin over the unopened pustule is first washed with absolute alcohol; then the pustule is punctured and the grains squeezed out, and after washing in saline two grains are planted on each tube of medium. This medium can be obtained from the Calcutta School of Tropical Medicine.

Three or four expressed grains should also be sent in normal saline in order to study whether actinomycoses or maduramycoses infection is present. Tissues for section should be sent in a solution of formalin, 5 per cent. in normal saline, and the sections should be cut very thin, not more than 4 to 5 mm., if possible.

* * * * *

This is the first time that we have utilized these columns in an appeal for material; but we hope that it will not be the last. The problem in question is a most interesting one: it can only be solved by the co-operation of a number of willing workers. What one man cannot hope to carry out in a single lifetime, may readily be carried out by team work by a number of helpers. We would like to express our gratitude to those who have responded to Colonel Acton's first appeal, which was privately circulated; but the problem is so big, that we invite the co-operation

of the whole medical profession in India. It only remains to add that cultures or material, case notes, photographs, etc., should be sent to Lt.-Col. H. W. Acton, I.M.S., Director, Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

CORRIGENDA.

SPECIAL ARTICLE.

THE TREATMENT OF INTESTINAL AMŒBIASIS: (AN ANALYSIS OF RESULTS, AND A REVIEW OF THE LITERATURE.)

By R. KNOWLES,

LIEUT.-COL., I.M.S.,

ASST. SURGEON B. M. DAS GUPTA,

ASST. SURGEON AJIT KUMAR DUTT GUPTA,

M.B. (Cal.), D.T.M. (Bengal),

and

UMAPATI GUPTA, M.B. (Cal.), D.T.M. (Bengal).

From the Department of Protozoology, Calcutta School of Tropical Medicine.

SINCE the introduction of emetine into medical practice by Sir Leonard Rogers (1912)—following the lead given by Bardsley (1829) of Manchester, who had used the drug generally in dysentery, Tull Walsh (1891), who used it in the treatment of dysentery in Calcutta, but reported that it did not give better results than other drugs, and Vedder (1911), who tested its action on free-living amœbæ, and suggested its therapeutic use—the treatment of acute and sub-acute amœbic dysentery has become a relatively simple matter. The patient is put to bed and daily injections of emetine are given. The result in almost every case is very rapid clinical improvement; indeed, there is hardly any medicinal line of treatment which gives more immediately gratifying results; on the day of admission the patient may be in real misery; twenty-four hours later he may be in comparative comfort. On the other hand, there is ample evidence to show that, whilst this line of treatment effects a clinical cure in the vast majority of patients, it fails to eradicate the infection in some 70 per cent. or more of infected persons, and that the "cured" patient is all too liable to suffer from one or more relapses at a later period.

But there is another condition due to infection of the mucosa of the colon with *Entamoeba histolytica*, and that is *chronic intestinal amœbiasis*, and the successful treatment of this condition is one of the most difficult and pressing problems in the practice of medicine in the tropics. There are so many vaunted "cures" for this condition on the market to-day, that the medical practitioner is positively embarrassed in his attempt at choice. Yet, the efficacy of any or all of them, seems very much open to question. We shall discuss the pathology of the carrier state later in this memoir, but we may here state that the trend of evidence of recent years goes to show that infection with *E. histolytica* may be of any grade of severity; it is possible that in some persons the amœba lives for only a short period in the lumen of the gut, causing no symptoms, and that the infection is speedily got rid of. In the great majority of cases, however, the parasite lives in and at the expense of the mucous membrane of the colon, and the patient's symptoms may vary from a mild carrier condition which is nearly (but not quite) symptomless, to a state of affairs in which he suffers from frequent or incessant relapses, and in which he may be tortured with dysentery for years on end.

Since the opening in 1921, of the Carmichael Hospital for Tropical Diseases (116 beds), attached to the Calcutta School of Tropical Medicine, certain routine tests have been applied to the great majority of all persons admitted; no matter what the disease from which they were suffering. Thus, thin and thick blood films are examined for blood-inhabiting protozoa; thick blood films are taken at night and examined for filarial infection; the Widal and the Wassermann reactions are performed; the total and differential leucocyte counts are observed; the agglutination reaction of the serum against the bacilli of Shiga and of Flexner is tested; and often a routine blood culture, both in glucose broth for blood-inhabiting bacteria and in N. N. N. medium for *Leishmania donovani* infection, is taken. The stools of every newly admitted patient are examined (a) in the Protozoology Department for intestinal protozoa; (b) in the Bacteriological Department for pathogenic bacteria; and (c) in the Hookworm Research Department for helminthic infections. These routine tests afford a means of making a general assessment of the patient's state of health, whilst very frequently secondary infections—for which the patient has not been primarily admitted—are discovered.

The examination of the stools in the Protozoology Department shows a general incidence of infection with *E. histolytica* of about 14 per cent. Thus in 1927, the stools of 1,030 persons were examined, once only, and *E. histolytica* infection was found in 145;

incidence 14:1 per cent. This figure, however, is perhaps higher than the true figure for carrier incidence in the population dealt with, since it includes a number of cases admitted for the treatment of actual amœbic dysentery.

The hospital records from 1921 to the end of 1923 are scanty and not too well kept. But from January 1924, a system was introduced in the Protozoology Department of keeping full laboratory records, and of detailed case sheets in the hospital, and we believe that we have now a sufficient number of observations collected for detailed analysis. These range over the period January 1924 to May 1928.

The classes of patients admitted to the hospital are chiefly—(a) Europeans from the mercantile firms in Calcutta, or European tea planters from Assam or the Dooars. These chiefly occupy the private paying "cabins," and we have been struck by the extreme frequency of chronic and relapsing amœbiasis in this class of patient. (b) Anglo-Indians, almost all of them residents of Calcutta city, and usually in rather poor economic circumstances. (c) Middle class Bengalis, chiefly clerks and artisans. Fletcher and Jepps (1924) have given a very striking account of severe and often fatal amœbic dysentery, as seen among the immigrant Indian labourers in Malaya, poverty-stricken and saturated with malaria. In such a class of patient, amœbic dysentery naturally tends to kill. Amongst our patients, however, we have only had one death, due to perforation. On the other hand, we have been very much impressed with the tremendous importance of chronic intestinal amœbiasis as a cause of sickness and invalidism, especially among the European commercial community of Calcutta city. These patients do not die (in India at least), but they have attack after attack of amœbic dysentery, prolonged absences from work, spells of sick leave to England, only to be followed by recurrence of the disease on their return to India: finally, they pass into a state of chronic ill-health and in the end are invalided Home. Indeed, in our opinion, chronic and relapsing amœbic dysentery is one of the most important problems facing the European mercantile community of Calcutta. Hence the imperative necessity of finding a true cure for the condition, if possible.

Can a chronic intestinal infection with *E. histolytica* be eradicated by drug treatment? The very abundance of the supposed "cures" for amœbiasis on the market is in itself enough to make one doubt, for it is a truism that where there are many "cures" for a disease, the true specific cure is still to seek. Throughout this paper we do not use

the term "cure" in its clinical sense. It is easy enough to rid a patient for the time being of all symptoms due to amœbic infection, but to eradicate the latent infection in his colon is quite another matter. The term "cure" throughout this paper means eradication of the infection, so that relapse shall be impossible; hence, to our regret, we shall frequently have to use the modified term "probable cure." When Ehrlich gave to the world his splendid idea of the *therapia magna sterilans*, we are afraid that he rather misled the medical profession. Even in the case of syphilis, it has been found that prolonged courses of treatment and repeated injections are necessary to eradicate the infection. In the case of protozoal infections, the case is even more difficult; the *therapia magna sterilans* for trypanosomiasis has not yet been found; to cure kala-azar, a regular course of antimony injections is necessary; to eradicate malaria, continuous administration of quinine over a sufficiently long period is essential. The *therapia magna sterilans* seems an unrealisable ideal with regard to protozoal infections; what does seem to be possible, however, is to aim at the much lower but more practicable idea of reducing the infestation to such a low level, that the patient's own natural powers of resistance will overcome the few parasites that still remain.

In searching through the literature on the subject from 1910 onwards, we have been amazed at the number and ingenuity of the treatments suggested. Disappointed with the standard remedies in general use, some workers have been driven to most unusual remedies. Thus Neubert (1913) advocated a diet of sour milk, with de-emetinised ipecacuanha. Niles (1914) treated patients by the daily administration per rectum of a pint of kerosene oil, run in slowly with the patient in the knee-elbow position. Van der Togt (1921) gives cane sugar enemata, and is satisfied with the results; but "in some cases the cure had to be repeated." Da Costa and Silva (1921) give each patient three enemata a day, one of a 2 per cent. solution of sodium sulphate, one of a 4 per cent. calcium chloride solution, one of a 1:4,000 potassium permanganate solution; together with normal saline by the mouth. Andresen (1926) makes the interesting suggestion of treating patients by the duodenal tube; a strong solution of magnesium sulphate is first given in order to flush out the gut, then a suspension of powdered ipecacuanha in warm water, then a final flushing with cold water; the duodenal tube being retained for some time lest its withdrawal should provoke vomiting. Lwoff (1925) comments on the fact that *E. histolytica* is frequently parasitised by the micro-organism known as *Spharita*. We very much doubt his statement that *Spharita* harms

the amœba, and we have once seen *Sphærita* inside a cyst of *E. histolytica* at the mononucleate phase. He goes on actually to advocate the use of *Sphærita* in amœbic dysentery and in the carrier condition to eradicate the infection with *E. histolytica*.

None of these methods are suitable for general out-patient or dispensary use however, and what is urgently needed in India is some cheap yet efficacious method of oral treatment.

Nothing illustrates better the tendency to follow the prevailing fashions in medical treatment than the history of the treatment of intestinal amœbiasis. Graph I illustrates

recognition of his life-saving work. At the beginning of the present century, the ipecacuanha treatment was in full swing and was used for all cases of dysentery indiscriminately, the drug being generally administered after a preliminary dose of opium, or in salol-coated pills.

Early in the present century de-emetinised ipecacuanha was introduced, owing to the nauseating qualities of powdered ipecacuanha. This fashion was in vogue in 1908 when the senior author first came out to India, and was then regarded as the best method of treatment for those who could afford it. This "wave," however, did not last long.

GRAPH I.

Graph to illustrate the changes in methods of treating intestinal amœbiasis in the 20th century.

the general impression which we have gained in searching through the literature. According to Sir Leonard Rogers (1913, p. 27) the ipecacuanha treatment for dysentery dates back to 1658, and was used in India as early as 1660. It was used by Annesley and Twining in the early days of the 19th century in India, and in 1846, in relatively large doses, by Parkes. The ipecacuanha treatment then gave way to treatment by calomel and saline purgatives, the calomel being given in doses sufficient to produce salivation. Docker in 1858 appears to have been the worker who re-introduced the ipecacuanha treatment; he lost only one out of fifty patients treated among the British troops in Mauritius, and received a small pension from the Government of India in

Emetine alkaloid was first isolated by Pelletier in 1817, and was used in the treatment of dysentery by Bardsley of Manchester in 1829. In the form of emetine mercuric iodide it was employed in Calcutta by Tull Walsh in 1891, but he concluded that it did not give better results than other drugs. Vedder (1911, 1912) showed that emetine killed free-living amœbæ in dilutions of 1: 100,000, and suggested the use of this alkaloid in the treatment of amœbic dysentery. This suggestion was immediately taken up by Sir Leonard Rogers (1912; 1912a, 1912b, 1913), and emetine injections rapidly became the standard treatment for intestinal amœbiasis. With the introduction of emetine, and emetine "wave" set in, and the use of powdered ipecacuanha and of de-emetinised

ipecacuanha practically disappeared, though a few "die-hards" still continue to prescribe the former drug.

During the Great War it was soon ascertained that, although emetine is the ideal drug in the treatment of amœbic dysentery, yet it failed to cure the carrier condition. DuMez (1915) introduced emetine bismuthous iodide and also prepared emetine mercuric iodide, obtained promising but rather irregular results in dogs, and advocated both compounds in the treatment of intestinal amœbiasis. Dale (1916) published his first paper on the use of the double emetine and bismuth iodide in 1916, and "E. B. I." rapidly came into fashion, especially in the treatment of carriers. It appears to be the drug chiefly used to-day by British workers, though its nauseating qualities are freely admitted by almost all observers.

Yatren was first used (at Hamburg) by Mühlens and Menk (1921), and now occupies a very prominent position in the literature, despite its expense. It appears to be chiefly employed by German and Dutch workers, though Manson-Bahr and Morris (1925) and Manson-Bahr and Sayers (1927) speak very highly of it from practical experience. Whether the yatren wave has yet topped the emetine and "E. B. I." waves it is difficult to say.

Stovarsol, first introduced in the treatment of and prophylaxis against syphilis and other spirochætal infections, was first used in the treatment of intestinal amœbiasis by Marchoux (1923). Since that date, a stovarsol "wave" has set in and although it has not yet reached the popularity of yatren, the drug is steadily coming to the front. It appears to be used chiefly by the French workers, though some of the American and British workers have also reported on it.

We might have inserted other curves in Graph I for such other lines of treatment as emetine periodide, the use of the arsenobenzylic derivatives either intravenously or per rectum, auremetine, rivanol, and other compounds, but sufficient has already been said with regard to the difficulty of the position. If we may represent the medical practitioner of to-day by a vertical line drawn through the point 1928, it will be seen that when faced with the treatment of a case of chronic intestinal amœbiasis, he has a considerable variety of drugs from which to choose. A study of the literature, further, will not help him much in his decision as to which of these drugs to use, for he will find in it almost any opinion on any one of these drugs, from the faint praise which is equivalent to damnation, to the wildly optimistic reports based entirely upon clinical impressions.

Methods of Examination at Calcutta.

The 154 patients, whose cases are reported in this paper and who received in all 220 treatments, were under the treatment of the

different professors and research workers at the Calcutta School of Tropical Medicine, although the majority of the cases of actual amœbic dysentery admitted have been in the care of the senior author of this paper. Hence, since the prevailing fashions influence the doctor quite as much as the patient, several different lines of treatment have been utilised during the four and a half years reported on. The effects of the following different lines of treatment have to be recorded:—

(i) The use of the total alkaloids of ipecacuanha in the form of "Alcresta Ipecac" (Lilly & Co.); 7 cases; Table I.

(ii) The use of emetine alone, either by subcutaneous, intramuscular or intravenous injection; 32 cases; Table II.

(iii) The administration of emetine intramuscularly together with the administration of large doses of bismuth orally (Deeks' intensive bismuth treatment). This has been prescribed chiefly by the senior author of this paper in the treatment of patients infected with *E. histolytica*, and suffering from actual amœbic dysentery on admission; 55 cases; Table III.

(iv) Emetine bismuthous iodide. This has been used chiefly by Colonel Acton and the senior author in the treatment of carriers; 23 cases; Table IV.

(v) Yatren, either orally, or by the combined oral and rectal method. The majority of these patients were under Colonel Megaw's care, but a few of them were treated by the senior author; 29 cases; Table V.

(vi) Stovarsol; used chiefly in the treatment of the carrier state by the senior author; 32 cases; Table VI.

(vii) Kurchi, administered orally; used chiefly by the senior author in the treatment of patients with actual dysentery at the time of admission; 16 cases; Table VII.

(viii) The intramuscular injection of conessine or of the total alkaloids of kurchi bark; 11 cases; Table VIII.

(ix) Combinations of any two of the above methods, given simultaneously; 15 cases; Table IX.

In one instance a patient was admitted suffering from what was apparently amœbic dysentery, but no *E. histolytica* was found in the stool. He was treated by kurchi orally, but subsequently showed *E. histolytica* in his stools, and was therefore almost certainly a case of amœbic dysentery. Six patients were treated because Charcot-Leyden crystals were found in their stools, though no protozoa were seen; of these four subsequently showed *E. histolytica* in their stools, and two did not. The remaining 147 cases were all treated on account of the finding of *E. histolytica* in their stools.

It frequently happened that when a first line of treatment had proved a failure, after

a short interval the same patient was given a second or even a third—in one instance as many as six—different lines of treatment. The same patients may therefore figure in more than one of the tables. In each case, however, the stools were examined before and after each treatment, and each individual course of treatment therefore counts as one test of that treatment from the point of view of an analysis of the results.

The Question of Accuracy of Diagnosis.

All the stools of the patients concerned were examined in the Protozoology Department of the School, chiefly by the two junior authors, each of whom has acted in turn as Clinical Pathologist to the Department, though all four authors have taken part in this work. The question of accuracy of diagnosis therefore comes up for consideration. In all cases of difficulty or doubt the opinion of one or other of the two senior authors, and often of both of them, was asked.

The diagnosis of the vegetative form of *E. histolytica* in an amoebic dysenteric stool presents but little difficulty to the trained laboratory worker. The diagnosis of *E. histolytica* infection in the stool of the carrier, however, is sometimes a difficult matter. A surprising feature which comes out on a study of the tables is the great frequency with which the vegetative forms of *E. histolytica* were encountered in the stools of carriers. This may surprise workers in Europe, but we have grown accustomed to it in India. As shown by Chandler (1928) the vast majority of stools in India are not formed, but are pasty or semi-fluid, and this particularly applies to in-patients in hospital to whom saline or other aperients may have been administered. In routine work in the Protozoology Department of the School, it is rather unusual to come across a formed stool. It is this fact which accounts for the frequency with which the vegetative forms rather than the cysts of *E. histolytica* were encountered. Frequently also in such stools one comes across both the vegetative forms and the cysts together.

All stools were examined both in saline emulsion and in iodine emulsion; this being an invariable rule in the Department. We think that the diagnosis of the cysts was in all, or almost all, cases accurate; the points of identification upon which we depended were the massive chromatoid bars, the invisibility of the nuclei in saline, and the "histolytica type" of the nuclei as seen in the iodine preparation.

The chief trouble encountered is in the case of the small amoeboid vegetative forms. The same difficulty has been commented on by W. M. James (1926). "It is truly remarkable,"

he writes, "to see the variations in the number of amœbæ that occur, not only in histolytica infections, but in those with the other species as well. On one day the amœbæ will occur in great numbers and are easily found. On another day, they will be uncovered only by a prolonged search in permanent preparations, and the fresh specimen will often be entirely negative." He especially advocates the examination of permanent stained preparations from every stool, in addition to examining saline emulsions. "Survey figures show that one examination uncovers about one-third of the actual number of infections present in a given community; three examinations, between one-half and two-thirds, and six examinations up to about 90 per cent.; an indefinite number of examinations may be required before the remaining 10 per cent. of infection is found. . . . "Frequently in fresh preparations, and sometimes in permanent ones, the precystic stages of *Entamoeba coli* and *Entamoeba histolytica* cannot be differentiated with certainty. In fresh specimens *Iodamoeba bütschlii*, *Entamoeba coli* and *Entamoeba histolytica* are often mistaken for one another, and small *Entamoeba nana* and *Entamoeba histolytica* organisms are very similar indeed."

Such an opinion from a very experienced worker is important, and one must confess that the vegetative forms of *Endolimax nana*, and especially of *Iodamoeba bütschlii*, present difficulties. James does not mention the use of iodine however, though he remarks: "If someone were to make a diagnosis of *E. histolytica* infection on me, I should want a fixed and stained specimen so that I might look at it and see it for myself."

In identifying these small vegetative forms of *E. histolytica*, we have relied chiefly upon (a) the characters of movement of the organism, (b) its large volume of ectoplasm, (c) the absence of ingested bacteria, (d) the invisibility of the nucleus in saline, and (e) the "histolytica type" of nucleus as seen in the iodine preparation. It is obvious from James' paper that the examination of stained preparations is very important in diagnosis; unfortunately, when one has 20 to 30 stools a day to examine as a routine measure, one rarely has time for more than the examination of the saline and iodine emulsions. We can only say that we believe the diagnosis in connection with the patients reported on in this paper to be approximately accurate. In many doubtful cases we have had a second fresh specimen sent in a bed-pan, whilst culture has frequently been resorted to.

In dealing with these different lines of treatment, we propose in each instance to give first a brief historical résumé of the results of previous workers, and then to give

our own results. The protocols will be found in the various tables.

In going through the literature we have made very free use of that invaluable journal, the tropical practitioner's vade-mecum, the *Tropical Diseases Bulletin*.

One paramount difficulty we have encountered throughout. We have tried to retain these patients in hospital for as long as possible after the cessation of treatment, in order that their stools should be frequently examined. After all treatment has ceased, two days are allowed for the elimination of the drug used from the body, and then stools are sent either every day or every other day to the laboratory for examination.

What constitutes a real test for cure (i.e., eradication) of an infection with *E. histolytica*, it is difficult to say. Malins Smith and Matthews (1917) are of opinion that in untreated cases *E. histolytica* reveals itself at examination with remarkable constancy; in 395. examinations of the stools of 20 carriers, cysts or vegetative amœbæ were encountered 129 times. Wenyon and O'Connor (1927, p. 38) state that: "The examination of a single sample from any individual for intestinal protozoa gives a result which is far from reliable. In a series of cases examined with a view to the discovery of the error, the number of *E. histolytica* infections resulting from repeated examinations was three times as great as the result obtained at the first examination."

Dobell and Low (1922, p. 1377) remark as follows on this matter: "It is the general rule that patients undergoing treatment with emetine become 'negative'—i.e., no amœbæ or cysts are discoverable in the stools—whether they are ultimately found to be rid of their infections or not. Negative examinations made during treatment are therefore of no value as a criterion of cure. This 'negative phase' may continue for some time after the administration of the drug has ceased, though the effects of the emetine usually disappear within two or three weeks of the cessation of treatment. It is, moreover, frequently impossible to discover either free amœbæ or cysts of *E. histolytica* in the stools of infected persons—even when they have not been subjected to specific treatment; in other words, the stools of untreated cases, infected with the parasite, are frequently negative. For such reasons, therefore, it is necessary to make a considerable number of examinations of the stools of any patient, and to make them at suitable times, if negative findings are to have any decisive value as an index of non-infection."

"In dealing with a few cases only, the stools may be examined microscopically every day after treatment; and if they remain consistently negative for three weeks, the chances

are that the patient has been permanently freed of his infection. The parasites rarely re-appear in the stools after such a period—if the examinations have been made daily, and by a competent and careful protozoologist. In practice, examination of the stools every few days for a period of about a month after treatment is usually sufficient to establish with considerable probability—if all examinations have been negative—that the patient has been cured..... Six negative examinations made in three weeks should be regarded as the irreducible minimum required before one even ventures to speak of a 'cure' having been effected."

It is precisely in this matter that we have encountered the greatest difficulty. The moment the treatment is over, the patient, having recovered from his symptoms, refuses to stay in hospital. It is usually possible to get one or two stools after the termination of treatment, but by that time the patient has usually left hospital and no more stools are procurable. Even in the case of European patients, it is extremely difficult to secure the samples week by week after the cessation of treatment, for the patient, having recovered from his symptoms, will not take the trouble to send specimens to the laboratory. Dobell and Low's criterion of six negative examinations in three weeks is very difficult to secure. Occasionally a careful patient, interested in his own case, and really desirous of knowing whether the infection is or is not eradicated, can be induced to send a specimen once a week for eight weeks, but such patients are the rare exception and not the rule.

Donaldson, Clark and McLean (1918) advise that "at least five examinations ought to be made in cases of amœbic dysentery." We have been particularly unfortunate in this matter; in reality the testing of any supposed "cure" for amœbiasis should be tried out in the army or in jails or other institutions where the patients can be followed up for some considerable time after the cessation of treatment, and the necessary samples obtained for examination; and we would appeal to those who are in a position to do so to carry out tests on such material. Here we can only give our own imperfect results.

It is necessary, however, to establish some standard test and to stick to it. Accordingly we may adopt the following terms:—

(a) "*Failures of treatment.*"—If either the vegetative or the encysted form of *E. histolytica* be found in the stools after the cessation of all treatment, it is clear that the infection has not been eradicated; such cases we may term "failures of treatment."

(b) "*Probable cures.*"—These are cases in which the examination of five or more stools after the cessation of all treatment has failed to show any form of *E. histolytica*. It

TABLE I.
Alcresta Ipecac.

No.	Name.	Caste.	Sex.	Age.	Disease for which admitted.	Previous intestinal history.	Previous treatment.	Findings in stool on admission.	Treatment.	Findings in stool after treatment.	REMARKS.
1.	P. C. D.	H.	M.	38	Colitis	Diarrhoea for 4 months with much abdominal colic.	9 injections of conessine.	<i>E. histolytica</i> : veg. and cysts.	2 tabs. daily, 10 days.	7 examinations. Negative.	
2.	O. A. C.	Jew	M.	48	Dysentery, relapse.*	Previous attack the year before.	Emetine injections.	Veg. <i>E. histolytica</i> .	2 tabs. daily, 10 days.	5 examinations. <i>E. histolytica</i> cysts at 5th examination.	Then put on "E. B. I."
3.	J. W. C.	A. I.	M.	39	Chronic amoebiasis.	Previous courses of conessine and emetine.	Veg. <i>E. histolytica</i> . <i>Giardia</i> cysts.	4 tabs. daily, 10 days.	1 examination. Veg. <i>E. histolytica</i> .	
4	A. E. M.	E.	M.	42	Gastric ulcer	Prolonged history of abdominal pain, 7 years. Mucus frequently in the stools.	Veg. <i>E. histolytica</i> . C. L. crystals.	4 tabs. daily, 10 days.	1 examination. Veg. <i>E. histolytica</i> .	
5.	E. W. B.	A. I.	M.	43	Tabes dorsalis	Dysentery 5 years previously.	Veg. <i>E. histolytica</i> . <i>E. coli</i> cysts.	3 tabs. daily, 10 days.	16 examinations in 2 months. Negative.	
6.	H. G. L.	A. I.	M.	42	Filarial lymphangitis.	Mild attack of dysentery, 13 years previously.	<i>E. histolytica</i> cysts.	3 tabs. daily, 10 days.	5 examinations. <i>E. histolytica</i> cysts + at 4th and 5th.	Then put on kurchi alkaloids.
7.	Mr. R.	E.	M.	32	Dysentery.	Emetine injections 9 grs. with bismuth.	<i>E. histolytica</i> cysts.	4 tabs. daily, 10 days.	5 examinations. Negative.	

* Note.—Throughout the Tables the sign * means that the patient was passing blood at the time of admission, i.e., a condition of actual dysentery was present.

is very far from certain that all such cases have really been cured, but the chances appear to be on the side of a favourable prognosis at least, for the future.

(c) "*Indeterminate cases.*"—These are cases where less than five stools have been secured for examination after the cessation of all treatment, but in which those that have been examined have given negative results. It is impossible to say whether such cases will or will not relapse. Unfortunately, the bulk of our cases fall into this "indeterminate" group. It is for this reason that it has taken us so many years of work before we considered that we had accumulated a sufficiently large series of observations to warrant publication.

With so much by way of preliminary, we may pass to the consideration of the different lines of treatment tried.

I. ALCRESTA IPECAC. (LILLY & CO.)

Historical.—The makers state that "Alcresta Ipecac." is a product in which the total alkaloids of ipecacuanha bark are adsorbed with Fuller's earth, each tablet containing the total alkaloids from 10 grains of ipecacuanha, U. S. P. The dosage advocated in amoebic dysentery is 2 or 3 tablets three times a day. The retail price in India is Rs. 4 per bottle of 40 tablets.

We have not been able to find many papers in the literature dealing with this preparation. Allan (1916), as the result of observations on 10 cases, came to the conclusion that the results are unsatisfactory on account of the variation in absorption from the intestinal tract, and claims that emetine given hypodermically is twice as efficacious. Stephens and Mackinnon (1917) used the preparation in 81 cases, all carriers. Their paper is a particularly valuable one on account of the detailed following up of the patients and the repeated examination of the stools after treatment. Of the 81 cases, 13 left hospital immediately after treatment and could not be followed up; 12 had not completed treatment when the report was written; 38 had apparently been freed from infection and had not relapsed up to periods of 3 to 7 weeks after the completion of treatment; 14 relapsed, but of these, 4 subsequently cleared up after a second or third treatment; 4 were definite failures of treatment. "Our results," they write, "compare very favourably with those obtained by the injection of emetine hydrochloride." Macgregor and Frew (1922) treated 15 cases by alcresta ipecac. given orally in doses of 30 grains a day, combined with daily injections of emetine. The cases were all examples of old standing chronic infections, and in only 2 of the cases could the results be considered permanently satisfactory.

Results in Calcutta. In all we have treated 7 patients with Alcresta Ipecac. The results are shown in Table I. Of these, 1 showed blood in the stool at the time of admission, 3 were cases of chronic amoebic colitis, and the other 3 were carriers only.

The results are:—

Cases treated,	7.
Probable cures,	3 (Nos. 1, 5, and 7).
Failures of treatment,	4 (Nos. 2, 3, 4, and 6).

These results are very unsatisfactory. The general findings may be expressed, perhaps, in terms of positive and negative stool examinations, as a measure of the degree of reduction of

the parasite numbers by treatment. Before treatment 7 stools were positive; after treatment, out of 40 stools examined, 35 were negative and 5 positive. The ratio of probable cures to failures is 1 : 1.3, and the ratio of positive to negative stools after treatment is 1 : 7.

It is clear that Alcresta Ipecac. will occasionally eradicate an infection with *E. histolytica*: Case 1 of Table I yielded 7 negative examinations after treatment, and Case 5 of the table—a carrier—was almost certainly cured. On the other hand, the results are usually disappointing, whilst the preparation is too expensive for dispensary use in India. The retail price of a bottle of 40 tablets on the Indian market is Rs. 4; the cost of treating these seven cases therefore works out at an average cost of Rs. 3-2-4 per patient. On the other hand, there are certain points in favour of the preparation; the drug is well tolerated, and its administration is not followed by nausea or vomiting, as with emetine bismuth iodide. We have usually prescribed it the last thing at night, as an alternative to emetine bismuth iodide. It is a suitable preparation for the private and paying patient.

II. EMETINE INJECTIONS ONLY, AND NOT ACCOMPANIED BY ANY OTHER TREATMENT.

Historical.—The literature on the treatment of amoebiasis by injections of emetine is so enormous that we cannot do more here than mention only the most important of the papers. Very many—perhaps the majority—of the published papers on emetine have very little value, since patients have not been followed up, and stools not examined after the cessation of treatment. The general consensus of opinion amongst the more careful observers appears to be that, whilst there is hardly any line of medicinal treatment which gives more immediate and more striking clinical results in the treatment of amoebic dysentery, yet emetine injections appear to fail to eradicate the infection with *E. histolytica* in quite the majority of patients.

The alkaloid emetine was first isolated by Pelletier in 1817. According to Sir Leonard Rogers (1913, p. 29) it was used by Bardsley of Manchester in 1829, who reported favourably on it. Tull Walsh (1891) gave it orally in the form of mercuric emetine iodide in Calcutta, but concluded that it did not give better results than other drugs. Vedder (1911) found that it was a powerful amoebicide against free-living amoebæ, killing them in a solution of 1 : 100,000. He further found that de-emetinised ipecacuanha is without action on amoebæ. In 1912 he claimed that the emetic action of ipecacuanha is chiefly due to its cephaelin, not to emetine, and suggested the use of emetine in amoebic dysentery. Lyons (1912) working independently failed to find that ipecacuanha has any effect on free-living amoebæ, but on analysis of one of the samples used, found that it had only one-fifth of the total alkaloids demanded by the U. S. Pharmacopeia. Wherry (1912) found emetine to be lethal in dilutions up to 1 : 200,000 to free-living amoebæ at body temperature, if the exposure given is sufficiently long.

In the meantime, Sir Leonard Rogers had for many years been a strong advocate of ipecacuanha in the treatment of amoebic dysentery and hepatitis, and in June 1912 he reported on 2 cases of severe amoebic dysentery and 1 of acute hepatitis cured by emetine.

The introduction of emetine therapy, indeed, is one of Sir Leonard's greatest contributions to tropical medicine.

The literature on emetine rapidly became enormous, and several papers by Rogers and other authors followed. These earlier papers are summarised by Vedder (1914) in a paper with a full bibliography. He quotes 110 cases of dysentery treated, with 99 cures and 11 deaths, and 16 cases of amœbic hepatitis, all cured by emetine. Rogers (1912a) contrasted the extremely rapid and effective action of emetine with the much less certain and less satisfactory results with ipecacuanha, and later in the same year (Rogers, 1912b) recorded a fatal case of gangrenous amœbic dysentery, where emetine had been given, and where prolonged microscopic examination of the scrapings from the ulcers failed to show any amœbe, whilst sections of the gut wall also showed no parasites. It was soon established that the hypodermic administration of emetine is the most certain, rapid and efficacious line of treatment in amœbic dysentery and hepatitis.

On the other hand, whilst clinical results* were eminently satisfactory, and whilst emetine came into universal use (and is to-day undoubtedly the best line of treatment for a condition of actual dysentery due to infection with *E. histolytica*), doubts began to arise in the minds of careful workers as to the permanency of the cure. Thus, Baermann and Heinemann (1913) comment on the fact that after an interval of 10 days or so from the cessation of treatment, the amœbe tend to reappear in the stools, although the patients remain in good health. Walker (1913) writes, "None of the 20 experimentally infected, or of the 9 naturally infected men has ceased to be a 'carrier' of the *Entamoeba histolytica*, although some of them have been under observation for over 2 years." Vedder (1914) notes that the infection may often not be eradicated, and suggests irrigations of quinine or of silver nitrate for the carrier state. Emetine, he remarks, is without effect in bacillary dysentery; it is also toxic, and too large doses should not be employed.

Whitmore (1914) reported a trial of emetine in 34 cases of dysentery. He notes that relapses after apparent cure are not uncommon, and draws attention to the danger of failing to recognise cases of mixed bacillary and amœbic infection, illustrating this point with notes of three such cases. Willets (1914) says that 4 cover-glass preparations should be examined and be found to be negative at each of 3 examinations of the feces after the cessation of treatment before a case may be said to be free from entamœbe. Ipecacuanha, he notes, may be superior to emetine in finally exterminating the infection.

From this point onwards we may perhaps consider only the more important papers, and especially those in which the test for cure consisted in repeated examination of the stools after the cessation of treatment. Phillips (1914) emphasises that no patient should be considered cured until after several examinations no cysts of *E. histolytica* have been found in the feces. Emetine often fails to eradicate the infection; and after a course of emetine, a course of treatment with calomel and thymol is advocated to eradicate the residual infection. Sandwith (1914) in the Lettsoman lectures on dysentery advocates large doses of bismuth as a subsidiary measure, and records fatalities in spite of emetine treatment. Chalmers and Archibald (1915) draw attention to cases of infection of prolonged duration—up to three years or more—without noticeable diarrhoeic attacks; they advocate repeated courses of emetine at suitable intervals. Barlow (1915) with an experience of treatment of over 300 cases, notes that 75 patients who were treated for only 3 to 6 days with emetine all relapsed. On the other hand, the administration of emetine should not be continued for more than 2 to 4 weeks; the ill-effects of the drug are seen after prolonged treatment, rather than with large doses. He advocates following up the emetine injections with a course of ipecacuanha orally, and subsequent examination of the stools once a month. Low (1915) comments on the small residuum of cases which prove to be refractory to emetine

treatment. J. G. and D. Thomson (1916) advocate half a grain of emetine hypodermically each night and morning until a total of 7 to 10 grains has been given, whilst saline aperients are given at the same time. Insufficient treatment they consider dangerous as it converts the patient into a carrier. Dobell (1916) notes that the infection was not eradicated in 14 out of 21 patients to whom a course of from 12 to 14 grains was given; in the remaining 7, examination of the stools gave negative results for 2 to 3 weeks after the cessation of treatment.

A very important memoir on the subject, and one which should be read in the original by all interested in it, is Dobell's report to the Medical Research Committee (Dobell, 1917). He points out that after a course of emetine injections there is an after-phase during which the stools may continue to be negative up to 3 weeks, before cysts reappear in them. Thus the value of early negative findings after treatment is far less than that of consistently negative findings some weeks or months after the cessation of treatment. He gives the following table of results after full emetine treatment:—

Number of treatments	.. 74.
Number of cures	.. 15, or 20.27 per cent.
Number of doubtful cures	7, or 9.46 per cent.
Number of certain failures	52, or 70.27 per cent.

His conclusions with regard to emetine are as follows:—

(i) Emetine hydrochloride administered hypodermically in small quantities (less than 10 grains in total amount) very rarely rids a carrier of *E. histolytica* of his infection.

(ii) Full courses of the drug (10 to 12 grains or more) are successful in about one-third only of the cases treated.

(iii) Re-treatment—with equal or larger amounts of the drug—of patients who have already received full courses of treatment offers little hope of success.

A most instructive paper is one by Jepps (1916), who gives full protocols in tabular form. Of 23 persons treated, from 5 to 14 examinations of the stools after treatment showed only 7 apparently permanent cures. After the injection of at least 10 grains of emetine, 12 out of 21 cases were certainly not permanently freed from *E. histolytica* infection. Mauté (1916) notes that 6 per cent. of patients still show cysts after a course of treatment; a rectal irrigation with iodine 1 gramme, and potassium iodide 2 grammes in a litre of water should be given and the stools be examined the next day; this will often lead to the finding of cysts where previous examinations have had negative results. Job and Hirtzmann (1916) found that 28 per cent. of convalescents who had had one or more courses of emetine still showed cysts in their stools.

An exhaustive report is that by Carter, Mackinnon, Matthews, and Malins Smith (1917) on the protozoological findings in 910 cases of dysentery examined at the Liverpool School of Tropical Medicine. Up to 6 examinations are necessary to reveal all carriers. Craig (1917) writes, "It is not believed that anywhere in the world has emetine been more thoroughly and extensively used in the treatment of this disease than it has in Base Hospital No. 2. Not only has a single course of 12 grains been given, as advocated, but this course has been repeated in not a few instances, but despite this thorough treatment no less than 65 of 115 patients treated at Base Hospital No. 2 developed cysts of *Entamoeba histolytica* and became 'convalescent carriers' of the disease. The treatment of these carriers with the same drug has resulted in curing but 4 cases that have been observed for as long as 2 months since the cessation of treatment, or slightly over 6 per cent. . . . The fact that following treatment with emetine the motile forms and cysts may disappear from the stools within a short period of time, is no proof that the infection is really cured, for examinations made at a later date often result positively." (Seven illustrative cases of this state of affairs are given.) "The

drug has a wonderful effect upon the acute symptoms of the disease, causing them to disappear in most instances within a few days after its administration, but, even when given until toxic symptoms appear, it does not actually cure the infection or prevent 'carriers,' save in a very few instances."

Wenyon and O'Connor (1917) advocate a 12-day combined emetine treatment, consisting of 1 grain a day by injection *plus* half a grain orally. They give the following tabulated results:—

		Emetine, 1 gr. a day by injection.	Emetine, 1 gr. a day by mouth.	Emetine, 1 gr. a day by injection; $\frac{1}{2}$ gr. a day by mouth.
Carrier cases	37	6	30	
cured.				
Carrier cases	10	2	0	
relapsed.				
Carrier cases	5	1	0	
no reaction.				
Acute cases	0	0	2	
cured.				
Acute cases	6	2	5	
relapsed.				
Acute cases	0	1	0	
no reaction.				

The authors contrast the much better results of this treatment for the carrier state than for actual dysentery.

Carter, Mackinnon, Matthews and Malins Smith (1917a), in their second report, comment on the use of methyl emetine; of 6 cases treated with 1 grain daily for 15 days, in only 1 was the infection eradicated, as judged by subsequent stool examinations. Savage and Young (1917) record the results of several different lines of treatment, the test for cure being absence of parasites from the stools for 3 weeks after the cessation of treatment. Nineteen patients were treated by emetine injections alone: of whom 7 relapsed and 3 proved to be failures of treatment. Seven were treated with emetine injections and pulv. ipecacuanha: of whom 1 relapsed. Four were treated by emetine given both orally and hypodermically: of whom none relapsed. MacAdam (1918) studied the problem in Mesopotamia. Twenty known carrier cases were followed up after treatment and discharge from hospital; at the first stool examination 10 were found to be still positive; and after seven consecutive stool examinations only 3 out of the 20 had remained negative. Of 195 men recently discharged from hospital after treatment for dysentery, 38 or 19.4 per cent. were found to be carriers. The attempt to "clear" carriers seems to be a hopeless one. The same author (MacAdam, 1919) reports further on the combined treatment with emetine hypodermically and orally. Eighty cases were treated, each for 12 days with 1 grain of emetine hypodermically and half a grain orally. The stools were then examined on 26 days for a period of from 6 to 8 weeks, and in 71 of the cases the further progress was followed up for from 6 to 9 months. Of the 80 cases, 62 were cured and 18 relapsed, mostly within 4 weeks of the cessation of treatment. He speaks very highly of the combined treatment.

A most important memoir on the subject is that by Gunn and Savage (1919), who worked at Alexandria. The stools of all patients were examined from 4 to 7 times weekly after the cessation of treatment. The patients fell into the following series:—

(a) Daily injections of emetine; 21 cases; 4 of acute dysentery, 1 cured; 17 carriers, 11 cured.

(b) Emetine bismuth iodide, gr. iii orally daily for 12 days. 24 cases; 10 acute, of whom 4 were cured; 14 carriers, of whom 9 were cured.

(c) Emetine gr. i by injection daily, *plus* emetine bismuth iodide gr. iii orally at night; for 12 days: 12 cases; 5 acute cases cured and 1 relapsed; 6 carriers, all cured.

The authors consider this the most satisfactory line of treatment, but remark that it is rather "rough" on

the patients who become weak, depressed, and emaciated.

(d) Emetine gr. i daily by injection, *plus* 10 grains of ipecacuanha daily in pill form. 16 cases; 4 acute cases, of whom 2 were cured; 12 carriers, none cured.

(e) Emetine gr. i daily by injection for 12 days, followed by oral administration daily of emetine bismuth iodide gr. ii for 14 days. 58 out of 68 carriers cured.

(f) Emetine gr. i by injection daily for 12 days, followed by oral administration of emetine bismuth iodide gr. iii daily for 14 days. 103 out of 122 carriers cured. This is the line of treatment finally recommended by the authors whose paper is one of the most important in the whole literature.

Brug (1919) considers 7 examinations during a month after cessation of treatment a criterion for cure, but records disappointing results with emetine in Batavia. Of 19 cases of infection in Europeans only 4 were cured, and 6 out of 12 cases among Javanese patients. MacAdam (1919) considers that at least one-third of the men returned from the war fronts to the convalescent depot at Deolali were *E. histolytica* carriers; he considers the suggestion of treating all carriers in the army an impracticable one. Of 80 cases of infection studied, 36 were chronic dysenterics with a history of more than 6 months' duration, and with two or more relapses. Thirty per cent. of patients treated showed signs of persistent infection within 6 weeks of completion of treatment, and 8 out of 36 persistent carriers reported an acute relapse within 6 months of completion of treatment. Carriers without symptoms proved easier to cure; in only 4 out of 32 such cases did the infection persist.

Fletcher (1922) records an interesting point. During the first 6 months of 1921, experience at Kuala-Lumpur seemed to indicate that emetine was not active in amoebic dysentery, but in July 1921, fresh preparations of emetine were made up in the laboratory, and with these the subsequent results were uniformly good. Some of these patients died from other diseases and in these at post-mortem it was found that the healing of the amoebic ulcers was taking place "with almost magical rapidity."

Hage (1923), working on the personnel of the German navy after the war, reports that energetic treatment with emetine during the acute stage appeared in no way to minimize the liability of the patient to become a carrier. Willmore (1923) has an important memoir on a large series of cases treated at the Ministry of Pensions' Hospital, all of them diagnosed microscopically. His practice is to give 20 grains of emetine and 60 grains of emetine bismuth iodide in 20 days. Of 358 cases so treated—

99 were presumably cured after the first course 28 per cent.
259 relapsed 72 per cent.

(2) Of these 259 relapse cases, 183 received a second course—

36 were presumably cured 20 per cent.
147 relapsed 80 per cent.

(3) Of these 147 relapse cases, 59 received a third course—

3 were presumably cured 5 per cent.
56 relapsed 95 per cent.

(4) Of these 56 relapse cases, 26 received a fourth course, 8 of them a fifth course, and 7 of the last a sixth course; all relapsed. The author concludes that neither emetine nor emetine bismuth iodide is a specific cure for amoebiasis. Ipecacuanha in bolus or cachets, and alcresta ipecac. proved still more disappointing; and the author advocates supplementing hypodermic or oral medication by rectal irrigations of emetine base suspended in olive oil with the aid of ether.

Oliver (1924) reports on 292 cases of amoebic dysentery treated at Basra. The patients were given an early morning saline aperient, gr. i of emetine hypodermically, and gr. $\frac{1}{2}$ of emetine orally every day for 12 days. Seventy-eight per cent. of cases still showed cysts after treatment, and emetine *per se* must be looked upon as a total failure in eradicating the infection. The presence

of malaria as a complication made matters even worse, and the task of eradicating an amœbic infection in a patient debilitated by malaria appeared almost hopeless. Mixed infections were common, and the *B. dysenteriae* were isolated from 21 of the cases. The author observes that emetine treatment appears to be much more successful in the warm weather than in the cold. The combination of salol in liquid paraffin with emetine treatment gave better results; 11.2 per cent. only of 53 uncomplicated cases so treated were found to pass cysts after cessation of treatment.

Petzetakis (1924) advises the administration of emetine intravenously. In the treatment of acute cases a course of 7 such injections is given; then 20 to 30 days later a second course of 5 or 6 injections, given on alternate days; later, within 1 year of the attack, 3 further courses, making 5 courses in all during the year. During the next two years 2 or 3 further courses are advised. In chronic cases he records that surprisingly good results are obtained, and sometimes eradication of the infection. Calcium chloride intravenously is also advocated as a supplementary treatment.

Traviagino and Soedjono (1924) report on the treatment of some 350 cases in Java. They place yatren first in order of therapeutic efficacy, emetine second, and emetine bismuth iodide third. Sellards and Leiva (1923) have shown that the hyperacute amœbic dysentery which results in kittens from inoculation per rectum with infective material can be cured by rectal administration of emetine at a dose of 20 mgm. per kilo. In man they consider that recovery from amœbic dysentery results from two factors: (a) the natural resistance of the host, and (b) a moderately toxic action of emetine on the entamœbæ.

A very full investigation is reported by P. W. Brown (1926). There were 153 cases with active dysentery or liver abscess; 258 cases with diarrhoea and similar abdominal complaints; and 122 carriers without symptoms. A study of gastric test meals showed that chronic diarrhoea in infections with *E. histolytica* may be associated with achlorhydria, and administration of dilute hydrochloric acid may be a useful measure. "To establish a cure," he writes, "is very difficult; repeated examinations of stools must be made over a period of months, and reinfection must be prevented. Ipecacuanha or its derivatives are effective in only 58 or 70 per cent. of cases. Emetine and arsphenamin form a useful combination. With the resistant case, persist rather than temporize. The parasite can eventually be eradicated."

Dobell and Laidlaw (1926) in a very important memoir report on the action of emetine *in vitro* on *Entamœba histolytica* in culture. Their conclusions are as follows:—

(1) Emetine and cephaeline have been found to be specific poisons for *Entamœba histolytica* under cultural conditions.

For the amœba (in culture) these alkaloids are at least 50 times as poisonous as isoemetine, psychotrine, methylpsychotrine, demethoxyemetine, or noremetine.

For this species also emetine has been found to be about 10 times as poisonous as stovarsol, and about 50 times as poisonous as quinine—under identical conditions of experiment.

(2) *Entamœba coli*, *Entamœba gingivalis*, and *Endolimax nana* have been found comparatively insensitive to the presence of emetine in cultures—*E. coli* being able to withstand a concentration of the alkaloid at least 100 times that which is lethal to *E. histolytica*.

(3) The effects of solutions of emetine on *E. histolytica* are peculiar. Very strong concentrations (1 per cent. or more) are needed to kill this parasite instantaneously, but only very weak solutions (1 in 50,000 or less) are necessary to kill it if allowed to act for a sufficient time.

(4) In view of these findings it is concluded that the curative effects of emetine in human amœbic dysentery are best explained as a result of the direct lethal action of the alkaloid on *E. histolytica*.

Drake-Brockman (1926) notes that pushing the use of ipecacuanha and its derivatives to excess, renders the

amœbæ emetine-fast. Courses of treatment should, therefore, be given at intervals, notwithstanding the presence of entamœbæ in the stools. Between the courses, yatren or kurchi may be given. In some cases benefit follows the use of massive doses of bismuth. In out-patients good results were obtained by the use of bismuth subnitras, gr. 30, combined with sodæ bicarbonas, gr. 10, given t.i.d.; later, doubling the bismuth and continuing the treatment for 3 or 4 months with pulv. ipecac. radix in 10 to 20 grain doses in a cachet at bedtime for the first month or two only. When the lesions are in the cæcum or high up the colon, no drug can at present replace ipecacuanha and its derivatives.

Young and Tudhope (1926) describe the pathology of prolonged emetine administration in man and in experimental animals. Comparing the findings in rabbits with a man of 12 stones weight, 11 doses of 1.9 grains would prove fatal, and 35 doses of 0.8 grains would be distinctly risky. Not more than 1 grain should be given in the 24 hours, and not more than 12 grains in a course. The patient should be kept as completely at rest as possible, owing to the toxic action of emetine on the heart muscle; exercise whilst under treatment is directly contra-indicated. Newman and Davies (1926) also emphasise the dangers of emetine therapy on the heart; a course of 12 to 15 grains should not be exceeded. Stovarsol is nearly as efficacious as emetine, and a combination of the two drugs may eventually prove to be the best method of treatment.

Schur (1927) stresses his almost unfailingly good results with emetine therapy in ulcerative colitis. These cases are in fact amœbic, though it may sometimes be difficult to demonstrate the amœbæ in their stools. He gives the emetine in small divided doses—0.02 gramme 3 times a day subcutaneously. In this dosage, no toxic or harmful results have been detected. Together with emetine therapy he insists on the necessity for daily irrigation of the colon with mild astringents. van Steenis (1927) states that hypodermic injections of emetine are still indispensable in the treatment of amœbic dysentery; dose 30 to 60 mgm. daily on 5 consecutive days, not more than once a month. Houssiau and Duwez (1927) claim that emetine, given alone, is a sufficient and effective cure for amœbic dysentery, if given from the first onset of the disease. It has little or no effect on the carrier state, and in such cases emetine treatment should be combined with stovarsol or yatren administration.

In summing up the above series of papers, the general consensus of opinion appears to be (a) that emetine injections are by far the most satisfactory immediate line of treatment for amœbic dysentery, but (b) that emetine therapy is generally a failure in the treatment of the carrier condition. It has been shown by S. P. James (1926) that primary malaria, as therapeutically induced in the treatment of general paralysis of the insane, is a disease which is very readily amenable to quinine treatment; only a few days of quinine treatment are necessary to effect a cure without relapses. On the other hand, the experience of all workers in the tropics is that established and relapsing malaria is very difficult to eradicate. Possibly a similar state of affairs exists with regard to amœbic infection; the prospects of eradicating the infection by emetine therapy may be much better in patients seen when suffering from their first attack of amœbic dysentery, than in cases where the infection has become a chronic and established one.

RESULTS IN CALCUTTA.

Thirty-two patients were treated by injections of emetine only, unaccompanied by any other form of treatment. Details are given in Table II. Seven of these patients had blood in the stools on admission; 17 were cases of chronic amœbiasis; and 8 were

carriers admitted for conditions other than amœbiasis.

The results may be summed up as follows:—

Cases treated, 32.

Possible cures, 6 (Nos. 3, 4, 6, 15, 22 and 28).

Failures of treatment, 10 (Nos. 13, 16, 17, 18, 20, 21, 24, 25, 26 and 30).

Indeterminate, 16 (Nos. 1, 2, 5, 7, 8, 9, 10, 11, 12, 14, 19, 23, 27, 29, 31 and 32).

(Case 23 was re-admitted with amœbic infection 3½ years after discharge, but this may have been either a relapse or a fresh infection).

The ratio of possible cures to failures on this table is as 6:10 or as 1:1.7, which is somewhat worse than the results with Alcresta Ipecac. After treatment the ratio of positive to negative stools was as 12:84 or 1:7, a figure which corresponds exactly to the one for Alcresta Ipecac. The average number of grains of emetine administered per course was 7.4, and the cost at Rs. 2 per tube of 6 one-grain-tablets of emetine works out at an average of Rs. 2.7-6 per treatment.

These results are very similar to those of other workers. There is no doubt that emetine injections will occasionally eradicate an infection with *E. histolytica*—and apparently the alkaloid is more active when an actual condition of dysentery is present than in cases of chronic amœbic colitis, but in the majority of cases the injections do not achieve more than cleaning up the symptoms. Case 3 in Table II, a case of active dysentery, appears to have been completely cured. Case 4, one of chronic and relapsing dysentery, was almost certainly cured. Case 28, with a similar history, was also almost certainly cured.

The results, on the whole, however, are very disappointing.

III. EMETINE INJECTIONS PLUS THE ADMINISTRATION OF LARGE DOSES OF BISMUTH ORALLY. (Deeks' treatment.)

Historical.—The treatment of dysentery by administration of very large doses of bismuth orally was resorted to about 1908 by Dr. W. E. Deeks at the Ancon Hospital, Panama Canal Zone, and gave promising results. These were analysed in a first paper by Deeks (1913), and in a later paper by the same author (1914). In the meantime the use of emetine in the treatment of amœbic dysentery had been introduced by Sir Leonard Rogers in 1912, and Deeks now turned to a line of treatment by daily injections of emetine, combined with oral administration of massive doses of bismuth salts. W. M. James (1913) studied the effects upon the vegetative forms of *E. histolytica* of bismuth and of emetine respectively, and showed that the amœbæ passed by patients on bismuth or on emetine treatment were degenerating, but that the type of degeneration was different with the two drugs. He suggests that to some extent the bismuth subnitrate may be converted into bismuth sulphide in the gut, and that this may deprive the amœbæ of hydrogen sulphide, which may be an essential element of their food supply. He advocates a course of from 9 to 12 grains of emetine by injection, and

bismuth subnitrate, 3 drs. suspended in water orally every 3 or 4 hours; and compares the combined emetine and bismuth therapy to the combined salvarsan-mercury treatment in syphilis.

Deeks (1914), in publishing his first results with emetine, notes that the simultaneous administration of bismuth subnitrate in teaspoonful doses 3 times a day will control any diarrhoea which may be present, and writes, "I believe that with the two drugs, either singly or combined, almost every case of amœbic dysentery can be cured..... It is better to combine bismuth with the emetine."

W. M. James (1916) is emphatic in his claim for the value of the combined treatment "Intestinal amœbiasis, whether acute or chronic, can be eradicated," he writes, "provided the patient is not in *extremis* with the acute form, with the same certainty as malaria and with more certainty than syphilis, by the use of a liquid diet until the stools are formed, and of bismuth given in doses of not less than a teaspoonful 4 times a day, continuing over a period of several weeks, and emetine carried to the point of physiological reaction."

Warrington Yorke (1919) speaks very highly of the value of this treatment in active amœbic dysentery. "A preliminary saline purge is given unless the acute dysentery has already persisted for several days, in which case it is unnecessary. Emetine hydrochloride, gr. i, is injected subcutaneously, and bismuth subnitrate drs. ii or drs. iii, suspended in milk or water is given by the mouth 3 or 4 times a day for a period of 12 days. Occasionally, a morning saline may be necessary if the bismuth causes constipation. This treatment, in my experience, invariably clears the stools of entamœbæ—a result which can by no means be claimed for emetine alone."

Connor (1918) records over 100 cases treated by this method between 1914 and 1918 at Ancon, and states that, as far as could be ascertained, only one relapsed. James and Deeks (1924) state that 75 persons who had been cured by this treatment between 1914 and 1923 were living in the Canal Zone, and none of them had relapsed. They believe that certain products of putrefaction are essential to the life of the amœbæ, and that bismuth acts either by destroying the putrefactive bacteria, or by neutralising some product essential to the life of the amœbæ. Occasional untoward effects are noted, due to the use of impure bismuth. Judging from clinical experience, cases of amœbic dysentery are cured in this manner with but few relapses.

Deuskar (1926) has tried the method with very good results in the Andamans. Newman and Davies (1926) contrast the results by this treatment with the results obtained with stovarsol. The stools were examined at the 4th, 11th, 18th, 19th, 20th and 21st days after completing treatment; of 9 cases treated, 1 died from pneumonia and 1 relapsed; the 7 others appear to have been definitely cured.

RESULTS IN CALCUTTA.

Fifty-five patients received this line of treatment. Of these 11 had blood in the stools on admission, 34 were cases of chronic amœbic colitis, 1 was a case of mild amœbic hepatitis with a previous history of dysentery and cysts of *E. histolytica* in the stools, and 9 were carriers admitted for diseases other than colitis. Details are given in Table III. This treatment is the one usually given by the senior author of this paper and by Colonel Acton for all cases of amœbic infection where a dysenteric state is actually present.

The results may be summed up as follows:—

Cases treated, 55.

Probable cures, 9 (Nos. 1, 18, 19, 35, 37, 39, 48, 51 and 52).

Failures of treatment, 16 (Nos. 17, 23, 27, 32, 33, 34, 36, 38, 40, 45, 46, 47, 49, 50, 53 and 55).

Indeterminate, 30 (Nos. 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16, 20, 21, 22, 24, 25, 26, 28, 29, 30, 31, 41, 42, 43, 44 and 54).

Unfortunately, it proved to be impossible to follow up no less than 30 of the series treated; a fact the more to be deplored since our clinical impression of this line of treatment for cases actually suffering from dysentery at the time of admission is that it is far and away better than treatment with emetine alone.

The ratio of probable cures to failures on this table is as 9 : 16 or 1 : 1.8, a figure which is just slightly worse than that for emetine alone (though our clinical impression of this line of treatment does not in any way tally with this). On the other hand, the proportion of negative stools after treatment is higher than with the emetine or alcresta treatments; it works out at 16 positive to 139 negative stools or a ratio of 1 : 8.7. Our standard course of this treatment is the administration of 9 grains of emetine in 12 days, together with 2 drs. of bismuth subnitrates t.i.d. on 9 out of 12 days. The cost of bismuth subnitrates (Howards') being Rs. 3-12-0 per lb., the approximate cost of this treatment works out at Rs. 4-9-4.

The very large proportion of indeterminate cases renders the results reported in Table III too vague to be of much value, but in some instances this line of treatment appears to establish a definite and certain cure; instances in the table are Cases 1, 18, 19, 27, 35, 37, 39, 48, 51 and 52. Case 39 was particularly interesting. This patient, a European male, aged 35, had been suffering from chronic relapsing amœbic dysentery for three years; he had received all sorts of irregular treatment from various practitioners in Calcutta as an out-patient, and finally came into the hospital as a last resort. After treatment he systematically sent one stool a week to the laboratory for examination for eight weeks; all examinations were negative, and two years after treatment he was in excellent health, with no return of symptoms.

In our experience the addition of the "Panama bismuth" treatment, from the clinical point of view at least, certainly improves results; but even the combined treatment appears more often than not to fail to eradicate the infection.

IV. EMETINE BISMUTH IODIDE. "E. B. I."

Historical.—The history of the introduction of emetine bismuth iodide is interesting. Tull Walsh (1891), being dissatisfied with the results of oral administration of emetine, tried the double iodide of emetine and mercury in Calcutta on 22 cases. The average number of days during which dysenteric stools were passed was 49 and he reported that "although emetine mercuric iodide seems a useful drug, it is not proved to be much better

than preparations of *Wrightia antidysenterica*..... nor do I recommend it above other drugs." No further attention to the use of double iodides was paid until DuMez (1915) manufactured emetine mercuric iodide and emetine bismuthous iodide, and suggested as the result of experiments on dogs that these two compounds might be capable of administration in large and frequent doses, which would permit of the emetine coming into contact for a prolonged period with the entamœbæ.

The treatment of carriers during the Great War with emetine or with ipecacuanha having proved extremely unsatisfactory, Dr. Dale under the auspices of the National Medical Research Council took up the study of emetine bismuth iodide in 1916. It was found that large cats weighing 3 kilograms could stand doses up to 40 mgms. without vomiting, and the drug was first tested on 10 human carriers. Of these, 6 were followed up with stringent daily examination of the stools for 6 weeks, and appeared to be permanently cured. A seventh relapsed, but was free from infection after a second course of treatment. The eighth case was unable to stand the full course, but cysts were still absent. The ninth patient relapsed, whilst the tenth could not continue with the treatment owing to the vomiting and diarrhœa it caused.

From this date onwards the literature on "E. B. I." became abundant, and the drug appears to have been used chiefly by the British school of workers. Low and Dobell (1916) reported on 3 cases: 1 of acute dysentery, the other 2 carriers, with good results. Dobell (1916) reported on the treatment of 11 carriers who had not been cured by injections of emetine. Twenty-one carriers were first treated with a full course of emetine injections; and subsequent stool examinations showed that 14 were not cured. Of these 14, 11 were put on to "E. B. I." treatment, and the other 3—as controls—on to a second course of emetine injections. All 11 of the former series were discharged as cured, examination of from 6 to 10 stools after treatment in the case of 10 of them having failed to show any forms of *E. histolytica*. None of the 3 controls, re-treated with emetine, were cured. Two further uncured controls were now treated with "E. B. I." and gave respectively 16 and 15 negative findings in the stools after treatment. Four further newly detected carriers were also treated, and subsequently gave from 4 to 9 negative findings. "The effect of the administration of the double iodide upon the protozoal content of the stools—which are the effects that have especially come under my own observation," writes Dobell, "is truly remarkable. Within 4 days of the commencement of treatment all stages of *Entamœba histolytica*, whether amœbæ or cysts, have completely vanished from the feces, and in no single instance have they been subsequently found. When it is remembered that some of the cases had been found to be passing cysts in large numbers almost every time they had been examined previously—for weeks, and in some cases for months—it will cause no surprise when I say that the results of the double iodide treatment have appeared to be astounding."

Dobell's second paper on the subject was now followed up in 1917 by the most important memoir that has appeared in the literature. *Medical Research Committee Special Report Series*, No. 4 (Dobell, 1917). After treatment with "E. B. I." in fairly large doses, the following results were obtained:—

Number of patients treated ..	26.
Number of cures ..	14, or 53.8 per cent.
Number of doubtful cures ..	9, or 34.6 per cent.
Number of certain failures ..	1, or 3.8 per cent.
Number of doubtful failures ..	2, or 7.7 per cent.

"It seems reasonable to conclude," he writes, "that there is no direct evidence that treatment with the double iodide has ever been unsuccessful when given in sufficient quantities. For most cases, 36 to 40 grains will suffice; for others, however, more—up to 60 or

even 70 grains—may be necessary." His conclusions are as follows:—

(i) Emetine bismuth iodide, properly administered, has successfully cured the majority of carriers of *E. histolytica* that have hitherto been treated.

(ii) In acute dysentery the results obtained have been very satisfactory, but further trials are necessary.

(iii) For treatment to be successful, the drug must be given in large quantities—not less than 36 to 40 grains, in daily doses of 3 or 4 grains. Less than this amount is seldom efficacious, and more may be necessary in individual cases.

(iv) Emetine administered in this form has generally been successful, even when previous treatment with emetine hydrochloride injections had proved a failure."

As the result of the publication of this report, the "E. B. I." treatment became the standard one for carriers. Imrie and Roche (1917) reported 6 cases, 4 of whom had previously been unsuccessfully treated with emetine injections, cured by "E. B. I." with negative findings in the stools up to a month after the cessation of treatment. Low (1917) records that 2 cases previously treated by Dobell and himself had been followed up for 6 and 7 months respectively, and their stools had remained consistently negative. Three further cases in whom amoebic hepatitis was present as a complication rapidly yielded to the treatment, also one of "general amoebiasis"—i.e., a febrile state without definite symptoms, but with cysts of *E. histolytica* in the stools. Two convalescent carriers and a relapsing case of amoebic dysentery were cured. In all these cases repeated examination of the stools after the cessation of treatment gave negative results. In connection with the method of administration a small meal of arrowroot is given at 10 p.m., followed by 3 grains of "E. B. I." in a gelatine capsule. The pillows are removed and the head kept low; whilst the patient is instructed to sip hot water if any sign of nausea is felt. A course of not less than 12 consecutive doses, each of gr. iii, is essential. Leboeuf (1917) advocates keratin-coated pills, but these were found to be most unsatisfactory by the British workers. Savage and Young (1917) record 22 cases cured out of 33 to whom one course of "E. B. I." was given; 3 relapses out of 3 resistant cases to whom a second course was given; and only 3 cures out of 10 cases treated by emetine injections plus "E. B. I." orally.

Waddell, Banks, Watson and King (1917) report on 102 carriers treated. The dose was given at 1 p.m. after the midday meal, and vomiting and purging were marked in most of the cases. (Almost all authorities are agreed that the treatment should be given the last thing at night.) They found "E. B. I." much more effective than emetine in the treatment of carriers, but from 20 to 25 per cent. of failures occurred. Using keratin-coated tablets, 19 out of the 102 cases treated were failures. The patients should be kept under observation for 14 days after the end of treatment, and the stools examined at least 4 times. Lillie and Shephard (1917) treated 104 carriers. They contrast the use of salol-coated and keratin-coated pills, and state that the former gave the more consistently successful results. Previous injections of emetine may render the carrier more resistant to "E. B. I." treatment. In cases which had received no previous treatment two courses of salol-coated pills led to a cure rate of 78 per cent., the test for cure being not less than 5 negative stool examinations in 5 weeks after the cessation of treatment. The last series treated was at the Barton Convalescent Depot; and 142 carriers were cured out of 160 = 88.7 per cent. Lambert (1918) treated 40 Indian cases suffering from amoebic dysentery in Mesopotamia either with "E. B. I." only, or with "E. B. I." and emetine injections. He reports that for acute cases the combined treatment gives the best results. In relapsing cases and carriers "E. B. I." alone is better than the combined treatment. "We have in emetine bismuth iodide a combination of considerable potency in the treatment of amoebic dysentery, particularly when the amoebae are assuming their resistant stage." He remarks

that for the debilitated Indian troops with whom he was dealing the nightly dose should be gr. ii.

Low (1918) records an acute first attack of amoebic dysentery in a patient who was cured by "E. B. I." with 21 subsequent observations of the stools; 2 cases of acute exacerbation cured, with 53 subsequent negative examinations; and 2 subacute cases, of whom 1 was cured (35 subsequent negative examinations) and 1 relapsed. Watson-Wemyss and Bentham (1918) treated 30 carriers from the Mediterranean war fronts. The test for cure was a minimum of 4 weeks subsequent observation, with 6 stool examinations. Only 3 of the cases were failures of treatment, of whom 1 was cured after a second course, and the other 2 proved completely refractory. Broc and Chatton (1918) record 6 cases of amoebic dysentery cured by "E. B. I." A second paper by Lambert (1918a) appears to deal with the series of 40 Indian patients upon whom he had previously reported in another journal.

A useful summary, based upon a study of 463 cases observed at the Reading War Hospital, is that by Donaldson, Clark and McLean (1918). In order to detect all cases of infection at least 5 examinations of the stools should be made. Considering the amount of previous treatment with emetine which these patients had received before being invalided, they consider that emetine is comparatively useless in eradicating the infection. "E. B. I." and an emetine absorption product tested both yielded approximately equal results,—cure rate 50 to 60 per cent.,—but the latter induced less vomiting and gastric disturbance. They advocate the following up of carriers discharged from the army to civil life. Mackinnon (1918) records the results of "E. B. I." treatment in 131 carriers. Of these, 62 remained clear of infection for 4 weeks, and 69 relapsed. Of 16 men who received a second treatment, 6 remained clear and 10 relapsed. Two men who had a third course were clear for 4 weeks after treatment. (One of these also received emetine injections.)

Turner and Taylor (1919) used "E. B. I." in the treatment of 284 carriers; after 1 course of treatment 57.4 per cent. cleared up; after 2 courses 71.8 per cent.; after 3 courses 75.7 per cent. Of 932 men transferred to the Barton Depot after negative findings in their stools at different hospitals, both convalescents and non-dysenterics, 49 were subsequently found to be positive. The strains of *E. histolytica* with small cysts appear to be more amenable to treatment than the strains with larger cysts. Gunn and Savage (1919) report the following series:—

(i) "E. B. I." orally for 12 days; 4 acute cases cured out of 10; and 9 out of 14 carriers.

(ii) "E. B. I." orally plus emetine injections for 12 days; 5 out of 6 cases cured; and cure in all 6 carriers so treated.

(iii) Emetine hypodermically for 12 days, followed by "E. B. I." gr. ii daily for 14 days; 15 out of 24 acute cases cured; and 58 out of 68 carriers. They report this to be the best line of treatment tested.

(iv) Similar treatment to (iii), but the daily dose of "E. B. I." was gr. iii; 67 out of 96 acute cases cured; and 103 out of 122 carriers.

Brug (1919) is by no means as satisfied with the value of "E. B. I." as are most of the British workers. He records only 1 out of 7 cases as cured; the test for cure being 7 negative stool examinations within one month from the end of treatment. He advocates the supplementary use of salvarsan.

In common with other workers, Jepps (1921) finds salol-coated pills of "E. B. I." unreliable. After a 12-day course consisting of 36 grains, 45 per cent. relapsed out of a series of 26 cases tested. A suspension of "E. B. I." in powder form in liquid paraffin gave better results; 12.7 per cent. of relapses in a series of 63 cases treated. After two treatments, 11.1 per cent. of the cases were still not cured. In the whole series of patients treated with "E. B. I." 75 in all, in 10 instances the treatment had to be temporarily or permanently stopped on account of untoward symptoms. The "E. B. I." was given the last thing at night half an

hour after a dose of 10 minims of chlorodyne, and the patient allowed to sip hot tea afterwards, if desired.

Rennie (1922) deals with 87 cases treated at the London Hospital for Tropical Diseases, 59 of them diagnosed microscopically, and the remaining 26 on clinical grounds. It was not possible to follow up many of the patients subsequently, though 3 are known to have relapsed. He notes that the patients must be kept in bed whilst under treatment; delayed vomiting appears to indicate that the drug is beginning to take effect; diet must be light and restricted; and the gain in weight on cure is often remarkable.

The findings of Willmore (1923) have already been quoted. His standard course consisted of 10 grs. of emetine by injection, and 60 grs. of "E. B. I." given orally concurrently in 20 days. All cases were microscopically diagnosed, and 358 treated in all. The relapse rates were: after one treatment, 72 per cent.; after 2 courses (given to resistant cases), 80 per cent.; after 3 courses, 95 per cent., whilst 3 very resistant cases which received respectively four, five, and six courses all relapsed. He advocates the additional administration of emetine base in oily suspension by enema. Oliver (1924) records treating 8 cases of amoebic dysentery in Mesopotamia with "E. B. I."; of these 6 relapsed. French and Sellards (1924) comment on the difficulties in carrying out a thorough course of "E. B. I." treatment, even with salol-coated pills. The response was poor and the results unsatisfactory. Many patients refused the drug in capsule form on account of the attendant nausea and vomiting.

Manson-Bahr and Sayers (1927) state that many cases which failed to respond to emetine responded to "E. B. I." given orally. Forty cases were treated, but 5 which received full courses failed to respond. In those that were cured, the gain in weight was remarkable. Three cases relapsed after no less than 9 courses of treatment. "There is no doubt," they write, "that its introduction has considerably raised the percentage of cases of chronic amoebic dysentery permanently cured, but there still remains a fairly large residue who, in spite of all known treatments, live with the certainty that sooner or later they will relapse to their former condition..... Not even the most enthusiastic advocate of emetine or emetine bismuth iodide would claim that such treatment is ideal from the point of view of the patient..... a less toxic and more efficient drug had clearly become very desirable in the treatment of amoebiasis."

RESULTS IN CALCUTTA.

Twenty-three patients received the "E. B. I." treatment. Two of them were passing blood in the stools on admission; 12 were sufferers from chronic amoebiasis; and 9 were carriers admitted for diseases other than amoebiasis. Details are shown in Table IV.

We have been particularly unfortunate in this series in not being able to follow up patients. The results, which are as follows, show a very large proportion of cases not followed up.

Cases treated, 23.

Probable cures, 2 (Nos. 2 and 17).

Failures of treatment, 7 (Nos. 14, 15, 18, 19, 20, 22 and 23).

Indeterminate, 14 (Nos. 1, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 16 and 21).

The ratio of probable cures to failures, 2:7 or 1:3.5 is a very low one. After treatment 10 stools were positive and 65 negative: a ratio of 1:6.5. Assuming a standard course to consist of 20 grains given in 10 days, the approximate cost per course of treatment works out at Rs. 3-5-4.

The degree of tolerance of patients to emetine bismuth iodide varies very widely. The weight of the ordinary Indian patient is much lower than that of the adult European, and very few will comfortably tolerate a dose of more than gr. ii. We have always given the drug in powder form, gr. ii suspended in half an ounce of liquid paraffin the last thing at night. It may be necessary to give either Omnopon (Roche) gr. 1/6th, or 10 minims of chlorodyne half an hour previously. The patients recorded in Table IV for the most part tolerated this line of treatment very well, but in three other cases (not included in the table) the "E. B. I." treatment had to be stopped on account of vomiting or diarrhoea.

Certain individual patients seem to do much better on "E. B. I." than others. Case 2 in Table IV was a patient who had irregular and recurrent attacks of amoebic dysentery for ten years. He tolerated a dose of gr. iii each night for ten days without any trouble, and appeared to have been completely cured, as eight examinations of the stools after treatment gave negative results, whilst he put on 18 lbs. in weight. Whilst our general opinion of the value of "E. B. I." is not as high as that of Dobell (1916, 1917), yet we are bound to admit that the treatment is eminently successful in certain individuals and often surprisingly well tolerated. On the other hand, results usually appear to be uncertain, whilst the nauseating qualities of the drug are prominent.

V. YATREN.

Historical.—The makers of "Yatren 105" (Behring and Co.) claim that it is 7-iodine-8-oxyquinolin-5-sulphonic acid, containing 36.2 per cent. of iodine, with sodium bicarbonate added to increase its solubility. It is an odourless, finely crystalline powder, of light yellow colour, with a solubility of about 4 per cent. Their further claim, that "yatren is as specific a cure for amoebic dysentery as quinine is for malaria," in our opinion at least, is too optimistic.

The first workers to use yatren were apparently Mühlens and Menk (1921). They treated 8 resistant cases (two of whom had even undergone caecostomy) and remarkable clinical improvement took place. By the mouth keratin-coated pills of 1 gramme each t.i.d. are well borne, they claim, whilst if ulceration is found to be present by sigmoidoscopy, the oral treatment should be supplemented by rectal injections of a 2½ per cent. solution of yatren. The scheme of treatment outlined consists of a first course of 8 to 14 days of the combined rectal and oral treatment, with sigmoidoscopic and microscopic controls; then a week's interval; then a repetition of the treatment for from 3 to 7 days; then a second interval; and finally a third course of 3 to 5 days. Rest and strict dieting are essential.

Mello (1922) reports successful treatment with yatren in 6 cases which had proved refractory to emetine. The combined oral and rectal treatment was given, and the rapidity and completeness of cure is said to have been "truly surprising."

Menk (1922) reported 3 cases successfully treated, but states that thorough treatment lasting 5 to 6 weeks is essential, and that it should be continued even after the stools have become normal. One such treatment every 6 months (two courses in all) is advised. Birt

(1923) reports on the use of yatren in chronic cases at Shanghai, and records the treatment of 28 cases, 14 of them recent ones, the other 14 cases of old standing. He considers that 16 of them must be considered as completely cured. He states that he used a 10 per cent. solution per rectum, and comments on the pain and tenesmus which some of these injections caused. Menk (1923) points out that the solubility of yatren is only about 5 per cent. and that Birt's 10 per cent. solution must have contained undissolved yatren, which would account for the pain and tenesmus complained of. Initially an enema of 200 c.c. of a 5 per cent. solution should be used; later the patient can often tolerate up to 400 c.c. Kuenen (1922) reports on the treatment of 4 cases with yatren, 1 gm. t.i.d. orally for 8 to 14 days, and speaks of the results as very favourable. Huppenbauer (1923) reports 2 cases of chronic intractable dysentery cured by yatren lavage, with subsequent after-treatment by yatren orally.

From this point onwards, the literature becomes very extensive, and we may confine our attention only to the more important papers. R. M. Gordon (1923) reported on a chronic case of 5 years' duration treated by enemata, 200 c.c. of a 5 per cent. solution for 10 days, then 6 days rest, then a final injection; this patient relapsed 28 days later. A second patient to whom the full course advocated by Mühlens and Menk was given relapsed 14 days after the completion of treatment. Menk (1922a) records the treatment of 17 cases of chronic amœbic colitis; 3 were uninfluenced; in the others amœbæ rapidly disappeared, but in 2 instances returned "after a time." He advocates following up the yatren treatment with emetine injections. de Langen (1923) records very satisfactory results in 36 cases treated, from both the clinical and parasitological points of view. Apart from the diarrhoea which it causes, the drug is well tolerated. Lichtenstein (1923) reports on 4 cases: 1 treated with subsequently negative stools; 1 clinically cured; 1 a complete failure; and the fourth, in whom the treatment had to be suspended on account of the untoward symptoms caused by the drug. Kop (1923) speaks very favourably of the drug, and quotes a refractory case in a boy aged 10 where after 2 days' treatment all protozoa vanished from the stools and had not returned on several examinations; the cost of the double course of treatment, however, was £5. Traviaglino and Soedjono (1924) place yatren first on a trial of different methods in 350 cases, but seem to rely on clinical cure, since they apparently do not consider the presence of cysts as proof of continuing infection. Bax (1924, 1925) uses a concentration method in examining the stools for cysts after yatren treatment; 25 cases were treated and controlled by stool examination, with the following results: 6 permanently cured and under observation for 1 year; in another 10, amœbæ were apparently completely eliminated; 5 cases apparently cured and under observation for 6 months; 2 improved; 2 no improvement. Jacobi (1924) recommends oral treatment with yatren in cachets; each cachet contains 0.5 gm.; 4 cachets are given on the first day, 6 on the 3 succeeding days; afterwards 4 a day. A course should consist of about 40 cachets. An illustrative instance is quoted of the success with this drug in a case where other treatments had failed. Beijnen (1924) records a series of 22 carriers and 9 patients passing vegetative amœbæ treated orally with doses of $\frac{1}{2}$ to $\frac{3}{4}$ gramme t.i.d. for 10 days. The stools were subsequently examined every fortnight for periods varying from 2 to 18 months. In 17 cases so controlled, in only 1 did cysts re-appear. The author concludes that yatren is a most efficient remedy in amœbiasis, and should be given orally.

Kessel and Willner (1925) treated 19 cases; 0.5 gm. in gelatine capsules was given 6 times daily on the 1st, 3rd, 5th and 7th days; and 3 gms. dissolved in 200 c.c. of distilled water as an enema on the 2nd, 4th, 6th, 10th, 14th and 21st days. Rest in bed for 7 days and for half days on the 10th, 14th and 21st days; the dietary arranged according to the degree of purgation present. With this course of treatment 17 out of

19 cases remained negative for a period of 6 months after the completion of treatment, and 6 examinations of the stools yielded negative results.

Manson-Bahr and Morris (1925) record 4 cases controlled by periodic microscopic examination of the stools and apparently permanently cured by the combined oral and rectal treatment. Mühlens (1925) gives an account of his first 5 years' experience with the drug. He gives the following comparative figures:—

	Emetine.	Yatren.
Cost per treatment	Mex. \$5.60	Mex. \$6.40.
Time in hospital ..	12 days	7 days
Working days lost ..	26 days	9½ days

Huppenbauer (1925), in an address to the German Society of Tropical Medicine, claims that the supreme test of the value of yatren is its efficacy in the treatment of chronic amœbiasis and its complications—just where emetine and "E. B. I." failed. It is claimed as a redoubtable victory for German chemistry and pharmacology. Rodenwaldt (1925) says that doses of 1 gm. powder or pill t.i.d. are well borne by the patient; and that in severe cases or relapses 9 gms. can be given by the mouth a day. Katsurada (1925) states that his experience with yatren has been very satisfactory; he gives 1.8 gm. per day for 7 days, after which the stools become negative. Hirayama (1925) records 13 cases treated with very satisfactory results. Boyers (1925) writes, "Yatren has been much used by us in the past 2 years. We have yet to obtain by yatren complete eradication of both motile and encysted *E. dysenteriae* in any case. However, we have found it a valuable adjunct to treatment. It is especially useful in feeble patients and in the treatment of the ever-present colitis." Lamberts (1926) states that in his experience yatren is the drug of choice for all cases of intestinal amœbiasis, and speaks of the prophylactic use of yatren pills. Buchmann (1926) considers that emetine is dangerous in children, and advocates yatren as safe in the treatment of amœbiasis in children; he considers that yatren will ultimately supersede emetine in the treatment of chronic amœbic dysentery in adults. Ruge (1926) gives an 8 to 10 day course of 3 gms. daily in divided doses; then an interval of 3 to 4 weeks; and then a second course. When administered per rectum the enema should not be too large. Bach and Steinhauer (1926) record the results of yatren treatment in a patient who had been suffering from chronic amœbic dysentery for 27 years. Rapid and complete restoration to health resulted, and the stools were negative up to 5 months later. Drake-Brockman (1926) advocates 9 pills a day for a fortnight; then 6 pills a day for 1 week; then 3 pills a day for a fourth week. If the sigmoidoscope shows ulceration in the rectum yatren enemata should also be given; he is of opinion, however, that when the lesions are high up in the colon or cæcum no drug can replace ipecacuanha and its derivatives. Rehbein (1926) has treated over 200 cases of acute or chronic amœbic dysentery with yatren, and emphatically states that for the treatment of all forms of amœbic dysentery yatren far surpasses other known remedies. Mühlens (1926) emphasises that chronic cases clear with great rapidity on oral treatment alone; whilst in acute cases its action is almost abortive on the condition. For very chronic cases rectal administration must be combined with oral treatment. Dalmeyer (1926), working in Java, states that in 4 years' experience of the drug, yatren has been unfailingly successful, both in acute and chronic and in "larval" amœbic dysentery. It was not always necessary to admit the patients to hospital. It is especially well tolerated by children, and can even cure liver abscess. Turner and Jones (1926) record 2 acute cases clinically cured, but not yet followed up after treatment; in 5 other cases, followed up for 1 month or more after yatren treatment, the stools have remained negative, and the patients in good health. Choy (1925) records the results in 29 cases, in 15 of which follow-up examinations were made. He considers the drug superior to emetine in "latent" and chronic cases; but that emetine is better for acute cases,

as yatren is apt to produce profuse diarrhoea and colicky pains.

Vogel (1927) has studied the action of yatren on cultures of *Entamoeba histolytica* in vitro. A solution of 1 : 100 killed the amœbæ in a few hours; solutions of 1 : 1,000 to 1 : 5,000 inhibited multiplication and the cultures gradually died out. The amœbæ proved resistant to a solution of 1 : 10,000 through 10 subcultures, but could revive in culture after 15 hours' exposure to a solution of 1 : 1,000. Funke (1926) gives a somewhat guarded opinion: "in all probability it will in a large measure replace ipecac., and.....is considerably superior to stovarsol." Juhl (1927) emphasises his opinion that for the worst type of case in children, yatren is the sole drug which will prevent a fatal termination. In purely amœbic infections one can count on its bringing about complete cure. He notes that round-worms are frequently expelled during the course of yatren treatment.

An important recent paper is one by Manson-Bahr and Sayers (1927). The usual dose by the mouth, 15 grains thrice daily, causes diarrhoea; but pills or cachets containing 4 to 8 grains thrice daily proved satisfactory. After cleansing the rectum with a 2 per cent. sodium bicarbonate enema, 200 c.c. of a 2.5 per cent. solution of yatren are run in slowly, and the patient instructed to retain it for as long as possible. As a rule patients can retain the injection for 8 hours or longer, and proof of absorption can be obtained by testing the urine with iron perchloride; yatren gives a greenish colour. The standard course is 4 to 8 grains t.i.d. for 10 days, with one daily injection per rectum. After a 5 or 7-day interval the course is then repeated. No toxic symptoms have been observed; and the authors can fully confirm the efficacy of yatren in curing long standing cases of amœbic dysentery which have proved resistant to emetine and "E. B. I." Yatren appears to be especially curative when the lesions are in the lower portion of the colon; but not where the lesions are chiefly in the cæcum and upper part of the colon, and resistant cases should be treated by a combination of "E. B. I." by the mouth and yatren per rectum. The course advocated for this condition is 3 grains of "E. B. I." every night, and a rectal injection of 200 c.c. of a 2½ per cent. yatren solution every morning for 10 days. Twenty-two intractable cases were treated with this combined treatment, and the results, as controlled by sigmoidoscopic examination, were excellent. "The combined treatment has much to be urged in its favour," they write. "It has, we think, been abundantly demonstrated that both these drugs possess a definite curative value in amœbiasis, which may be limited in its extent when they are used singly, but is much more intensive when both are combined..... Moreover, as the treatment is continuous both by day and by night, the parasite is given no chance to recuperate. Whatever may be said about the rationale of the method, the combined drugs are remarkably well tolerated, and the results, as controlled by the sigmoidoscope and backed up by clinical observations, are very satisfactory."

Waldorp (1927) reports good results with yatren, but says that a combination of yatren orally with emetine injections is better. A table of 9 cases is given. van Steenis (1927) states that yatren has no toxic or cumulative action, but that the diarrhoea induced, though harmless, is sometimes annoying. Houssiau and Duwez (1927) advocate for resistant cases courses of either emetine plus stovarsol, or emetine plus yatren; and for enfeebled patients or those with gastric derangement yatren per rectum. Buchmann (1927) states that yatren is a "specific" for amœbic dysentery, and especially suitable for administration to children, to whom emetine injections are apt to be dangerous; he gives the drug in solution, using a 2 per cent. solution and giving 1 c.c. per day for each age-month of the child. In older children this dose can be doubled.

It will be seen that, in general, the reports on yatren therapy are very favourable. On the other hand, the position with regard to the drug is suspiciously like that with regard to emetine in the days after its

first introduction. The earlier papers are very enthusiastic; later the writers become less optimistic; finally, the drug comes to be combined with some other form of treatment.

RESULTS IN CALCUTTA.

We confess that we have not used yatren in the heroic doses recommended by the makers; the reason being that any dose of more than 15 grains a day seems to cause diarrhoea immediately. Whilst there is but little tenesmus with this diarrhoea, yet it is troublesome to the patient. On the other hand, unless diarrhoea is produced, the results appear to be poor. The drug, in fact, seems to act chiefly by causing irritation of the mucosa of the colon, such irritation sometimes leading to eradication of the infection.

Twenty-three patients were treated with yatren orally. Details are given in Table V. The results may be summarised as follows:—

Cases treated, 23.

Probable cures, 6 (Nos. 1, 2, 9, 11, 15 and 23).

Failures of treatment, 8 (Nos. 10, 12, 13, 17, 18, 19, 20 and 22).

Indeterminate, 9 (Nos. 3, 4, 5, 6, 7, 8, 14, 16 and 21).

The ratio of probable cures to failures is 6 : 8 or 1 : 1.3, a figure exactly the same as that obtained with alcresta ipecac. After treatment 8 stools were positive and 64 negative; a ratio of 1 : 8, which would appear to indicate that the drug has a fairly considerable value in eradication of the infection. The retail cost of a bottle of 40 of the 0.25 gm. pills in Calcutta is Rs. 4-14-0; and assuming that 30 pills in 10 days is about a standard course of treatment, the average cost of treatment works out at Rs. 3-10-6.

As with almost all treatments, certain individual patients appear to respond better than others. Thus Case 1 in Table V cleared up completely with yatren, whereas previous courses of emetine and "E. B. I." had failed to eradicate the infection. Case 2 was a medical man from the Punjab. He had had no end of irregular treatment with emetine, and finally came to Calcutta, stating that he was so sick of life that he would commit suicide if he could not be cured. (The markedly neurasthenic tendency in some of these chronic cases of amœbic infection is often very pronounced.) Case 11 came from Secunderabad for treatment, with an almost exactly similar history. He was an European official in a very high position; had been suffering from relapsing amœbic dysentery for four years, and feared a complete nervous breakdown. He said that unless he could get the infection eradicated, he might have to retire prematurely. This patient was most conscientious in sending one stool each week for examination after the completion of treatment, and appears to have been definitely cured. He

wrote a year later that he was in good health. Case 15 was another very chronic and emetine-resistant case, who appeared to clear up rapidly on yatren treatment. Case 22 unfortunately refused to stay in hospital for a proper course of treatment; the stools were still full of motile *E. histolytica* on the day he left hospital.

Only six patients were treated by the combined treatment with yatren orally and yatren simultaneously by the rectum. These are not unselected cases, as this line of treatment is so very expensive that it was reserved for very intractable cases. Details are given in Table V. The results were as follows:—

Cases treated, 6.

Probable cures, 2 (Nos. 1 and 2).

Failures of treatment, 3 (Nos. 3, 4 and 6).

Indeterminate, 1 (No. 5).

The ratio of probable cures to failures is as 2:3 or 1:1.5; but it must be remembered that the treatment was reserved for very intractable cases. After treatment 4 stools were positive and 25 negative; a ratio of 1:6.2.

Again, certain individual cases responded much better than others. Thus Case 2 had had amoebic dysentery for four years with frequent relapses and no end of emetine and other treatments. In his case a hæmolytic streptococcus was isolated from the stool, and an autogenous vaccine of this organism administered together with the combined yatren treatment; he appeared to have been completely cured. On the other hand the three failures of treatment were all exceedingly resistant cases. Case 4 finally left hospital uncured; Case 6 was still positive two months after leaving hospital.

The chief trouble with combined yatren therapy in India is its very high cost. Assuming that a standard course consists of 3 pills orally a day for 10 days, with a daily rectal injection of 200 c.c. of a 2.5 per cent. solution for 10 days; then this means 30 pills in the 10 days, which costs Rs. 3-10-6, and 50 grammes in all of yatren powder, which costs Rs. 15-12-0. The combined figure, Rs. 19-6-6 per course of treatment, absolutely rules it out of court for ordinary hospital and dispensary use in India. Also the method is troublesome to the patient, and very few patients can be persuaded to continue with the rectal injections for more than five days. Even Manson-Bahr and Sayers (1927), who praise yatren very highly, it will be noted, suggest that for chronic carrier cases its use should be combined with that of "E. B. I."

The combined yatren treatment appears to be the best available for private patients in nursing homes or in the paying wards of large hospitals.

VI. STOVARSOL.

Historical.—Stovarsol was first introduced into the practice of medicine by Fourneau and Levatidi in 1922 as a prophylactic against syphilis, and for the treatment of spirochætal infections. Chemically its constitution is said to be acetyl-oxy-amino-phenyl arsenic acid. It is a white powder, practically insoluble in water, and is stated to contain 27.2 per cent. of arsenic in organic combination. It is stated to have a marked hæmatinic action.

Marchoux (1923) appears to have been the first to test this drug in the treatment of amoebiasis. He gave it in a case of amoebic dysentery which had resisted emetine injections, in doses of 0.25 gm. in pill form twice daily. No amœbæ or cysts could be found in the stool after treatment. In a chronic case of 4 years' duration a 10-day course of treatment led to clinical cure, but cysts re-appeared in the stools 10 days later. His opinion of the drug, however, determined him to give it a more extensive trial.

Nogue and Leger (1923) gave the drug in cachets of 0.25 gm.; a course of 29 cachets in 13 days, with a break at the 4th, 8th and 12th days. Under this treatment 3 cases of acute amoebic dysentery did well, but 1 relapsed 9 days after treatment. Delanoë (1923) administered the drug in doses of 0.25 gm. twice daily to a case of 4 years' duration, which had proved resistant to emetine, "E. B. I.," and novarsenobillon treatments; the patient recovered and put on weight rapidly. Couvy (1924) records 3 cases apparently cured. Garin and Lépine (1924) record good results with the drug in the treatment of chronic amoebiasis; they give a course of 75 cgms. daily for 10 days, followed by an anti-relapse treatment of 25 cgms. every second day.

Marchoux (1924) gives a list of 59 cases, mostly of long standing that had already suffered much and varied treatment—treated by a 6 weeks' course of stovarsol. For recent cases the course consisted of 0.5 gm. stovarsol daily for 3 weeks, then 0.25 gm. daily for a further 3 weeks; for chronic cases 0.5 gm. was given on the first day; then 1 gm. every alternate day until the eighth day; then 0.75 gm. every second day for a week, reduced to 0.5 gm. daily for another week; and finally 0.25 gm. daily for the last 3 weeks. The drug was given in tablet form with meals. It is claimed that 57 of the cases were cured. Garin and Lépine (1924a) give a course of intermittent treatments; 0.75 gm. is given daily for a week, intermitted for a week, then resumed. The after-treatment consists of stovarsol every other day for 1 or 2 months. They claim that vegetative amœbæ disappear at the fourth day and cysts at the eighth day of treatment. As an alternative stovarsol treatment may be combined with emetine, in which case a course of 4 weeks' treatment is outlined.

Johns and Jamison (1925) report on 27 cases treated, including chronic and severe cases. The diagnosis was in all cases confirmed microscopically. Symptoms subsided under treatment by about the third or fourth day. Twenty of these cases were followed up for a period of 55 days; of these 16 had remained well and free from entamœbæ in the stools, 4 relapsed. Three others remained well and free from entamœbæ in the stools for 70, 74 and 99 days respectively. In the discussion which followed the reading of this paper, Gessner described the occurrence of a measles-like rash after exhibition of the drug, and Bass stated that he considered the effects of stovarsol to be superior to any previously obtainable with emetine.

In a second paper Johns and Jamison (1925a) record the results of treatment of 46 patients as eminently satisfactory. The treatment was found especially advantageous in patients with severe cardiac lesions, in pregnant women, and in young children. In a series of 27 patients, 4 were cured by 1 week's course; 16 by 2 courses with an interval of a week between them; 21 remained free from all symptoms and with negative findings in the stools for an average period of 3.8 months. They comment on the simplicity of administration of the drug. Petzetakis (1925) reports on an extensive

trial of the drug at Alexandria. Citing a number of clinical records, he believes that stovarsol is an excellent remedy for parasitic infections of the intestinal tract. It may be exhibited over prolonged periods without any ill-effects. In chronic and relapsing infections prolonged treatment is necessary, and may be supplemented by injections of emetine. In children who cannot tolerate emetine, he claims that the drug is invaluable. It is also of value as a prophylactic; a volunteer swallowed capsules containing amœbæ and cysts and was then treated with 4 tablets of stovarsol daily for 4 days. No infection resulted. Spencer (1925) reports a case of a persistent carrier, who had resisted emetine and "E. B. I." treatments; 144 grains of stovarsol were given in 12 days, and his stools after treatment were persistently negative, whilst he was in good health and free from symptoms 6 months later. A second case was one of amœbic hepatitis, which rapidly cleared up under stovarsol therapy. A third was one of amœbic dysentery in a child aged 2½, where 2 courses of stovarsol were necessary to eradicate the infection.

Manson-Bahr and Morris (1925) record 2 cases of carriers, where "E. B. I." treatment had failed, apparently cured by stovarsol, with negative findings in the stools after treatment. To avoid toxic symptoms from the drug, they recommend that the dosage should not exceed 2 tablets (8 grains) daily for 7 days, or 1 tablet (4 grains) daily for 14 days. A second paper by Johns and Jamison (1925a) appears to deal with the same series of cases as in their first (1925) paper. They note the occurrence of rashes in two patients to whom stovarsol was administered. Rivero (1925) records six cases of dysentery, of which five were apparently cured by stovarsol treatment; the sixth patient, suffering from both malaria and dysentery, died in spite of stovarsol and emetine treatment. Newman and Davis (1926) give the following table comparing results with emetine and stovarsol respectively:

	Emetine hy- drochloride.	Stovarsol.
Cases treated ..	9	9
Relapses ..	1	3
Deaths ..	1	0
Average number of days in hospital; un- complicated cases.	17.6	16.0
Average number of days to clearing up of symptoms.	8	4.5
After-effects ..	Inappreciable	Distinctly tonic.
Approximate cost per course of treatment.	Rs. 3-0-9	Rs. 4-4-4

Their test for cure was systematic examination of the stools for 25 days after the cessation of treatment, and they conclude that it is possible that a combination of the two drugs may be the best method for the treatment of amœbic dysentery.

P. W. Brown (1926) considers that stovarsol is more effective in eradicating the parasite than emetine. He considers that cases where ulceration of the rectum has occurred are those most liable to relapse. van den Branden (1925) did not have too good results with stovarsol; he treated 8 cases; of these 2 relapsed a few days after the completion of treatment; in another 4, parasites were still present; in 2 both symptoms and amœbæ disappeared. He thinks it may be best to combine emetine and stovarsol treatments. van Steenis (1927) finds stovarsol less effective than emetine or yatren, but very useful against the "minuta" type of *E. histolytica*. It was given in doses of 250 mgm. 3 times daily for 1 week, then in diminishing doses for another 2 months. No toxic effects were noticed. Houssiau and Duwez (1927) advocate the treatment of relapses by combined treatment, either with emetine plus stovarsol, or emetine plus yatren, and recommend stovarsol treatment for the layman out of reach of medical aid. Seibert (1927) reports the trial of stovarsol on a series of 300 cases, together with emetine. Stovarsol was given orally in doses of 0.25 grm., t.i.d., together with an

injection of emetine gr. 2|3rds b.d. for 7 days. All medication was then stopped for 3 days, followed by salts every morning for 6 days, and daily examination of the stools. If the stools were negative for 7 days, the patient was discharged with the recommendation to have a further specimen examined 60 days later. If the stools were positive, a second course of stovarsol (usually without emetine) was given. He records that the results in this series were very much better than with "E. B. I." Four patients out of over 300 treated with stovarsol showed a mild rash.

Sautet (1927) finds stovarsol lethal to *E. histolytica* in culture within 24 hours at a dilution of 1 : 600, and notes that it appears to be more active in the presence of liver extract than when added directly to the cultures.

In summing up this series of papers, it will be seen that on the whole results with stovarsol are not too bad. Almost every writer comments on the method as one easy to administer and well tolerated by the patient. On the other hand, it would appear to be a less effective amœbicide than emetine, and some of the authors comment on its toxicity. Certain cases of acute exfoliative dermatitis have been recorded in the literature as following on the administration of stovarsol.

RESULTS IN CALCUTTA.

Thirty-two patients were treated with stovarsol. None of these patients had blood in their stools on admission to hospital, but 24 of them had suffered from chronic amœbic colitis; the 8 others were carriers admitted for the treatment of diseases other than amœbiasis. Details are given in Table VI. The results were as follows:—

Cases treated, 32.

Probable cures, 8 (Nos. 10, 13, 18, 19, 20, 22, 27 and 30).

Failures of treatment, 9 (Nos. 8, 9, 14, 17, 24, 25, 26, 28 and 29).

Indeterminate, 15 (Nos. 1, 2, 3, 4, 5, 6, 7, 11, 12, 15, 16, 21, 23, 31 and 32).

The ratio of probable cures to failures, 8 : 9 or 1 : 1.1 is a relatively high one, and we regard stovarsol as definitely having a place in the treatment of chronic amœbiasis. After treatment, 8 stools were positive and 109 negative; a ratio of 1 : 13.6, which shows a greater degree of eradication than with any other drug tried. We have been very much struck with the ease and simplicity of this treatment; one of the 4 grain tablets is given each night and morning for 10 days. In none of our patients were there the slightest toxic symptoms, whilst the drug appears to be of special value as a hæmatinic, and patients on stovarsol therapy are not the miserable unhappy beings who are trying to keep down "E. B. I." or being injected with emetine. We have had reported to us one case of a measles-like rash following the administration of this dosage by a medical practitioner in Calcutta, and there are several instances in the literature where the drug has caused exfoliative dermatitis. It is clear therefore that the patient should be warned to report the appearance of any rash, however mild, or any ocular symptoms; and at once to discontinue the treatment if such occur. The retail cost

of a bottle of 28 of the 4-grain tablets in Calcutta is Rs. 3-4-0; so the average cost of a 20-tablet treatment works out at Rs. 2-5-2.

It is particularly in the chronic type of case that stovarsol is useful, and it would appear that it offers the patient about a 40 per cent. to 50 per cent. chance of eradication of the infection. It is a drug which is suitable for use in out-patient work and in dispensaries in the field.

The senior author is accustomed to prescribe the 10-day course of stovarsol outlined above especially as an after-treatment. In cases of amoebic dysentery, clinical relief of the symptoms is first obtained by the use of emetine injections with Deeks' bismuth treatment; a few days are then allowed to pass for the elimination of all emetine from the system; and the patient is then put on the 10-day course of stovarsol. This usually leads to a rapid improvement in his general condition, and may eradicate the infection. For chronic carriers our usual treatment has been first a course of "E. B. I." treatment; then an interval of a few days; then a course of stovarsol.

It may ultimately prove to be the case that the arsenical compounds are of more value in eradicating infection with *E. histolytica* than the ipecacuanha derivatives; at least they deserve further investigation. On the other hand a drug, which definitely fails to eradicate the infection in 9 out of 32 patients treated, leaves one desiring something better and much more certain in its action.

VII. KURCHI AND ITS ALKALOIDS.

Historical.—The use of the bark and seeds of *Holarrhena antidysenterica* in the treatment of the dysenteries of India dates very far back into ancient days, and is a special feature of the indigenous systems of medicine. Tull Walsh (1891) refers to the use of the bark (the so-called kurchi) as being approximately equal in its effects to emetine mercuric iodide, and draws attention to previous publications on the use of the drug in 1880 and 1881. The latter paper is one by R. C. Datta (1881), who records clinical cure of 7 cases of dysentery, 5 of them acute, and 2 chronic cases of old standing by the administration of 1 dr. doses t.i.d. (The 1880 paper is unfortunately not available.)

It appears to be used in the indigenous systems in two forms: as kurchi bark, either in powder or aqueous extract (extract kurchi liquidum); or as *indra jan*, an emulsion of the seeds. Unfortunately neither preparation makes any pretence to standardisation. The one claim that can be made at once for the kurchi treatment is that it is a very cheap one. Its efficacy, however, remains to be determined.

H. C. Brown (1922) appears to have been the first worker to test the power of the chief alkaloid of kurchi—conessine—as an amoebicide. Working with cultures of pond amoebæ, he found conessine to be distinctly lethal to these amoebæ, and that when it was incorporated with the culture-medium at a strength of 1:1,000,000 it inhibited their growth. Experiments with mice showed it to be 50 per cent. less toxic than emetine, but its subcutaneous administration in medicinal doses produced local necrosis. On the other hand, he found that it can be safely given by the mouth in large doses. Henry and Brown (1923), on testing the tannins of kurchi bark

and of ipecacuanha against the free-living ciliate protozoon, *Glaucoma*, found both to be highly toxic to this ciliate. Drake-Brockman (1926) speaks well of kurchi as a useful adjuvant in the treatment of chronic amoebic dysentery.

The pharmacological action of conessine has been fully studied by Chopra, Gupta, David and Ghosh (1927). They found it to be lethal to *Paramoecium caudatum* in a dilution of 1:2,800 of its molecular weight, and in a dilution of M/20,000 in the presence of N/200 NaOH. It killed free-living amoebæ at a dilution of M/1,000 and in the presence of N/200 NaOH at a dilution of 1:280,000. Its action on the vegetative forms of *Entamoeba histolytica* was tested on the dysenteric stools of experimentally infected kittens. In mucous flakes in such stools it killed the motile amoebæ in dilutions of 1:280,000 in 8 minutes in the presence of an alkali, and in 18 minutes in the absence of alkali. Emetine in dilutions of 1:200,000 was found to be inactive against the amoebæ, but killed them if alkali was present. Conessine had but little action upon *Trichomonas hominis*, but was markedly lethal to the coprozoic flagellate protozoon, *Bodo caudatus*. Conessine salts can be given subcutaneously and intramuscularly, but intravenous administration is dangerous, owing to their action on the auriculo-ventricular bundle. Contrary to what was reported by Brown, these workers found that no necrosis of the tissues followed its hypodermic injection. In dilutions of 1:120,000 it has no effect on the perfused mammalian heart. Although the alkaloid has a markedly narcotic action on frogs, it has no marked effect on the central nervous system of mammals. These workers accordingly suggest the treatment of amoebic infections, either by oral administration of kurchi extract, or by subcutaneous administration of either conessine hydrochloride or of the hydrochloride of the total alkaloids of the bark. In addition to the alkaloid conessine, Ghosh and Ghosh (1928) have recently shown that two alkaloids, kurchine and kurchicine are also present in the bark.

RESULTS IN CALCUTTA.

(i) *Kurchi orally.*—In this series, details of which are given in Table VII, 16 patients were treated. Of these 4 had blood in the stools on admission; 8 were cases of chronic amoebic infection; and 4 were carriers admitted for diseases other than amoebiasis. Six were treated with "Tabloid" Extract Kurchi Corticis (B. W. & Co.) and ten with extract kurchi liquidum purchased locally and made in Calcutta by different firms. The results were as follows:—

Cases treated, 16.

Probable cures, 7 (Nos. 1, 2, 3, 6, 10, 11, and 13).

Failures of treatment, 8 (Nos. 4, 5, 7, 9, 12, 14, 15 and 16).

Indeterminate, 1 (No. 8).

The ratio of probable cures to failures, 7:8 or 1:1.1, is surprisingly high for so simple a remedy. After treatment 8 stools were positive and 57 negative: a ratio of 1:7.1.

The treatment is simplicity itself, and none of the patients showed any toxic symptoms. With the "Tabloid" product the dose could be pushed to 60 grains a day without discomfort. With the bazaar liquid extract 10 drs. a day can be given (2 drs. five times a day) for 10 days on end without the patient complaining of any symptoms. In the treatment of actual dysentery the improvement is

less rapid than with emetine, but cure appears to be much more permanent. It is rather curious that this finding of ours in 1928 should confirm that of Tull Walsh in Calcutta in 1891. *Plus ce change, plus c'est la même chose.*

(ii) *Conessine intramuscularly.*—Lieut.-Col. R. N. Chopra, I.M.S., Professor of Pharmacology, Calcutta School of Tropical Medicine, very kindly placed at our disposal a freshly prepared sample of conessine hydrochloride, and 9 patients were treated with this drug. At first we gave it in gr. i doses daily, intramuscularly, but as this was very well tolerated, with the last two patients we pushed the drug to gr. i twice daily (giving the injections into one deltoid, one buttock, the other buttock, and the second deltoid in turn). Throughout the whole series of injections the drug was very well tolerated, and no local or general toxic reactions were noted. Details are given in Table VIII.

The results with conessine, to date at least, are rather disappointing, in view of the finding by Chopra, Gupta, David and Ghosh (1927), that the drug is very lethal to *Entamoeba histolytica* in vitro. We are still continuing the trial of the drug, however. The preparation is very hygroscopic, and ready prepared ampoules would be preferable to a powder which has to be weighed out and dissolved. Of the 9 patients, 3 were passing blood in the stools on admission, 4 were cases of chronic amœbic colitis, and 2 were carriers admitted for diseases other than amœbiasis. The results may be summarised as follows:—

Cases treated, 9.

Probable cures, 3 (Nos. 1, 2 and 3).

Failures of treatment, 6 (Nos. 4, 5, 6, 7, 8 and 9).

This gives a probable cure: failure ratio of 3:6 or only 1:2, which is a very poor figure. After treatment 6 stools were positive against 36 negative: a ratio of 1:6.

Case 9 in this series is of considerable interest. After treatment he appeared to be very fit, and examination of 10 consecutive stools had negative results. Ordinarily, one would have thought that this patient was cured. He now commenced to pass blood in the stools again, however, and at the 11th examination motile *E. histolytica* were found. This case emphasises that the "cures" referred to in this paper are relative rather than absolute.

It is curious that intramuscular injections of conessine should yield far worse results than simple oral administration of extract of kurchi. As mentioned above H. C. Brown (1922) found conessine to be an active amœbicide to free-living amœbæ; but Henry and Brown (1923) also found the tannins of kurchi bark to be highly toxic to free-living protozoa. When kurchi extract is administered by the mouth the action of both conessine and the tannins appears to come into

play, and results are better than after intramuscular injections of conessine.

(iii) *Total alkaloids of kurchi.* Colonel Chopra has also placed at our disposal the hydrochloride of the total alkaloids of kurchi bark. Up to date we have only treated two patients with this preparation, giving it intramuscularly in doses of gr. i twice daily. Details are given in the second half of Table VIII. In both cases the injections were very well tolerated, but both proved to be failures of treatment; in fact this preparation appears to be even less useful than conessine.

Our results to date with kurchi and its alkaloids are insufficient to warrant any definite conclusions, and a further investigation with the drug is badly needed. Kurchi is extremely cheap; it is available in bulk in India, and its alkaloids can be readily extracted. Should it prove to be efficacious in the treatment of intestinal amœbiasis, it might well become the standard treatment in India. In addition to conessine hydrochloride and the hydrochloride of total kurchi alkaloids, Colonel Chopra has now very kindly placed at our disposal a standardised liquid extract of kurchi, with which we hope to carry out further trials.

VIII. COMBINED TREATMENTS.

In view of the fact that all the remedies at present on the market appear to act only as very weak amœbicides, the exploration of the possibilities of combined treatments is obviously one which demands attention. We hope to investigate this possibility later, but our few results to date are given in Table IX.

(i) *Emetine plus kurchi.*—Nine patients were treated by injections of emetine, gr. i daily for six days, together with large doses of extract kurchi liquidum by the mouth. Of these 1 was passing blood in the stools on admission, 7 were cases of chronic amœbic colitis, and 1 a carrier. The results were as follows:—

Cases treated, 9.

Probable cures, 3 (Nos. 5, 7 and 8).

Failures of treatment, 3 (Nos. 3, 6 and 9).

Indeterminate, 3 (Nos. 1, 2 and 4).

The ratio of probable cures to failures of treatment, here 3:3 or 1:1, is not too good, but perhaps insufficient emetine was given, and a 9-day course might give better results. After treatment the ratio of positive to negative stools was 3:28 or 1:9.3, which appears to indicate a considerable degree of eradication of the infection. The cost of a course of 9 grains of emetine, with 10 drs. daily of liquid extract of kurchi, would be approximately Rs. 4-9-3.

This line of treatment, at least for cases where active dysentery is present, appears to be worth further investigation. Case 7 in Table IX of this series was a most inveterate carrier, who had resisted treatment with

TABLE VIII.

Concussine Injections.

o.	Name.	Caste.	Sex.	Age.	Disease for which admitted.	Previous intestinal history.	Previous treatment.	Findings in stool on admission.	Treatment.	Findings in stool after treatment.	REMARKS.
1.	S. S.	H.	M.	14	Filariasis	Veg. <i>E. histolytica</i> . <i>E. nana</i> cysts.	Concussine injection, gr. i daily for 9 days.	5 examinations. Negative.	
2.	J. N.	H.	M.	..	Dysentery *	Dysentery 5 years previously, followed by relapsing diarrhoea.	1 course of emetine injections.	Veg. <i>E. histolytica</i> . <i>E. nana</i> cysts.	Concussine injection, gr. i daily for 9 days.	7 examinations. Negative.

emetine, yatren, and stovarsol, and had had repeated relapses during a period of one year. Her condition cleared up at once on the combined emetine and kurchi treatment; 8 stools, one a week for 8 weeks, gave negative results, and she is now, two years later, in excellent health. Case 8 was very similar, but could only be followed up for ten days.

(ii) *Emetine plus stovarsol*.—Five patients were treated by emetine injections combined with stovarsol orally. These consisted of 1 case of active dysentery, 2 of amoebic colitis, and 2 carriers. The results of treatment were: were:

Cases treated, 5.

Probable cures, 2 (Nos. 3 and 5).

Failures of treatment, 0.

Indeterminate, 3 (Nos. 1, 2 and 4).

It is to be noted that in none of the 20 stools examined after this course of treatment was any form of *E. histolytica* found.

The number of cases observed is of course too small to justify any conclusion, but this line of treatment certainly deserves further investigation. Cases 3 and 5 in this series were cases of very chronic and relapsing amoebic dysentery, and appeared to clear up at once with the combined treatment. The cost of a course of 9 grains of emetine and 18 tablets of stovarsol, given in 9 days, would be approximately Rs. 5-1-7.

(iii) *Emetine plus yatren*.—Only one patient received treatment by injections of emetine combined with yatren by the mouth. He appeared to have been cured, though he was a very chronic and old standing case.

The possibility of efficient cure with one or other of the combined treatments certainly deserves further investigation.

DISCUSSION.

A summary of our results is given in Table X. Whether we consider them or the analysis of the literature previously given in this memoir, we are bound to admit that the present-day treatment of chronic intestinal amoebiasis is profoundly disappointing. The medical practitioner of the present day in fact is in a worse position than his predecessor of a century ago. In that day remedies were few and drastic, whilst ignorance as to the causes of dysentery did not prevent by way of treatment the application of "the method of trial and error." To-day, thanks to the work of Sir Leonard Rogers, Dobell, Wenyon and O'Connor, Fletcher and Jepps, W. M. James, Manson-Bahr, and others, our knowledge of the pathology of chronic intestinal amoebiasis is fairly extensive; yet from amongst a whole host of supposed "cures" for the condition there is not one that appears to be really efficacious or reliable.

We have seen that the degree of severity of symptoms in a person infected with

E. histolytica may vary very widely, from the almost symptomless carrier state to acute amoebic dysentery, with extensive ulceration of the colon. This variation may be due to one of two principal causes:

(a) Variation in the resistance of different individuals to the inroads of the parasite. To this possibility we shall return later.

(b) Variation in the tissue-attacking power of the parasite.

Let us take up this latter question first. It is likely that various strains of *E. histolytica* may vary widely in their capacity for attacking and dissolving tissue. This has been especially emphasised by Brumpt (1925, 1926). He goes so far indeed as to distinguish two species of entamoebæ, which have a practically identical morphology, and produce tetranucleate cysts—*Entamoeba dysenteriae*, which is pathogenic and gives rise to amoebic dysentery and the symptoms of amoebiasis, and *Entamoeba dispar*, which is not pathogenic. Dobell (1926) vigorously and in our opinion rightly criticises this as unsound. He quotes the work of Walker (1913) which showed that experimental infection with the same strain of *E. histolytica* may give rise to amoebic dysentery in one man, but not in another.

Now the classical work of Boeck and Drbohlav (1925), subsequently fully confirmed by many workers, has shown that in culture *E. histolytica* takes to feeding on bacteria, although in full vigorous activity. W. M. James (1925) writes as follows: "It is of great interest to me to learn through a recent letter from Professor Dobell that he has revised his opinion that *E. histolytica* is always a tissue parasite. He is now convinced that it can occur in the large intestine without tissue penetration. In other words, a latent infection does not necessarily mean ulceration of the bowel, but is capable of establishing an ulcerative process at any time."

It is becoming increasingly clear, indeed, that in some carriers the entamoebæ may live in the lumen of the gut (where they presumably feed upon bacteria) and never invade tissues. Such infections would be unaccompanied by any symptoms, and would be likely to be transient ones. Above all they should prove exceedingly amenable to treatment.

In our series of cases the following appear to be instances of this state of affairs:—

(i) Table I, Case 5; a case of tabes dorsalis in an *E. histolytica* carrier; the carrier condition rapidly, and apparently permanently cured by alcresta ipecac.

(ii) Table IV, Case 17; a patient with filariasis, who was a dysentery carrier. Rapid and apparently permanent cure followed a 10-day treatment with "E. B. I."

(iii) Table VI, Case 10. A carrier with a gastric ulcer. Rapid and apparently perma-

nent cure followed a course of stovarsol administration.

On the other hand, the proportion of carriers who are absolutely free from any symptoms which can be attributed to the infection in the gut is small, and it is evident that this state of affairs must be the exception, rather than the rule.

At the other end of the scale, it would appear that the amœbæ are more susceptible to treatment when actual dysentery is present, than when it is not. When actual dysentery is present, although the amœbæ are innumerable and in full pathogenic activity, yet the gut is hyperæmic, and any drug which is present in the blood-stream will have ready access to the amœbæ. Examples of what was apparently complete eradication of the infection from patients who were suffering from acute amœbic dysentery at the time, are as follows:—

(i), (ii), (iii) Table II. Cases 3, 4, and 15; treated with emetine injections only.

(iv), (v) Table III, Cases 1 and 18; treated with emetine injections and bismuth orally.

(vi) Table V, Case 1; treated with yatren orally. Also Case 1 in the series treated with yatren orally and per rectum.

It is the intermediate group of cases which are so extremely resistant to any form of treatment. A glance down the columns headed "Previous intestinal history" shows the state of affairs present in these patients. They get relapse after relapse, and their general health steadily deteriorates. Here there is often considerable thickening and fibrosis of the gut wall, the entamœbæ are walled in by fibrous tissue, there is anæmia rather than hyperæmia of the gut, and the chances that any weak amœbicide under such conditions will eradicate the infection are very poor. In this condition it would appear that eradication of the infection only takes place when the drug induces sufficient irritation of the mucosa of the colon to cause all the amœbæ to be shed. Instances of this state of affairs are:

(i) Table IV, Case 2. Cured by 30 grains of "E. B. I." in 10 days.

(ii), (iii) Table V, Case 2. This patient had suffered from chronic relapsing amœbic dysentery for eight years. He was apparently completely cured by 9 pills of yatren daily for 7 days, followed by 3 pills daily for 10 days. Case 23 of the same table is a similar instance.

(iv), (v) Table VII, Cases 2 and 10; treated with kurchi orally.

(vi) Table VIII, Case 2; treated with conessine.

The difficulty of eradicating a chronic infection with *E. histolytica* is such that we know three medical men who are infected, and who

have "given it up," so to speak. They carry on until some abdominal disturbance sets in, when they have a sufficient number of injections of emetine to alleviate the symptoms, and then carry on till the next recurrence. Such a policy, however, is one of despair, and a "*histolytica*-emetine life"—if we may coin the term—a most uncomfortable one.

The question may be asked: "If the patient is infected and shows but few symptoms, is it worth while attempting to eradicate the infection? Why not let it alone unless or until symptoms set in?" The answer to that question we believe lies in the column "Previous intestinal history" in the tables in this paper. We agree with Boyers, Kofoed and Swezy (1925) in their statement that the usual course of events in a carrier of *E. histolytica* is a progressive deterioration in health. The symptomatology of the carrier state is fully discussed elsewhere (Acton and Knowles, 1928, p. 125), and we need not here expatiate on it. The carrier is always a potential danger, both to himself and to others, and in our opinion the need for the discovery of some easily administered, ready, really efficacious, and yet cheap cure for the carrier state is most urgent. We consider that whenever the carrier state is present, every attempt should be made to eradicate the infection.

On the other hand, there are those who "darken counsel by words without knowledge," and we would deplore the present-day tendency of some manufacturers to flood the market with an ever-increasing number of new "cures." Such a policy does not help the medical man; it only makes matters worse for him.

To turn to the other side of the picture, the writers—at least—are coming more and more to believe that the final eradication of the infection may perhaps be more easily effected by raising the patient's general resistance than by the use of a weakly amœbicidal drug.

We seem to know a very great deal about the pathology of intestinal amœbiasis, but—to look the matter squarely in the face—is there not as yet a vast and unexplored territory awaiting investigation?

Why does *Entamœba histolytica* in one person cause amœbic dysentery, and in another few or no symptoms? Why does an infected person sometimes remain free from symptoms over long periods, and then pass into a condition of relapsing dysentery which may last for months or years, and may then apparently spontaneously recover? What, in brief, are the conditions which lead to the assumption of pathogenicity on the part of the amœba?

It is along this line of investigation, we believe, that investigation should be pushed. Instead of turning out numerous new drugs

of weak amœbicidal activity, let us try and understand the how and the why of chronic intestinal amœbiasis. Other factors than the amœbæ are concerned in this state of affairs.

The surface only of this problem has so far been scratched. Oliver (1924) notes that the treatment of intestinal amœbiasis in Mesopotamia was more successful during the hot weather than in the winter. Is this possibly associated with a lower endocrine rate of metabolism during the cold weather, leading to a loss of resistance on the part of the patient? Knowles, Napier and Das Gupta (1923), and Acton and Knowles (1924) have shown that in acute amœbic dysentery the stool is usually markedly acid, in fact is usually acid to blue litmus-paper. Is the hydrogen-ion concentration of the contents of the colon, or of the colon mucosa a factor which helps to determine whether the amœba becomes pathogenic or not? Is achlorhydria or hyperchlorhydria a determining factor in the assumption of pathogenicity by the amœba? Vogel (1927) notes the special association of a Gram-positive diplococcus with acute amœbic dysentery. Knowles (1928, p. 48) notes the association of a markedly hæmolytic streptococcus with fatal experimental amœbic dysentery in kittens. Dobell and Laidlaw (1926a), in their cultural work on *E. histolytica*, isolated a "Bacillus No. 1" which appeared to be particularly favourable to the excystation and growth of *E. histolytica*. It had the typical cultural characters of the bacillus of Shiga, but did not agglutinate with the specific high titre serum. "Bacillus III," which corresponded to typical *B. lactis aërogenes*, was definitely inhibitory to all the amœbæ tested, and "Bacillus IV" to the growth of *E. histolytica*. The same authors also note the extremely favourable action of certain grades of rice starch on cultures of *E. histolytica*. "The effect of adding solid starch to a culture of *E. histolytica* is often, indeed, astonishing. Within 24 hours a previously poor culture is teeming with amœbæ—most of them gorged with starch-grains in various stages of digestion," they write. The optimum temperature for culture was 37-38°C. and if the cultures were cooled to 30°C. the amœbæ rounded up and gradually died. The amœbæ grew best in media which were of neutral reaction; and acid and alkali alike were harmful. Changes in the viscosity of the medium did not appear to affect the growth of the amœbæ. Partial anaërobiosis did not kill the cultures. The amœbæ appeared to be but little affected by changing the salt-content of the medium. Small particles of sulphur and of cellulose were ingested by *E. histolytica*, but neither affected the cultures in any way.

This memoir of Dobell and Laidlaw's constitutes an important first step in the direc-

tion of studying the influence of its environment on the vegetative forms of *E. histolytica*, and such a line of investigation should be pushed, for its results may have a most important bearing on the treatment of intestinal amœbiasis.

Sellards and Leiva (1923a) have emphasised the importance of stasis of the gut contents and a fluid condition of the contents of the colon in inducing excystation of *E. histolytica* in experimental kittens; and it is possible that the same two factors may have an important bearing on the setting in of amœbic dysentery in a carrier. Acton and Knowles (1928) draw attention to the fact that in amœbic dysentery and in the carrier state with symptoms, the bacterial flora of the stools seems to be entirely changed from the normal. On a McConkey plate in such cases one gets large numbers of very fine dewdrop-like colonies. These consist chiefly of enterococci, which may or may not be lactose fermenters, and many strains of which are virulently hæmolytic; also fine types of yeasts. Another organism which is frequently present corresponds to *Staphylococcus mollis*, and this frequently has hæmolytic powers.

We would urge that what is wanted now is not to flood the market with new and weak amœbicides, but to carry out a thorough and complete investigation of the conditions under which a "healthy" carrier goes down with amœbic dysentery; in other words the factors which make for pathogenicity on the part of the amœba. This may involve gastric analyses, determinations of the hydrogen-ion content of the stools (and, if possible, of the fresh contents of the colon) in normal persons and in patients suffering from amœbic dysentery, and work with experimentally infected kittens. We know a great deal about the pathology of intestinal amœbiasis; we know scarcely anything however about its pathogenesis. It may be possible that some quite simple measure may render the colon inhospitable to the amœbæ, in which case the carrier would probably cure himself.

Even if the carrier does succeed in curing himself, however, he is always liable to re-infection when he goes back to the same environment in which he first contracted the infection. Dunn (1927) writes feelingly on this point: "Even prolonged treatment is more or less hopeless; for when one realises that 40 per cent. of the Chinese have amœbic cysts in their stools, it means that you and I have at least one servant handling our food from day to day, who is continually re-infecting us. One might eradicate cysts after six months' treatment, only to be re-infected a few days later. So, again, we, who live in the East, must look toward some prophylactic treatment as our ultimate hope." This author draws special attention to the necessity for securing an adequate supply of

vitamines in the patient's diet. "I put the patients on full diet," he writes, "rich in vitamins, and almost like magic they commence to gain weight, and all symptoms disappear."

SUMMARY AND CONCLUSIONS.

The patients dealt with in this paper numbered 154, and 220 treatments were administered to them. Whilst the series include many patients who were suffering from amœbic dysentery on admission, the great majority were cases of chronic and relapsing intestinal amœbiasis, together with some "healthy" carriers. Unfortunately the impossibility of following up patients discharged from hospital in civil life rendered the enquiry almost nugatory. On the other hand, such results as have been obtained may perhaps be expressed in terms of the relative ratio of "probable cures" to certain failures of treatment; and, with regard to the sterilising influence of the drug on the amœbic infection present in the gut, in terms of the relative ratio of the number of negative to positive stools after treatment.

The results obtained are summarised in Table X. With regard to the different individual remedies tested:

(1) "Alcresta ipecac." gave a ratio of probable cures to failures of 1: 1.3, and of positive to negative stools of 1: 7.

(2) Emetine injections (alone) gave corresponding ratios of 1: 1.7, and of 1: 7.

(3) Emetine injections plus "Panama bismuth" gave ratios of 1: 1.8, and 1: 8.7. The addition of large doses of bismuth appears—clinically at least—to improve the chances of eradication.

(4) Emetine bismuth iodide (chiefly administered to carriers) gave ratios of 1: 3.5 and 1: 6.5. (Possibly it was not given in sufficient doses or for a sufficiently long period.)

(5) Yatren given orally gave ratios of 1: 1.3 and 1: 8. With the combined method of yatren orally and yatren per rectum (on the few cases tested) results did not seem to be much better.

(6) Stovarsol appears to be of definite value in the treatment of chronic intestinal amœbiasis. The ratio of probable cures to failures was as 1: 1.1, and of positive to negative stools after treatment as 1: 13.6. This treatment is also of value for its hæmatinic effects.

TABLE X.

Summary of Results in Calcutta.

Treatment.	No. of cases treated.	Probable cures.	Failures of treatment.	Indeterminate.	Ratio. Probable cures: Failures.	Ratio +ive stools: -ive stools after treatment.	Approximate cost of treatment.
Alcresta ipecac. ..	7	3	4	0	1 : 1.3	1 : 7	Rs. 3-2-4
Emetine injections (only).	32	6	10	16	1 : 1.7	1 : 7	" 2-7-6
Emetine injections plus "Panama bismuth."	55	9	16	30	1 : 1.8	1 : 8.7	" 4-9-4
"E. B. I." ..	23	2	7	14	1 : 3.5	1 : 6.5	" 3-5-4
Yatren orally ..	23	6	8	9	1 : 1.3	1 : 8	" 3-10-6
Yatren combined orally and per rectum.	6	2	3	1	1 : 1.5	1 : 6.2	" 19-6-6
Stovarsol ..	32	8	9	15	1 : 1.1	1 : 13.6	" 2-5-2
Kurchi orally ..	16	7	8	1	1 : 1.1	1 : 7.1	" 1-2-1
Conessine or total kurchi alkaloids by injection.	11	3	8	0	1 : 2.7	1 : 4.8
Combined treatments.	15	6	3	6	2 : 1	1 : 18	From " 4-8-0 to 5-1-7
TOTALS ..	220	52 = 23.6%	76 = 34.5%	92	1 : 1.5	1 : 8.7*	

* As calculated on 752 stools examined after the cessation of treatment.

(7) The simple administration of kurchi orally gave surprisingly good results; the ratios being 1: 1.1 and 1: 7.1 respectively.

(8) On the other hand results with the hypodermic administration of conessine hydrochloride or of the hydrochloride of the total alkaloids of kurchi bark seemed to be worse than those with kurchi orally. Possibly in the oral administration of kurchi, the action of the tannins on *E. histolytica* is of value.

(9) Of the different combined treatments tried the simultaneous injection of emetine and administration of stovarsol orally appeared to give the best results. Further investigation on the possibilities of combined treatments is much wanted.

Our findings, together with a study of the previous literature, lead us to the conclusion that these drugs are *weak* amebicides, and that a policy of placing an increasing number of them on the market is going to confuse the issue, rather than clarify it. The medical practitioner, at the moment, does not know where he is, and a study of the literature and advertisements does very little to help him.

We would urge the necessity, at this juncture, for a thorough investigation of the rôle of the secondary factors in the causation of amebic dysentery, and of the influence of its environment on the pathogenicity of *Entamoeba histolytica*.

The Cause and Treatment of the Crisis in Lobar Pneumonia.

By ALEXANDER CANNON, M.B., Ch.B. (Leeds).
(*Brit. Med. Journ.*, April 21, 1928.)

THIS writer's suggestions for the administration of oxygen in pneumonia are worthy of note:—

There is a very small point which is of great importance in the use of oxygen in pneumonia, and is the secret of the success which has followed my treatment of all pneumonia cases: the oxygen should be used warmed. In the past, the use of oxygen has been the cause of more deaths in pneumonia than one cares to contemplate, simply because it was administered cold and not warmed to the required temperature; hence the lungs were chilled and the patient could not stand the

shock. The oxygen should be heated by passing the gas through coiled Litré's tubes immersed in a water-bath kept at a temperature of about 120°F., the gas being passed through the tube at a slow rate, which is gauged by the comfort of the patient, who breathes quietly and does not complain of the "choking" feeling which occurs when the gas is administered too quickly. By keeping a thermometer in the tube it was found that the temperature of the gas passing through at this very slow rate was about 99°F. when the water-bath registered 120°F. One thing to watch is the risk of sudden collapse when the crisis occurs; this can fortunately be avoided by the daily administration of pituitrin, 1/2 c.cm. being administered hypodermically morning and night, the heart action being safeguarded by the old-time proven remedy of digitalis administered from the onset of the disease; the omission of this has been responsible for the loss of many a case of pneumonia.

Danger of Intravenous Calcium Therapy.

(*Brit. Med. Journ.*, April 21, 1928, p. 662.)
Observations.

IN the first experiment, when 50 c.cm. of a 1 per cent. solution of calcium chloride was injected intravenously, an electro-cardiogram before, during, and for eight minutes after injection was taken. No subjective or objective symptoms beyond the normal were observed in the subject of experiment. The electro-cardiogram showed no changes from the normal during and following the injection other than a slight increase in the heart rate during the period in which the needle penetrated the skin.

The second experiment, in which 4 c.cm. of a 10 per cent. calcium chloride solution was injected intravenously, was more productive of results. When 2 c.cm. of the solution had been injected the subject experienced a sensation of warmth over the entire body, accompanied by slight headache and a feeling of fullness in the head. It was decided to continue the injection. Dizziness occurred during the period of injection of the second 2 c.cm., and this was closely followed in the course of the next three seconds by syncope, respiratory failure, upward deviation of the eyes, dilatation of the pupils, rigor of the masseters, and asphyxial extensor spasm and rigidity. The string of the electro-cardiograph at this time was seen to be standing still. The subject was taken away from the electrodes, placed in a supine position upon the floor, and artificial respiration instituted. An attempt was made to massage the heart through the abdominal wall and diaphragm at the left costal margin. In the course of four or five minutes voluntary respiration was again established, the pupils contracted, and consciousness was regained. No residual effects were noted.

The examination of the electro-cardiogram during this period showed the normal cardiogram to be replaced by one in which the rate of the heart was reduced to one-half. No changes were to be seen in the P.Q.R. complex at the time of this change in the frequency. Each wave possessed its normal order, time relationship, and character. After this bradycardia had lasted for ten seconds it was replaced by a series of small waves, which were suggestive of vibration of the string. There is no evidence in the cardiogram that the ventricle was beating during this period. At the end of the curve, when the subject was removed from the electrodes, these small fibrillary waves were less frequent but of greater amplitude. There was as yet no evidence of the R wave of ventricular contraction. The tracing was that of a prolonged sino-auricular block.

Comment.

From these few observations it is not possible to reach any conclusions as to the effect of calcium upon the normal electro-cardiogram.

Whether the effects noted in the second experiment are evidences of vagal stimulation or a direct action

upon the genetic nervous system of the heart independently of any extrinsic nervous supply it is impossible to state. The nature of the results obtained rendered it inadvisable to repeat the experiment following atropinization.

The disturbances of conduction noted are somewhat in accordance with those obtained by Walters and Bowler in the dog. I simply desire to call attention to the occurrence of cardiac disturbances of conduction as a result of intravenous calcium administration in a dosage that has been commonly used.

Summary.

The intravenous use of 4 c.cm. of a 10 per cent. solution of calcium chloride is dangerous. The electro-cardiogram shows what we believe to be a sino-auricular heart-block.

The Treatment of Pernicious Anæmia with Liver and Liver Extra.

By STANLEY DAVIDSON, B.A. (Camb.), M.D.,
F.R.C.P. (Edin.),

J. G. McCRIE, M.B., Ch.B. (Edin.)

and

G. LOVELL GULLAND, C.M.G., M.D., F.R.C.P. (Edin.).
(*Lancet*, April 28, 1928, p. 847.)

Treatment with Whole Liver.

THE diet advocated by Minot might be summarised as being a well-balanced, ample diet, high in vitamins, low in fats and carbohydrates, and having as its essential daily component 200 g. of liver. No two cases require the same amount of liver for the specific effect to be produced. Amounts in excess of 200 g. may be necessary, or less may suffice. From practical experience, we are very strongly of opinion that unsatisfactory results are attributable to one fact alone, and that is the giving of insufficient quantities of liver. In several cases of the series quoted below, the patients were unable at first to take more than 4 oz. liver and 4 oz. liver juice per day. Rapid improvement was seen for the first six weeks, by which time the red count was approximately three millions. No further improvement could be produced until the amount of liver eaten was substantially increased. Some patients have a great abhorrence of liver, owing to its nauseating effect, and in these it is extremely difficult to bring the blood picture back to normal. It may be generally said that pernicious anæmia patients tolerate liver better than do normal persons, and we have invariably found that, as improvement continues, the dislike of the diet decreases. Some of the patients with counts of a million or below were so nearly moribund that the taking of solid food was an impossibility. Liver juice was tried, but this requires to be given in very large quantities before satisfactory results are obtained. In a personal communication to one of us (S. D.) Minot states that the giving of liver juice is the most unsatisfactory dietetic method, while raw pulped liver is the most efficacious.

Treatment with Liver Extracts.

Cohn and his co-workers have shown that, by a method of fractioning, a non-protein substance can be obtained, 5—15 g. of which is as efficacious as 200 g. of whole liver. As this substance is soluble in water, and exerts its action when given by the mouth, the treatment is greatly simplified for patients who are too ill to take solid substances, and is far more pleasant to those who object to the large amount of liver it is essential to eat. For these reasons, liver extracts will, in the future, largely supersede whole liver. Six different preparations have been tested, one being American, two being German, and the remaining three British. Since all these preparations were found to be active,

the manufacturing process appears to present little difficulty. Their mode of action is identical with, but even more striking than treatment with whole liver, because it is possible to give the specific factor contained in 1000 g. of liver in one dose.

Conclusion.

One of us has had a long experience of pernicious anaemia and of the remissions that can be produced by all the methods of treatment formerly in use. The impression formed of treatment by liver and liver extract is that its effects are more promptly, rapidly, and regularly produced than by any former method, although occasionally treatment by arsenic or sometimes no treatment at all may be followed by remissions as rapid in their commencement. The period of recovery is certainly shortened. The recovery is more continuous. The production of a colour-index below unity, which under previous methods of treatment has been found to occur in cases which are going to do well, regularly develops under liver therapy. The most important point, however, is that recovery is more complete. Formerly one had too often to be content with a count of about 3,500,000 R.B.C.'s; now an extra million or more may be confidently expected; the whole blood picture returns to the normal with much greater frequency and certainty, and apparently remains so indefinitely, so long as treatment is persevered with. Two cases have been seen whose treatment was begun in America; they are not included in the foregoing lists. The first had begun liver treatment in 1925 and continued it steadily. The blood was examined twice at an interval of about a year and was practically normal on both occasions. The second was seen once 18 months after treatment was begun and the blood was normal. Both were in vigorous health. This return to vigorous health is certainly more frequent and complete—and, let us hope, permanent—than has ever been experienced as a result of previous methods.

It is important to notice that liver treatment is effectual at any age, and still more that it acts just as well in chronic cases as in acute ones. Some patients had had arsenic *ad nauseam* in various forms, had ceased to respond to it, and could no longer tolerate it, but they answered just as promptly to liver as if they had been fresh cases. It appears to be immaterial to the success of the treatment whether the patient is in his first attack or has suffered several relapses. It seems to be a matter of indifference whether the patient is treated with liver or with the liver extracts which we have tested. All the latter seem to be efficacious, and it will be a matter of personal liking and convenience whether liver or the extract is chosen for treatment.

Is the treatment free from risk? In the great majority of cases it certainly is. Nothing more serious than an occasional temporary diarrhoea is likely to occur, and this can be dealt with by stopping fruit and vegetables for a few days. But it is to be noted that renal complications may arise, though their connection with liver treatment is not definitely proved. One of our hospital cases had an acute nephritis and one died of uræmic vomiting and convulsions. One of us long ago pointed out that the only condition which will cause a persistent leucocytosis in pernicious anaemia is kidney mischief. In that case the leucocytosis should have been a warning, but the patient was in such magnificent health until the final collapse that the warning was disregarded. No pernicious anaemia comes to the post-mortem table with normal kidneys, but this is hardly ever evidenced by albuminuria. In cases with a persistent leucocytosis, it would probably be wiser to trust to liver extract alone, which contains no protein, and not give the large quantities of red meat advocated in Minot's original diet.

In the first few private cases one was inclined to give arsenic as well as liver, on the principle that it is unwise to throw away a crutch too soon, but that was soon found to be unnecessary. Hydrochloric acid

is of value in improving appetite and hence may be used in combination with liver therapy. It is certainly not responsible for the remarkable improvement following the exhibition of liver, as equally good results are obtained in cases which have never received any acid.

Minot has formed the opinion that the nervous symptoms are not benefited by liver treatment, except in so far that as the muscles become stronger the patient can walk better. We are inclined to differentiate a little more. It seems to us that in cases in which the symptoms are of the tabetic type very marked improvement may occur, but in cases of the spastic type we have, so far, either seen no improvement or, as in a case in the private series, a distinct increase of spasticity may supervene, possibly because the muscular tone is increased.

Reviews.

MEDICAL ANNUAL, 1928.—Bristol: John, Wright & Sons, Ltd. Pp. 630, with 130 illustrations. Price, 20s. net.

To the general practitioner in this country the *Medical Annual* is a godsend. It enables him by the expenditure of a comparatively small sum to keep up to date in all branches of his profession. To the specialist also it is an extremely valuable publication.

The *Medical Annual* for 1928 has fully maintained the reputation of this publication; there are no material differences between it and its immediate predecessors, but the yearly improvement has been maintained. The book has now reached its limit in size and if next year the publishers contemplate increasing the thickness of the book they will have to consider seriously the question of dividing it into two volumes.

It is impossible to discuss the individual contributions; the contributors are in each instance experts on the subject with which they deal. Most of the tropical diseases have been reviewed by Sir Leonard Rogers and the recent advances described clearly and concisely. The most striking recent advance in the treatment of non-tropical diseases is the liver treatment of pernicious anaemia. The results which are claimed from this treatment are most remarkable, more especially in view of the fact that it is a disease the aetiology of which is not very clear. A number of pages are devoted to this subject. Recipes for making raw liver less noxious and cooked liver appetizing are given; this is a practical point of great value as practitioners have often found that patients would prefer to die than to eat raw liver in the condition in which it has sometimes been presented to them.

There are numerous most excellent plates—the ones that particularly appeal to the reviewer are those showing the skin reactions in the Schick test and the Dick test, respectively—and some most interesting skiagrams.

L. E. N.

PUBLIC HEALTH LABORATORY PRACTICE.—By Lieut.-Col. A. D. Stewart, I.M.S., Professor of Hygiene, Calcutta School of Tropical Medicine, and Lieut.-Col. T. C. Boyd, I.M.S., Chemical Examiner to the Government of Bengal. Calcutta: Oxford University Press, 1928. Pp. 306, with 3 figures. Price, Rs. 9.

THIS book has been written by two senior members of the Indian Medical Service who have long been connected with laboratory work on foods, drugs, and water in their official capacities, and as such they have acquired very considerable experience. The book is therefore an embodiment of knowledge, long experience, and skill.

A valuable feature of the book is its special application to Indian conditions. There are several books written on the subject in general, but none of them deals with analysis of Indian foods and Indian water supplies. Hence the book is assured of a very warm reception at the hands of public health laboratory workers in India, especially of the students who are preparing themselves for the examination for the Diploma in Public Health of Indian universities. The book is the more welcome, because it contains completely up-to-date information on the subject; for instance the chapter on "hydrogen-ion concentration" which subject has been completely omitted in such a standard textbook as "Kenwood" is here fully described, and ten pages devoted to it.

The arrangement of the chapters dealing with the different subjects is here logical and methodical, and helpful from the student's point of view. This is often not the case with textbooks dealing with the subject. Generally it is very difficult for the medical student to follow the natural sequence in organic and inorganic chemistry in relation to public health, as he is very likely to have forgotten his elementary chemistry by the time he passes his final M.B. examination. So when he comes to read chemistry for his D.P.H. examination, he is quite at sea, when asked to commence straightaway with water and food analysis. The standard books on the subject for his instruction rarely give the student the necessary preliminary ideas on methods of general analysis, acidimetry and alkalimetry, thiosulphate titration, etc. This being the case, the student experiences difficulty when he is suddenly called upon to carry out food and water analysis. The book under review removes this difficulty by devoting one full chapter to this general analysis at the very beginning, and this will be most helpful to students.

In the fitness of things, analysis of alum, lime, and bleaching powder should be included in the chapter on water and sewage analysis, but this is, curiously enough, not to be found in any other textbook. The authors have not omitted to describe these analyses. The chapter on "aims, objects, and interpretations of the sanitary chemical analysis of drinking water" is very well written, and most instructive. Indigenous Indian samples have been well chosen here, a fact which will be much appreciated by all workers in India interested in the subject of water analysis. Some of the explanations are quite original, e.g., the free ammonia content in such a surface water as that of the river Hughli remaining low in spite of considerable pollution, owing to the heat of the tropical sun acting deleteriously on the "nitrifying organisms."

The subject of milk has been very comprehensively dealt with. It is pleasing to find here analyses of such indigenous articles as *chuana*, with suggestions for the standards to be fixed. These suggestions should prove useful guides to local authorities, if they choose to include such foodstuffs in future amendments of the Food Adulteration Act.

In the chapter on "oils and fats" their general chemistry and classification have been fully dealt with, and this section will be very useful to students in trying to grasp the principles underlying their analysis. The physics of the butyro-refractometer are fully explained with the aid of diagrams. Modern milling processes for preparing flour are well described—another matter which is not dealt with in other textbooks on the subject. D.P.H. students will much appreciate the schedules given of the latest regulations on preservatives in food. A good description is also given of the kata-thermometer. In brief, within the narrow compass of 306 pages the authors have included all possible information on the more important matters dealt with in public health chemistry.

Unfortunately, the table of atomic weights has been included in the section dealing with rag floc; this is clearly a printer's error. With the exception of a few minor printer's errors, however, which we hope, will be corrected in a second edition, the manner in which the book has been printed and got up leaves nothing to be desired.

This book can be heartily recommended to all public health workers in India, and, above all, to all students preparing for a Diploma in Public Health.

R. B. K.

THE USE OF SYMPTOMS IN THE DIAGNOSIS OF DISEASE.—By H. A. Hare, B.Sc., M.D., LL.D. Ninth Edition. London: Henry Kimpton, 1928. Pp. 528, with 124 illustrations and 4 plates. Price, 30s. net.

We have just received a copy of the 9th edition of this excellent book. The author has realised that at present the purely clinical side of medicine is being under-valued, and that more importance is being attached to laboratory examinations and laboratory methods. A well trained physician should carefully note the clinical signs and symptoms first and the laboratory investigation should be called in as a further aid when necessary. This book has been written to bring home to the physician the importance of physical signs and symptoms.

The plan of the book is very simple and effective. Different parts of the body are taken up one by one and are carefully studied with regard to any deviation from the normal, beginning from their general and superficial aspects and working down to deeper structures. Special chapters are devoted to important symptoms such as headache, vertigo, coma, convulsions, hiccough, vomiting, cough, and different kinds of pain, etc. The new edition will be welcomed by medical students and practitioners alike.

R. N. C.

THE SIMPLE GOITRES.—By Robert McCarrison, C.I.E., M.D., D.Sc., LL.D., F.R.C.P. London: Baillière, Tindall and Cox, 1928. Pp. x plus 106, with 43 figures. Price, 10s. 6d. net.

COLONEL McCARRISON is a well known authority on goitres, and his experimental work on this subject has been appreciated by the whole medical world. This volume was the outcome of a "Report to the International Conference on Goitres" held under the auspices of the Swiss Goitre Commission at Berne last year. The book is divided into two parts:—

Part I deals with the aetiology and epidemiology of simple goitre. Three main types are described. The factors concerned in their production include food deficiencies, food excesses, polluted water supplies, gastro-intestinal infections, and insanitary conditions of life. A large number of them can be prevented by attention to the fundamental principles of nutrition and personal and social hygiene. Various types of these goitres may prevail in the same locality, some being capable of amelioration by the prophylactic use of iodine while others are not and some may even be harmed by it. The author warns against the indiscriminate use of iodine as a preventive of goitre.

Part II is composed of illustrations, and contains many curves, reproductions of pictures of human cases and of animals in which goitre was experimentally produced, and numerous microphotographs of sections of the gland.

The book is very well got up and will be of great interest to the profession.

R. N. C.

COMMERCIAL DRUGS OF INDIA.—By L. R. Dutt, M.R.A.S. (Lond.). Calcutta: Thacker, Spink and Co., 1928. Pp. 256. Price, Rs. 5.

THE writer in his introduction says that this book is not intended so much for medical practitioners as for business men. Its object is to place before the drug grower, collector or dealer, as briefly and lucidly as possible, all the available information regarding the sources, method of collection and cultivation and marketing of drugs. Most of the common drugs found on the market are mentioned, but such drugs as *Ephedra vulgaris* which have lately assumed considerable importance from the commercial point of view and which grow in India abundantly have not been included.

Otherwise the book is quite up-to-date and most of the recent work on the indigenous Indian drugs has been included in it. The book ought to prove very useful to business men and also to medical men who are interested in Indian indigenous drugs.

R. N. C.

BEDSIDE MEDICINE. (A HANDBOOK OF DIAGNOSTIC METHODS.)—By A. R. Majumdar, M.B., Bengal Medical Service. Calcutta: The Book Co., 4-4A, College Square, 1928. Pp. 443, with 149 illustrations. Price, Rs. 6-8.

This is an admirable little book on which we congratulate both the author and the publishers. It is exactly what the Indian medical student wants; concise, well illustrated, original, and written with special reference to tropical diseases. The author was for some nine years tutor of medicine in the Medical College, Calcutta, and is now teacher of materia medica and physician at the Campbell Hospital, Calcutta. Hence he has had long experience of teaching Indian medical students, knows what they want in the way of instruction, and how to give it to them. In a foreword to the book Colonel Sandes, I.M.S., Professor of Medicine at the Medical College, Calcutta, writes "Twelve years teaching experience in the medical colleges of Bengal has fully demonstrated to me the necessity for such a book. It should prove of immense value, if properly used and applied. Every author, in some degree, portrays himself in his work, and the large mass of clinical facts, methods and measures that Dr. Majumdar has collected, co-related and put together in his book typifies his own undoubted teaching ability and tireless energy."

A specially useful feature of the book is its numerous original illustrations, photographs of cases of special interest, pulse tracings, electrocardiograms, diagrams, and the like. Unlike many authors, Dr. Majumdar has throughout relied on his own personal experience, and his own collected case notes. Where he borrows from other authors, he makes every acknowledgment.

The book is well printed and well bound, and of a convenient size. It deals with every aspect of bedside and clinical medicine, and we can thoroughly recommend it to medical students and practitioners in India and Eastern countries.

Annual Report.

REPORT ON THE KALA-AZAR SURVEY IN PATNA CITY. AUGUST–NOVEMBER 1923. BY LIEUT.-COL. WILLIAM C. ROSS, I.M.S., DIRECTOR OF PUBLIC HEALTH, BIHAR AND ORISSA. PATNA: SUPERINTENDENT, GOVERNMENT PRINTING, BIHAR AND ORISSA. 1928.

(1) *Introductory.*—In 1923 I received reports that kala-azar was very prevalent in Patna City, and that large numbers of cases were coming forward for treatment since the efficacy of injections of potassium antimony tartrate and subsequently sodium antimony tartrate had been established, and facilities for treatment had been provided in the hospitals. In August 1923, I had available a number of epidemic doctors whose services were not immediately required for epidemic duty, and I thought it desirable that definite information should be obtained as to the prevalence of the disease and as to the conditions associated with it. At that time there was no information available as to the epidemiology of the disease, and the conditions favouring its prevalence, and the work

of investigation had been chiefly confined to the search for a biting insect which would fulfil the double function of transmitter and host, on the analogy of the rôle played by the mosquito in malaria.

As it appeared that Patna was probably an endemic area of kala-azar infection, and as I had an available staff of eight doctors temporarily available at the time, I arranged for a detailed survey of an area of some considerable size in Patna City. The area was selected with a view to including both a congested bazar area, and a more open area with conditions similar to those in any village in Bihar. From the points of view of convenience, size, accessibility and representativeness, I selected an area comprising approximately two wards of Patna City, one of which was congested, and in one of which the houses were scattered. A schedule was prepared for recording and compiling the observations, and whilst the schedule was in press the hospital records of the Patna General Hospital and of the Patna City Hospital were examined, and a compilation was made of the statistics of kala-azar cases coming in for treatment. These statistics were subsequently completed up to the end of 1923.

The work was carried out very carefully and thoroughly by eight of the epidemic doctors of the provincial staff, who personally visited and inspected every house in the area, who examined all the inhabitants personally, and who filled in the schedules for each holding and subsequently abstracted the statistical results of the investigation. The work lasted for more than eight months.

(2) *Hospital Statistics.*—During the four years, from 1920 to 1923, 3,076 cases of kala-azar were treated in the Patna Hospital as shown in the abstract statements below:—

Statement I.

	Males.	Females.	Total.
1	2	3	4
1920 ..	550	183	733
1921	515	234	749
1922	420	186	606
1923	778	210	988
TOTAL ..	2,263	813	3,076

Statement II.

	Hindus.	Muham- madans.	Total.
1	2	3	4
1920	423	310	733
1921	410	339	749
1922	350	256	606
1923	692	296	988
TOTAL ..	1,875	1,201	3,076

Statement III.

	Under 10	10-20	20-30	30-40	Over 40	Total.
1	2	3	4	5	6	7
1920 ..	289	240	114	60	30	733
1921 ..	303	248	109	60	29	749
1922 ..	241	202	93	50	20	606
1923 ..	330	323	188	108	39	988
TOTAL	1,163	1,013	504	278	118	3,076
Percentage of total cases in each age group.	37.8 %	32.9 %	16.4 %	9.0 %	3.9 %	
Percentage distribution of population in each age group.	24.8 %	17.8 %	16.4 %	15.2 %	25.5 %	

The population of Patna at the last census was 119,976, comprising 90,248 Hindus and 28,200 Muhammadans. In other words there were more than three Hindus to each Muhammadan. The age distribution of the general population is shown in Statement III above.

The total of 3,076 cases treated in four years gives an average annual figure of 769, in a population of 118,448 Hindus and Muhammadans, which represents a general incidence of 6.5 cases per thousand of population. It is necessary, however, to discount this estimate to some considerable extent on account of the attendance of cases from surrounding villages outside Patna Municipality and it is probable that the incidence of 4.5 per thousand arrived at in our detailed survey, in a typical representative area, is more nearly accurate. Again, however, allowance must be made for the fact that the most congested and the most unhealthy parts of Patna City were not included in the survey, as it was desired to get some measure of the prevalence of the disease under ordinary conditions and not in a specially selected unhealthy or congested area.

I am of opinion therefore that the probable incidence of kala-azar amongst the general population in Patna City and in a large part of Bihar is between four and five per thousand.

(3) *Scheme of Survey.*—The area selected for survey was first selected because of its being a typical representative area of suitable size which included both congested and open areas, and which contained all types of houses, and all sorts and conditions of people.

(4) *Summary of Results.*—The population of the 7,897 holdings investigated in the survey was 36,062 of which 25,311 were Hindus, 10,561 were Muhammadans and 190 were Christians. The returns showed 162 cases of kala-azar of which 17 had recently died, 24 had just completed treatment and 121 were being treated, except in a few instances in which we advised them to go to the hospital for treatment. The general incidence of kala-azar in the area was therefore 4.5 per thousand during the year of the survey.

With regard to sleeping habits it was found that almost every one slept on a bed, and that practically no one used a mosquito net.

The information with regard to domestic water-supply indicated that differences in the water-supply were not associated with any material difference in the prevalence of kala-azar. The area surveyed was specially selected so as to include a long line of habitations on or near the bank of the Ganges and it was found that the majority of the population near the river used river water entirely, and that a large number of those

situated further away took river water for drinking and cooking, but there was no appreciable difference in the incidence of kala-azar either amongst those who used river water in part or altogether, or those who did not use it at all.

(5) *Site Incidence.*—A spot map of the distribution of kala-azar cases and probable cases in this area is given (but not reproduced here, Ed.). It is perhaps at this point necessary to explain that the distinction between kala-azar cases and probable cases, has reference to the fact that all cases are shown as probable cases in which the presence of the parasites was not demonstrated by spleen puncture. As a matter of fact, the probable cases were mostly being treated for kala-azar, and all the cases shown as probable cases presented the definite clinical picture of kala-azar. This explanation appears to be necessary as some of the workers investigating kala-azar are not so meticulous in regard to their statements as to what is proved, and what is suspected or probable, and the heading 'Cases of enlarged spleen probably kala-azar' might be misunderstood.

The general numerical distribution of the cases is roughly in proportion to the density of population. The most densely populated areas are those which show the largest number of cases.

Of the total number of the 162 cases, 138 occurred as single cases in separate houses, whilst only 24 multiple cases occurred in 11 houses. So far as it goes, this would appear to indicate that kala-azar is not a disease in which one case supplies the infection for producing other cases, and the general distribution of the cases throughout the area also supports this view.

(6) *Religious Incidence.*—In the survey population of 36,062, there were 25,311 Hindus and 10,561 Muhammadans. Amongst the Hindus there were 95 cases, whilst amongst the Muhammadans there were 66 cases. The case incidence, therefore, was equal to 6.2 per thousand amongst the Muhammadans against 3.7 per thousand amongst the Hindus. In the record of 3,076 cases tabulated in Statement II in paragraph 2 of this report, the incidence of kala-azar appears to be even greater. Taking the average of the four years' figures, the prevalence of the disease works out at 6.5 per thousand on the population of Patna, and the incidence amongst Muhammadans and Hindus works out at 10.6 and 5.2 per thousand, respectively. It is, however, necessary to discount these figures to some extent, as pointed out in paragraph 2 above, owing to the inclusion in the hospital returns of cases coming from outside municipal limits. That consideration, however, does not seriously affect the relative incidence between Muhammadans and Hindus, which, in this case, is 10.6 against 5.2 as compared with 6.2 against 3.7 in the survey returns. This preponderance of kala-azar infection amongst Muhammadans has been noted by other observers and appears to occur all over India. It must, therefore, be associated with some distinctive difference in customs and habits between the two religions, as it is not in any way a local phenomenon. I have gone carefully into the differences which are characteristic between the two religions. The housing and water-supply of both the religions are similar. The conditions regarding exposure to insect bites are identical, and the only fundamental difference from the health point of view is in the eating habits of the two religions. The Hindu—especially the high caste Hindu—always eats freshly prepared food and throws away what remains after every meal. A Muhammadan frequently eats food which has been prepared beforehand, and often eats food prepared several days previously. This is the most characteristic and in my opinion the most important difference between the habits of Hindus and Muhammadans, and I consider that it indicates that the probable source of infection is in the food, and that the invasion of the disease takes place through the intestinal tract.

The excess incidence amongst Muhammadans would not be so surprising if Muhammadans were in general more subject to disease than Hindus, but such does not

appear to be the case. I have compiled a table of the mortality rates of Hindus and Muhammadans for the whole province of Bihar and Orissa for ten years, which shows that the average annual death-rate amongst Hindus was 33.2 per thousand against 27.9 per thousand amongst Muhammadans. These figures have been taken from a population of over thirty millions for a period of ten years, and may therefore be accepted as a definite indication of the condition of health prevailing in these two religious communities. A consideration of these figures tends to increase the importance of the difference in the religious incidence of kala-azar.

(7) *Age and Sex Incidence.*—Statement I in the second paragraph of this report shows the sex incidence in 3,076 cases. The preponderance of males as represented by 2,263 cases against 813 female cases is probably more apparent than real. Owing to the reluctance of many Indians to bring their female relatives to hospital, it is not possible to accept these figures as a correct representation of a real difference in sex incidence. There may be such a difference. If so, it will be difficult to explain or to understand, and until such a difference in sex incidence has been established, I am not prepared to give any importance to these figures. If any real difference in sex incidence exists, it is probably associated with the greater freedom of habits permitted to boys as compared with girls.

The point of view that sex incidence is more apparent than real, is supported by the fact that amongst the 161 cases recorded in the survey amongst Hindus and Muhammadans, amongst the Hindus, in 96 cases, 74 were males and only 22 females; whereas amongst the Muhammadans, in 65 cases, 39 were males and 26 were females. The ratio of males to females amongst Hindus is roughly 7 to 2 whereas amongst Muhammadans it is only 3 to 2.

It is well known in India that there is some reluctance on the part of Muhammadans to bring their female relatives to hospital, and that the disinclination of Hindus to do so is much greater, especially amongst the higher castes. If the figures above quoted are interpreted in accordance with these known prejudices, it appears probable that the disease affects both sexes more or less equally.

In Statement III, in paragraph 2 above, the age incidence of 3,076 cases is tabulated and the percentage in each age group is shown,—and also the percentage distribution of population in each age group.

The age incidence of the 162 cases recorded in the survey was as follows:—

Statement IV.

	Under 10	10-20	20-30	30-40	Over 40	Total.
1	2	3	4	5	6	7
Number of cases.	64	54	30	8	6	162
Percentage of total cases in each age group.	39.5	33.3	18.5	4.9	3.7	
Percentage distribution of population in each age group.	24.8	17.8	16.4	15.2	25.5	

It is interesting to note the similarity that exists between the two tabulated Statements III and IV. Many other observers have recorded similar observations with

regard to the age incidence in kala-azar, and all of them have made a point of the extraordinary prevalence of the disease amongst children and adolescents. I have not however been able to find on record any correction for age distribution such as I have included in the two statements above.

When the age distribution of the disease is considered together with the figures for the general age distribution of the population, it at once appears that kala-azar is not so predominantly a disease of children as has previously been thought. The correction brings the relative age distribution into better perspective, and shows that whilst kala-azar is most common in children, it is at the same time very frequent in adults and cannot be considered to be characteristically a disease of youth.

Another very important point in the age distribution is that kala-azar is a very rare disease below the age of two years. In the 3,076 cases tabulated in Statement III there was no case below two, and amongst the 162 cases recorded in the survey there was only one case which was just under two. In my opinion this is a point of great importance, which further supports the theory that the invasion of kala-azar is through the intestinal tract. In Bihar and in general in India, children under two years of age are nearly all breast-fed, and would therefore not be liable to infection. On the other hand, infants in India are at least as liable as adults to being bitten by mosquitoes, sandflies, bugs, etc., if not more so, as they spend more of their time in sleeping, and are incapable of ridding themselves of these biting insects in the way that an adult can do.

Malaria, which is known to be transmitted by mosquitoes, and which is a prevalent disease in India, affects the youngest infants and is a frequent cause of disease and death in infants under three months of age. Kala-azar on the other hand has a peculiar age distribution in which infants are very rarely affected, and it is very difficult, if not impossible to reconcile this fact with any theory of transmission by a biting insect.

(8) *Housing Incidence.*—The distribution of the 162 cases amongst the 7,897 holdings was somewhat of a surprise. It was formerly held that kala-azar was a disease which was associated with defective sanitation and bad housing. Defective sanitation is a term which is very vague and very wide, and is a condition which is most probably directly associated with the explanation, but certainly bad housing has nothing whatever to do with the disease. Defective sanitation is a universal feature in Patna City. Decomposing filth and accumulations of rubbish and garbage are found all over the town in the courtyards and in the immediate vicinity of all premises, from mud huts to the best built masonry houses. Cows and goats are kept in large numbers within their owners' premises and are kept both by Muhammadans and by Hindus equally and quite irrespective of religion. They are kept chiefly as a source of milk supply and their presence adds very appreciably to the insanitary state of the premises where they are kept.

There were 800 masonry brick-built houses in the area surveyed, and in these 31 cases occurred, giving a house incidence of 38.7 per thousand, whereas there were only 131 cases in 7,097 mud houses and huts which show a ratio of only 18.4 per thousand.

Of the 800 masonry houses, 392 had masonry privies and 408 had only rough arrangements for use as privies, chiefly consisting of two bricks for the feet to rest on, with an earthenware receptacle between. In the 392 houses with masonry privies there were 19 cases of kala-azar, whilst in the 408 houses without masonry privies there were only 12 cases. The incidence in this respect is 48.4 per thousand against 29.4 per thousand.

If all the holdings are divided into three classes, viz., those with masonry privies, those with rough and ready arrangements consisting only of a stance with a removable earthenware receptacle, and those with no privies at all, the distribution of cases is even more remarkable as shown in the attached tabulated statements.

Statement V.

	Number of such houses.	Number of cases in them.	Ratio of incidence per 1,000 houses.
Masonry houses ..	800	31	38.7
Mud houses and huts	7,397	131	18.4
TOTAL ..	7,897	162	..

Statement VI.

	Number or such houses.	Number of cases in them.	Ratio of incidence per 1,000 houses.
Houses with masonry privies ..	392	19	48.4
Houses with open privies consisting of two bricks and a receptacle ..	5,471	112	20.4
Houses with no privies	2,034	31	15.2
TOTAL ..	7,897	162	..

From a consideration of these statements, the remarkable fact emerges that masonry houses with masonry privies, built in accordance with the prevailing ideas of progress in construction and in sanitation, are of all houses the most unhealthy from a kala-azar point of view, and that the simple hut of the poor man, which has no privy at all, is least of all invaded by the infection of kala-azar.

The question of poverty and of the nature of the diet has obviously therefore very little to do with the prevalence of the disease, as the poor man in his mud hut is much better off than his rich neighbour in a large masonry house. The explanation of this anomaly is difficult to comprehend, but it must be in accordance with some definite general principle, and must tally with all the facts in the life-history, distribution and habits of the transmitting agent.

(9) *General Conclusions.*—The abstracted results of a detailed survey such as this are of great interest, and form a valuable basis for the further consideration and investigation of the transmission of the disease. The observations of greatest importance appear to be those on the site incidence, the age and sex incidence, the religious incidence and the housing incidence, and in my opinion all of these observations point to the fact that kala-azar is not transmitted by biting insects, but that infection takes place through the intestinal tract.

In this report I have not entered into a detailed discussion of the observations made, but have indicated what appears to me to be the direction in which the explanation may be found."

[At the Congress of the Far Eastern Association of Tropical Medicine recently held in Calcutta, Col. W. C. Ross criticised the various investigators on the kala-azar transmission problem on the ground that they had not done any epidemiological investigation. This was an unfair charge and was refuted by one of the subsequent speakers, but it would perhaps have been fair had he said that insufficient work on these lines had been done. We cannot know too much about the epidemiology of the disease, and any scientifically collected and collated epidemiological observations will be pounced upon

hungrily by the research worker in this field. Col. Ross's report is, therefore, extremely welcome.

We have, however, one very grave charge to bring against Col. Ross; this investigation was carried out between August and November 1923, and yet it did not find its way into print before 1928, and, apparently, was guarded as a strict secret until December 1927, when at the Congress referred to above we were given some hint of its results.

Col. Ross concluded "in my opinion all these observations point to the fact that kala-azar is not transmitted by biting insects, but that the infection takes place through the intestinal tract." Yet, though he must have been aware that the Kala-azar Commission were devoting almost the whole of their activities to the sandfly and other biting insects, he did not divulge his secret, but allowed large sums of money to be spent in a futile quest. How amused he must have been to think that first class investigators like Col. Christophers and Major Shortt were wasting their valuable time, and the money of the Government, in attempting to persuade the sandfly to transmit the disease, when all the time he was sitting on a report which, in his opinion, would have shown them the error of their ways!

There are a certain number of points in the report which call for comment. In suggesting that the three thousand patients treated for kala-azar in the two Patna hospitals probably include a number of persons who live outside the city and have come in for treatment he is probably correct, but he does not seem to have taken into consideration the fact that a number of persons will have been treated privately, that a still larger number may never have applied for treatment at all, and that a third but probably smaller group will have gone elsewhere for treatment. It seems far more probable that his estimate of 6.5 per thousand is an under-estimate, rather than an over-estimate, as he suggests it may be. The fact that the figure based on the detailed survey is only 4.5 per thousand does not tend to make the reviewer change his opinion; such surveys, unless carried out over long periods and in conjunction with treatment centres (or hospitals), always produce too low a figure.

Col. Ross states later on in his report that "it appears probable that this disease affects both sexes equally." If this is the case, it means that 1,450 women (2,263 less 813, *see* Statement I) suffering from kala-azar did not apply for treatment; the addition of this number would increase the total by nearly 50 per cent., bringing it up to almost 10 per thousand for Patna town. In the same way 65 women would have to be added to the cases in the local survey, which would bring this figure up to 6.3 per thousand.

Site Incidence.—The rarity of multiple infections in households in Patna is very interesting. In Calcutta, the disease is very definitely a house infection. Our experience has been that the disease seldom appears simultaneously in two members of the same family but that a succession of cases, at intervals of 6 months to a year, come from the same house. Perhaps, it was on account of the fact that this survey only covered a very short period that multiple infections were so rare.

Religious Incidence.—There can be little doubt that in Patna town there is a slight preponderance of the disease amongst the Muhammadan community, but in calculating this, Col. Ross again made no allowance for the sex question. If the male patients of the two communities alone are taken into consideration, it will be seen that the incidence amongst Muhammadans and Hindus is 3.7 and 2.9 per thousand, total population, respectively, no very striking difference when one realises that the calculations are based on only 113 cases.

The preponderance of kala-azar infection amongst Muhammadans has, as Col. Ross says, been noted by other observers but it is not a constant factor. His explanation of the cause of this preponderance may of course be correct, but there are many other possible explanations. A biting insect would admittedly not distinguish between a Muhammadan and a Hindu, but if

the surroundings in which one or other lived were more congenial to the insect, then that one would be exposed much more frequently to the bites of this insect than would the other.

Age and Sex Incidence.—Col. Ross has scored a point in correcting the age distribution by giving the general age distribution of the population. He says, "It at once appears that kala-azar is not so predominantly a disease of children as has previously been thought." But surely Col. Ross is tilting at a windmill with a very indifferent lance! Is it fair to correct the percentages of kala-azar cases attending hospital by the general population figures? Should not the hospital attending population also be taken into consideration? As far as the detailed survey is concerned, it is probably fair to correct by means of the general population. Col. Ross has given us the figures for comparison, but has not done the calculation for us. The table below gives the incidence per mille amongst the various age groups and the percentage distribution of the disease amongst the various age groups had there been the same number of individuals in each group.

Age group.	Under 10	10—20	20—30	30—40	Over 40
Number of cases.	64	54	30	8	6
Per mille incidence in each group.	7.17	8.41	5.07	1.46	0.65
Percentage of total cases in each age group corrected according to distribution of general population.	31.6	37.0	21.8	6.1	2.9
Assam dispensary figures, uncorrected, %	36.76	37.8	18.0	9.7	3.8

As the reviewer has on more than one occasion recorded observations with regard to age incidence, it must be supposed that he is included in Col. Ross's remark that "all of them have made a point of the extraordinary prevalence of the disease amongst children and adolescents." In the reviewer's book on kala-azar published in 1927, he gives four sets of figures for age distribution for India. These are admittedly "uncorrected." If these figures show the "extraordinary prevalence of the disease amongst children and adolescents," then Col. Ross's figures tend rather to emphasise than correct the observation. For comparison the Assam dispensary figures, based on over fifteen thousand cases, quoted in the reviewer's book, are given.

In the reviewer's experience, the disease is not so rare in young infants as Col. Ross suggests. Infants in arms are not very often brought to dispensaries or hospitals, but amongst the few that have been brought, we have found that the percentage of those suffering from kala-azar is much the same as in other age groups.

With regard to the sex distribution, Col. Ross holds the views of most other observers. Almost all the figures that can be quoted show a much greater percentage amongst males, but the closer one gets to the village, the greater the percentage of women amongst patients, and it is generally agreed that, if at all, the disease is only slightly more prevalent amongst males.

The observation with regard to housing is very interesting and supplements the reviewer's observations in Calcutta; he found that multiple infection was much more common in dilapidated masonry houses than in huts.

The observations with regard to the sanitary arrangements of the dwellings are of considerable interest. At the Congress, Col. Ross suggested that the presence of the privy might be the cause of the spread of the infection in the house. In houses where there is a satisfactory privy the incidence is 4.84 per hundred houses, whereas it is only 1.52 in houses without any privies. This seems to confirm the above suggestion. But the largest group of all consists of houses in which there is a very primitive and unsatisfactory privy and in these houses the incidence is 2.04 per hundred houses, or considerably less than half the incidence in the houses with satisfactory privies. If infection were spread from a good privy, how much more readily would it be spread from a bad one. The houses in which there were privies were all masonry houses, and in this group—masonry houses—the distinction between the houses with and without privies was not so marked; furthermore, the figures—19 and 12—are very small. It seems, therefore, very likely that the privy has nothing whatsoever to do with it and that, if anything, it is the nature of the house that is the important point.

Col. Ross has shown us that the epidemiology of the disease in Patna is much the same as in other parts of India, more especially Bengal, and for that we must thank him, but in his brave jump from the recorded facts to sweeping conclusions we are not prepared to join him; we do not think that "all these observations point to the fact that kala-azar is not transmitted by biting insects, but that infection takes place through the intestinal tract."—L. E. N.]

Correspondence.

NOVEL METHODS OF TREATMENT.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—I beg the hospitality of your columns for the following comment:

Several of your contributors, when discussing novel remedies or unusual methods of treatment, star the brightest side of the picture to the profession. The cases of pneumonia which have been treated by rectal administration of potassium permanganate, or of rheumatism which have appeared to have improved on intravenous injection of sodium salicylate, are examples. The latter appeared to have been cured in every instance. This can hardly be said to be a correct presentation of the case, when we remember that even a specific such as quinine in malaria does not give completely satisfactory results in every patient.

A model contribution was that by Lieut.-Col. C. A. Sprawson, C.I.E., I.M.S., in your issue for December 1926 on the results of the sanocrysin treatment in pulmonary tuberculosis. He mentioned a large percentage of cases in which the result was unsatisfactory, or almost a failure.

I would be obliged if you would emphasise the suggestion that every medical man, when giving his experience with new and untried remedies, should not confine himself to cases where the cure has been magical, but should also give details of those instances in which there has been a complete want of success. Only by doing so will he enable others to make a correct estimate of the value of the treatment described.—Yours, etc.,

I. A. SUFIE, L.M. & S. (Bombay).

BRUCE ROAD, QUETTA.

25th May, 1928.

(Note.—We most cordially agree, but would point out that an editor can only edit such material as comes to hand. The medical profession includes the usual percentage of optimists to be found in any profession, and the tendency to follow the latest fashion was not confined to the ancient Athenians. Perhaps the article on the treatment of intestinal amœbiasis included in this issue may help to supply a corrective.—Editor, I.M.G.)

AN INDIGENOUS TREATMENT FOR SNAKE-BITE.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—The following case of cobra bite presents certain features of interest:—

B. R., male, aged 36, accidentally stepped on a bino-cellate cobra, some three inches in girth, which bit him on the back of the leg about 4 inches above the heel at 9 p.m. one evening. I saw the patient twenty minutes later, and discovered two puncture marks from the fangs, some three-quarters of an inch apart in that situation. When first seen, the patient showed no symptoms except numbness of the part bitten.

Having no antivenene available, I applied an indigenous treatment which is much in vogue in the Ratnagiri district. The fang marks were well incised and chickens, one after the other, with their anuses well stretched were applied to the site of the bite. The first few chickens dropped down dead within a few minutes. From the 42nd chicken onwards, the patient stated that he could distinctly feel the aspirating action of the chickens. In all 74 chickens died, 12 more were half-dead but recovered in about six hours, and the last 6 lost consciousness but recovered speedily; in all 96 chickens were used. The whole treatment took three hours and a quarter. Most of the chickens died within three minutes. The strongest suckers were hens in their prime. Hens which had laid eggs were quite useless, and young cocks unsatisfactory. Three or four incisions were made at the site of the bite, and from time to time refreshed with the knife.

Cases of cobra bite are generally treated in this way in the Ratnagiri district, and the patients are usually cured if the treatment is begun early enough. This case shows that cobra venom can be sucked out. Those who are in a position to do so, should try whether wet-cupping cannot cure such cases.—Yours, etc.,

K. V. KUBAB,
Medical Officer.

CHINCHANI DISPENSARY,
THANA DISTRICT.

(Note.—Ratnagiri district is famous for its Echis vipers, though we suppose that cobras are equally prevalent there. The "treatment" mentioned is a very ancient one; it is commented on by Fayrer and other authorities of the last century.

What does not appear to be certain is that the patient had received a lethal dose of venom. Fresh cobra venom has about the consistency of treacle, and it is difficult to see how so viscid a substance can be extracted when it is probably buried in the tissues at two spots, about a third of an inch or so away from the sites of the punctures on the skin. It is known that cobra venom can be absorbed through the conjunctiva—or at least it is supposed so—and workers with the desiccated venom should always wear protective goggles when grinding it into solution. But when administered by the mouth, venom is innocuous. It is a little difficult to state what these chickens died from. Even in a rat bitten by a cobra full of venom, death within three minutes is the exception, and not the rule. The minimal absorption period of a lethal dose of venom for the rat is 2½ minutes, and the fowl is a much larger animal. Any suggestion with regard to the treatment of cobra bite, however, is of interest.—EDITOR, I.M.G.)

MEDICAL ETIQUETTE.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—It is a matter for regret that medical men in Calcutta should show such scant respect for medical ethics. Why this should be so, one cannot explain; it is not due to ignorance, since medical men who hold responsible positions and are highly respected are the greatest sinners. I would be much obliged if you or some of your readers would give their opinion with regard to the following circumstances: (i) A patient is suddenly taken seriously ill, and his relatives in desperation telephone first for Dr. A and then for Dr. B.

Dr. A arrives first, examines the patient, and prescribes for him. After his departure Dr. B arrives. Can Dr. B take over, examine, and prescribe for the patient without the consent of Dr. A? (ii) Dr. A who is treating a patient, calls Dr. B in consultation. Is it right for Dr. B to take over charge of the patient and treat him independently without the knowledge or consent of Dr. A, and can Dr. B attend other patients in the same family without the knowledge of Dr. A?

(iii) Whilst a patient is in charge of Dr. A the relatives ask Dr. B to see him. Should Dr. B see the patient independently, or should he ask Dr. A to be present and to see the patient jointly? Suppose Dr. A refuses to call in Dr. B at the desire of the relatives, what is the position of Dr. A? Is he guilty of professional discourtesy?—Yours, etc.,

B. N. GHOSH, F.R.F.P.S. (Glasgow).

9, TALTOLE LANE,
CALCUTTA.

13th June, 1928.

(Note.—We are glad that our correspondent has raised this question, for there can be little doubt that medical ethics are honoured in the breach rather than in the observance in Calcutta. The Bengal Medical Council is less active in this matter than the Bombay Medical Council, probably owing to the fact that fewer actual instances are reported to them. In a city which is overstocked with medical practitioners irregularities are bound to occur, but the frequency with which they do occur is deplorable.

To turn to the specific questions asked by our correspondent; (i) Dr. B should certainly not examine or prescribe for the patient, if he knows that Dr. A has been there previously.

(ii) Dr. B has no business at all to steal the patient from Dr. A; though we regret to say that such a practice is not at all uncommon in India. He should refer the matter to Dr. A. On the other hand, if the relatives ask Dr. A to call in Dr. B he will be well advised to do so, whatever his own private opinion is of Dr. B. Courtesy between medical men is essential, and if the relatives desire a second opinion, their desire should be complied with.

(iii) Dr. B should refer the matter to Dr. A before seeing the patient. If the relatives definitely inform Dr. A that they do not wish him to hold further charge of the case, they are at liberty to call in whom they like.

The medical profession is often accused of being a "trade union"; but, unless the etiquette and conventions of medical practice are to be observed, progress is impossible. Dr. B can supplant Dr. A only if Dr. A asks him to do so; or if the relatives clearly give Dr. A to understand that they do not desire him to attend the patient any longer. Yet, the greatest difficulty which the medical practitioner experiences is not that from a rival practitioner, but from the relatives themselves. For the consultant, a wise rule is not to see the patient unless he brings a letter from his own medical adviser.—EDITOR, I.M.G.)

THE LIVER TREATMENT OF PERNICIOUS ANÆMIA.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—It is a commonplace that nothing is ever new and the recent discovery of the successful treatment of pernicious anæmia by the administration of liver, reminds me of an incident which occurred some years back.

In 1924, there was confined in the jail in Akola (Berar) a batch of Pathan prisoners from the N. W. Frontier under long terms of sentence. In the months of May and June three of these men complained of night blindness, which they said usually affected them in the hot weather months and begged for two ounces of liver which they said was a specific for this complaint. As I was previously in the Mandla District where night blindness is very common amongst the aborigines and is soon cured with a few days' administration of cod-liver oil or even with just the addition

of ghee or tilli oil in their food, I ordered cod-liver oil to be given to these men, treating their request for liver as but the natural craving for flesh of men who were used to it and were now on an enforced vegetarian diet. This did the prisoners no good—at least so they said—and they again begged of me, after a week of cod-liver oil, to allow them the small bit of liver which had never failed to cure and was much in vogue in their country. Out of a batch of 25 men only three complained of this blindness and one of them was an elderly man, and as the quantity of liver asked for was small—only two ozs. per man—I ordered it to be given. Two days later I was told—as I anticipated—that the blindness was cured. The liver was eaten practically raw.

Was there something in it after all? Medical men working on the Frontier may know something about this.—Yours, etc.,

J. M. RICHARDSON, I.M.S.,
Civil Surgeon.

NARSINGHPUR,
10th June, 1928.

Service Notes.

APPOINTMENTS AND TRANSFERS.

THE services of Lieutenant-Colonel A. G. Tresidder, C.I.E., M.D., I.M.S., are placed permanently at the disposal of the Government of Bombay with effect from the 1st April, 1928.

Lt.-Col. A. H. Napier, I.M.S., is appointed to be Civil Surgeon of Gaya with effect from the forenoon of the 3rd May, 1928.

Lt.-Col. P. S. Mills, I.M.S., is appointed to officiate as Civil Surgeon of Ranchi with effect from the 29th April, 1928 and to hold collateral charge of the duties of the Superintendent of the Radium Institute.

The following officers of the Indian Medical Service are appointed substantively to be Agency Surgeons under the Government of India in the Foreign and Political Department, with effect from the dates shown against their names:—

Captain H. J. H. Symons, M.C., 23rd November, 1927.

Captain A. K. Sahibzada, 28th April, 1928.

PROMOTION.

The promotion to his present rank of Major W. A. M. Jack, O.B.E., M.B., I.M.S., notified in Army Department Notification No. 1557, dated the 5th August, 1921, is antedated from the 31st July, 1921, to the 31st January, 1921.

The promotion to his present rank of Major B. C. Ashton, M.B., I.M.S., notified in Army Department Notification No. 1552, dated the 17th December, 1926, is antedated from 23rd November, 1926 to 23rd May, 1926.

Captains to be Majors.

P. A. Dargan. Dated 12th May, 1928.

C. M. Nicol, M.B. Dated 14th May, 1928.

L. Blake, M.C. Dated 22nd May, 1928.

D. R. Thomas, M.B. Dated 30th November, 1927.

LEAVE.

Major S. M. Hepworth, I.M.S., Acting Superintendent, X-Ray Institute, Dehra-Dun, is granted leave on average pay for 14 days, combined with furlough under military rules for 16 days with effect from the 4th June, 1928, or the subsequent date on which he avails himself of it.

Major B. G. Mallia, I.M.S., Superintendent, Alipore Central Jail, was granted by the High Commissioner for India an extension of leave on half average pay (not due) for eleven days, with effect from the 17th May, 1928.

Captain A. K. Sahibzada, I.M.S., Agency Surgeon, North Waziristan and Medical Officer, Tochi Scouts, is granted one year's combined leave (6 months' leave on average pay combined with 6 months' study leave) with effect from the 21st May, 1928, forenoon.

RETIREMENT.

His Majesty the King-Emperor has approved the retirement of Lieut.-Colonel E. L. Ward, C.B.E., I.M.S., with effect from the 28th April, 1928.

NOTES.

THE BRITISH HANOVIA QUARTZ LAMPS.

MESSRS. MALGHAM BROS., the agents in India of the original makers of mercury vapour lamps—the British Hanovia Quartz Lamp Co., Slough, England—write to us to claim that the mercury lamps manufactured by this firm have been fitted up in several hospitals in Bombay and elsewhere in India, and that they have received very satisfactory reports with regard to their use. They further state that they are prepared to install one of these outfits free of charge in any Bombay hospital for a short period in order that an entirely independent opinion may be obtained with regard to the efficacy of the lamps. If any Bombay hospital desires to avail itself of this offer, will the Superintendent kindly communicate with the firm—Malgham Bros., 19, Bank Street, Fort, Bombay? We would welcome any such independent opinion for publication, since one knows from experience that there are several cheap and inefficient models of ultra-violet ray apparatus on the Indian market to-day, and the practitioner who uses this form of therapy would do well to order his lamps only from firms of unquestionable standing, of which the British Hanovia Quartz Lamp Co., are a leading example.

HEWLETT'S ANTISEPTIC CREAM.

WE have received from the well known firm of C. J. Hewlett and Son, 35—42, Charlotte Street, London, E. C. 2, samples of their antiseptic cream (Cremor antisepticus, Hewlett's). This most elegant preparation is certain to interest medical men in India. It is put up in collapsible tubes, and is guaranteed to be absolutely free from animal fat of every description, and therefore suitable for the most fastidious type of Indian patient. It contains zinc and boracic acid, is of a white colour, and pleasant to use. As an emollient healing cream for use for cuts, burns, wounds, abrasions and skin eruptions it seems to be ideal, and several reports by medical men speak very highly of its use.

As put up in enamel collapsible tubes, the price is 18s. per dozen in England, and in bulk 5s. 6d. per lb. The preparation is a most elegant one, and suitable for toilet use as well as for medical emergencies. It will undoubtedly interest practitioners in India.

Publishers' Notice.

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles will receive 25 reprints *gratis*, if asked for at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions, Advertisements, and Reprints should be addressed to THE PUBLISHERS, Messrs. Thacker, Spink & Co., P. O. Box No. 54, Calcutta.

Annual Subscription to *The Indian Medical Gazette*, Rs. 16 including postage, in India. Rs. 18 including postage, abroad.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

BY APPOINTMENT TO
H.R.H. THE PRINCE OF WALES

KOLYNOS

DENTAL CREAM

THE DENTIST AND DENTIFRICES.

THE dentist by prophylactic and corrective methods places the mouth in a sanitary, healthful condition and dismisses the patient. If that mouth is to remain in a healthful condition until the next visit to your office, the patient must check the activities of the mouth bacteria which are the local cause of caries. This is the function of a dentifrice.

Kolynos Dental Cream encourages care of the mouth because of its attractive flavour and because the user feels that after brushing with Kolynos his mouth and teeth are clean. "How Clean My Mouth Feels!"—the typical exclamation after using Kolynos.

Carefully controlled experiments have shown that after brushing the teeth with Kolynos, 80 to 92 per cent of the mouth bacteria are killed and washed away. Thus Kolynos checks the progress of dental caries and assists the patient to maintain the healthful, sanitary condition which you established in his mouth.

On request our Distributors will gladly send you a dental package, free of charge.

Distributors: DAYTON, PRICE & CO., LTD.

FACSIMILE OF A LETTER RECEIVED FROM
MAJOR-GENERAL G. TATE, M.D., K.H.S., I.M.S., SURGEON-GENERAL
WITH THE GOVERNMENT OF BENGAL.

Far Eastern Association of Tropical Medicine
SEVENTH CONGRESS

3245

9/1/28

Patron: H. E. THE VICEROY AND GOVERNOR-GENERAL OF INDIA

President:

MAJOR-GENERAL T. H. SYMONS,
C.S.I., O.B.E., K.H.S., I.M.S.,
DIRECTOR-GENERAL, INDIAN MEDICAL
SERVICE.

Honorary Secretary-Treasurer:

F. E. A. T. M. FOR INDIA
ADDRESS: HEAD OFFICE.

HEAD OFFICE:

PASTEUR INSTITUTE
OF INDIA,

KASAUJI, PUNJAB,
BRITISH INDIA.

No. 9076/38

Vice-Presidents:

LT.-COL. J. D. GRAHAM, C.I.E., I.M.S.,
PUBLIC HEALTH COMMISSIONER,

LT.-COL. S. R. CHRISTOPHERS,
C.I.E., O.B.E., F.R.S., I.M.S.,
DIRECTOR, CENTRAL RESEARCH INSTITUTE.

General Organizing Secretary:

LT.-COL. J. CUNNINGHAM, I.M.S.
ADDRESS: HEAD OFFICE.

The 7th January, 1928.

Messrs. Bengal Immunity Co., Ltd.,
153, Dharamtollah Street, CALCUTTA.

Dear Sir,

On behalf of our Local Committee, I beg to thank your firm for their assistance during the Far Eastern Association of Tropical Medicine 7th Congress just concluded. The demonstrations at your laboratories were very much appreciated by the members who attended, who had an opportunity of seeing what local enterprise could do in biological research and production.

Yours faithfully,

(Sd.) G. TATE,

Major-General, I.M.S.,
Surgeon-General with the Government of Bengal.

ALOCOL

Colloidal Hydroxide of Aluminium

Successful Treatment of Hyperchlorhydria

"Alocol" is a triumph of colloidal therapy because it is completely free from the marked disadvantages associated with the usual alkaline medicaments.

Take bicarbonate of soda as an example. When in the stomach it is transformed into sodium chloride—the very product which goes to the formation of hydrochloric acid. To combat hyperacidity by such means is to create a vicious circle.

Note the different action of "Alocol." It absorbs excess of hydrochloric acid and the acid-containing mass is finally evacuated from the lower bowel. This colloidal chemical absorption removes from the system the causative acid radicle (Cl) instead of merely neutralising it.

Complete chemical history of "Alocol" with convincing clinical reports, and supply for trial, sent free to physicians on request.

"Alocol" thus prevents reabsorption, accumulation and consequent recurrence of the symptoms of the disease.

"Alocol" leaves intact the acid reaction of the gastric juice and its normal digestive and bactericidal functions. It is the remedy *par excellence* for hyperchlorhydria. The absorbent, healing and sedative properties of "Alocol" also prove of the greatest value in successful treatment of the more serious manifestations, such as gastræctasis, gastrectosis, pyloric and duodenal ulcers, infective enteritis, etc.

RAT-BITE FEVER AS AN INDIAN DISEASE.

By R. KNOWLES,

LIEUTENANT-COLONEL, I.M.S.,

Professor of Protozoology,

and

ASST. SURGN. B. M. DAS GUPTA,

Assistant Professor of Protozoology,

Calcutta School of Tropical Medicine and Hygiene.

RAT-BITE fever, due to *Spirillum minus*, is usually regarded as a somewhat rare disease. It is known to be of world-wide distribution and is said to be especially prevalent in Japan. Yet, in the course of ordinary routine work, during the last seven and a half years, we have seen no less than twenty-eight cases of this supposedly rare disease, of which we have preserved detailed notes, in addition to several others of which no detailed notes have been kept; and this is our reason for writing the present paper, for we believe true rat-bite fever to be much commoner in India than is usually realised. In Calcutta, at least, bites from rats appear to be very frequent. Everywhere throughout the city, and especially in the Kidderpore district, there are accumulations of *bustis* and slums swarming with rats, where people sleep on the earthen floor or on *charpoy*s only slightly raised above the ground level. Even in the better class houses, there is no attempt to keep the grain and other food supplies in rat-proof receptacles, and most Calcutta houses are overrun with rats, whilst bandicoots abound in most Calcutta compounds. A considerable number of persons bitten by rats come to the Pasteur Institute at Calcutta every year, only to be informed that they are in no danger of contracting hydrophobia.

Apparently what happens in the great majority of cases of rat-bite is that the lesion heals up and no further trouble is experienced. In some cases secondary septic infection occurs, giving rise to fever with rigors; in these the fever is due to sepsis and not to infection with *Spirillum minus*, and several such cases are seen every year in the Protozoology Department of the Calcutta School of Tropical Medicine and Hygiene. These cases clear up on the application of fomentations and are not instances of true rat-bite fever. In some, however, true rat-bite fever sets in with a relapsing temperature chart. As we shall show later, in a few instances there may be a primary relapsing fever due to *Spirillum minus*, with a secondary fever due to septic infection of the wound superadded, and in these cases the true diagnosis may be very difficult to arrive at and the temperature chart most misleading. The type of fever due to simple septic infection of the bite follows

the usual course of a fever due to sepsis, and we do not propose to deal with it here. Of the twenty-nine cases of which notes are given in this paper, *Spirillum minus* was isolated from twenty-five, whilst our reasons for including the four other cases in the series will be given later.

In giving details of this series of cases, we do not propose to attempt to put together a complete memoir on the disease, but only to give a historical introduction referring to previous observations on it by workers in India. What we desire to emphasise is that rat-bite fever is a relatively common disease in India, and one which should not be overlooked by the general practitioner. For fuller accounts of the disease in general we may refer the reader to the papers by Robertson (1924), who gives a full account of the parasite; by McDermott (1928), who gives a very full and detailed account of the disease and of the parasite, together with a complete bibliography; the account in the 8th edition of Manson-Bahr's *Manual of Tropical Diseases*; and that by Bass (1922) in Vol. II of Byam and Archibald's *Practice of Medicine in the Tropics*.

PREVIOUS OBSERVATIONS ON RAT-BITE FEVER IN INDIA.

As pointed out by Robertson (1924), the parasite of rat-bite fever was first discovered in the blood of a rat (*Mus decumanus*) by Vandyke Carter in Bombay in 1887. He described its morphology and movements very accurately, and rightly considered it a spirillum and not a spirochæte. He named it *Spirillum minor*, but the correct name should be *Spirillum minus* (Carter, 1887). Lingard (1899) found what was almost certainly the same spirillum in the blood of a bandicoot (*Mus giganteus*) in the Punjab and inoculated it into rabbits and guinea-pigs. Wenyon (1906) described a spirochæte in the blood of mice and named it *Spirochæta muris*. Morphologically this organism is probably identical with *Spirillum minus*. Breinl and Kinghorn (1906) found a spirochæte in the blood of a mouse inoculated with *Trypanosoma dimorphon*, and also found the same spirochæte in the blood of a wild mouse. They considered that this spirochæte was smaller than that described by Vandyke Carter and accordingly differentiated it as a new species, *Spirochæta laverani*. It is interesting to note that it was this organism that Ehrlich and Hata used in their classical experiments on the chemotherapy of spirochætal infections which led to the discovery of salvarsan.

Several of the earlier workers, such as Hata (1912), Surveyor (1913), Oda (1915) and Crohn (1915) suspected the spirochætal nature of rat-bite fever, but the first proof that this was the case was supplied by Futaki, Takaki, Taniguchi and Osumi in 1916, who isolated the organism from man, demonstrated it under the dark ground, and successfully inoculated monkeys, guinea-pigs and white rats. They named the organism *Spirochæta morsus muris*. Since that date it has been fully confirmed by many workers

that the cause of rat-bite fever is a spirillum, *Spirillum minus*. With the morphology of this parasite we shall deal later.

In searching through the literature, it is a little difficult to discover who was the first person to record the occurrence of rat-bite fever in man in India. In an editorial in the issue of the *Indian Medical Gazette* for September 1912, p. 370, the editor writes: "We in India are only too well aware of the fact that rats are disseminators of plague, but few have seen or even read of cases of a disease produced by the bite of a rat"; he then goes on to describe the symptoms of the disease as observed in the early Japanese cases. There is no mention of the disease in the Annual Report for 1913 of the Bombay Bacteriological Laboratory, but in the corresponding report for 1914 it is casually mentioned that the disease was being treated at Parel by injections of salvarsan. The discovery of the disease in man in India therefore appears to have been made about 1913.

Savant (1913) in a letter to the *Indian Medical Gazette* draws attention to cases of rheumatism persisting for one or two months after the bite of rats; and the cases with which he was dealing clearly appear to have been cases of true rat-bite fever. They occurred in Dewas, Central India. Surveyor (1913) gives a full account of a case referred to him by Dr. C. Fernandes of Bombay, and remarks that he had seen a similar case twelve years previously. The patient was cured by intramuscular injections of neosalvarsan. The patient was much emaciated when first seen, and the disease had lasted for two years; she put on 29 lbs. under treatment. The Wassermann reaction was completely negative. The urine contained albumin, a few leucocytes, granular casts and red corpuscles. The patient's serum was injected into the scrotum of two rabbits as the author considered that the disease might be of spirochætal origin, but no spirochætes were detected in these animals. [The rabbit indeed is not nearly as susceptible as the guinea-pig or white mouse, though McDermott (1928) records successful inoculation of rabbits by subcutaneous inoculation at the base of the ear or in the genitalia.] de Mello and Menezes (1917) described a case of rat-bite fever which occurred in Goa. and de Sousa (1917) a second case in Goa. Unfortunately we have not had access to either of these two papers, but neither author appears to have isolated the spirillum. The credit for first demonstrating the existence of *Spirillum minus* in man in India belongs to Row (1917). He remarks that "rat-bite fever comes under clinical observation fairly frequently in Bombay, but it is a rarity to have a case in the early and acute stage of the disease." He described the cutaneous lesions of the disease and demonstrated the spirillum in two mice inoculated with a minute quantity of citrated blood and lymph squeezed from a papule of the patient. He considered that, as this spirillum was only 2μ to 3μ in length, with only two or three coils, it differed from the Japanese one. In his second paper

(Row, 1918) he gives an account of five cases, with a good description of the cutaneous lesions; in this paper he again adheres to his opinion that the Indian spirillum differs from the Japanese one in its morphology. (His third paper we have unfortunately not had access to.) In his fourth paper (Row, 1922) he notes that the Wassermann reaction is negative in the disease, and states that he had not succeeded in infecting mice by inoculation of the patient's blood. He considers that the Bombay spirillum is less pathogenic to guinea-pigs and rats than the Japanese strain, and that it differs from it in morphology.

In the meantime, Powell and Bana (1918) described the successful treatment of cases of rat-bite fever by injections of sodium cacodylate, a drug which they remark is much cheaper than salvarsan—and mentioned that Row isolated the spirillum from one of their cases. Briggs (1922) recorded a case in a havildar in the Indian Army, cured by a single intravenous injection of 0.2 gramme of novarsenobillon; the patient had a positive Wassermann reaction, which immediately became negative after treatment. He states that the patient showed no evidence of syphilis. Chaudhuri (1923) records a case where the œdema and induration at the site of the bite were so severe that a carbuncle was suspected and an incision made, but no pus was evacuated. Severe rigors were present, but the case yielded promptly to a single neosalvarsan injection.

Spaar (1923) records two cases which occurred in Colombo. Two guinea-pigs injected from the first patient both died from sepsis, and no animals were inoculated from the second. Headache is mentioned as one of the most distressing symptoms of the disease. Neosalvarsan treatment was eminently successful.

Parmanand's first paper on the disease appeared in 1923, and is illustrated by admirable photomicrographs. He described four cases. In the first, spirilla were demonstrated in serous exudate from the local lesion; none could be demonstrated in the second case, which, however, was a typical one and showed a blotchy red eruption. Two white mice and a guinea-pig inoculated from the third patient showed spirilla eight days later, and also two white mice from the fourth patient. The material inoculated was serous exudate from the local lesions, and the injections were given subcutaneously. He gives a good description of the morphology of the spirillum, and remarks on its great activity when seen under the dark ground. The ends are tapering and there is a single terminal flagellum at each end. Division is by binary transverse fission.

Mehta (1924) gives a good clinical account of a typical case, but no attempt was made to demonstrate the spirillum. Treatment by intramuscular injections of sulfarsenol quickly cured the patient.

An important contribution to the study of the disease as it occurs in India is Parmanand's

second paper (Parmanand, 1925). He confirms an observation previously made by the present writers that the best method of maintaining a strain in mice is to inoculate the mouse with a mixture of the cardiac blood and ground up spleen emulsion of the previous infected mouse. He finds that the experimental disease is very fatal in guinea-pigs, killing them as a rule in about three and a half months. An investigation of the degree of infection of Bombay rats gave the following results:—

Mus rattus: 100 examined; 2 found infected.

Mus decumanus: 100 examined; none found infected.

Norvegicus bengalensis: 100 examined; 11 found infected.

that the Indian strain of *Spirillum minus* differs from the Japanese strain.

Into the controversy between Row (1917, 1918, 1920, 1922, 1924, 1925, 1926) and Parmanand (1923, 1925) with regard to the morphology of the Indian strain of *Spirillum minus*, it is unnecessary to enter, as the matter is now one of historical interest only. Colonel Row deserves every credit for his work on the disease as it occurs in India and for demonstrating the existence of the parasite in man in this country; while Dr. Parmanand is to be congratulated on his very careful and accurate observations on the disease and on the natural hosts of *Spirillum minus*. As shown in the text figure, however, there is no doubt at all, that the Indian strain of

Spirillum minus as seen in a blood film from an infected mouse. Stained by Tribondeau's modification of Fontana's stain. Note the terminal flagellum at each end.

He concludes that the lesser bandicoot, *Norvegicus bengalensis*, is the principal host of *Spirillum minus* in India. No spirilla were detected in smears from the salivary glands of the infected rats. Three of the bandicoots which showed spirilla in their blood also showed them in smears of kidney substance. He gives a tabular comparison of the morphology of the Indian and Japanese strains, and comments that the spirilla are more easily found in stained films than by examination by the dark ground. The spirilla isolated from naturally infected rats are morphologically identical with those isolated from human cases. He criticises Row's contention

that the Indian strain of *Spirillum minus* corresponds exactly in morphology to the Japanese strain, and that Row's contention is wrong. The flagella are difficult to stain, however, and require special methods for their demonstration: a matter to which we shall revert later. Hence Row's proposed name for the Indian spirillum, *Spirochaeta petit*, becomes synonymous with *Spirillum minus*.

Having given a résumé of the previous work on rat-bite fever as an Indian disease, we will next proceed to give a brief résumé of the 26 cases that we have ourselves observed between

1920 and 1928. In order to make these notes as brief as possible, we have included a large number of temperature charts, a study of which will show the typical course of the fever better than any written description.

OUR OWN CASES.

Having summarised the previous papers dealing with the disease as observed in India, we may next give a brief clinical account of our series of 26 cases, taking them in historical sequence.

Case 1 (1920).—This was the first case which either of us had encountered during the course of some 12 years of medical work in India, and was seen at the Pasteur Institute, Shillong, in 1920. He was a Hindu male, aged 45, a Marwari merchant. Whilst sleeping at

swollen, and there was difficulty in swallowing. No skin eruption was noticed, but there was pain in the joints, especially in the upper limb. There was marked constipation.

On the 19th day an incision was made into the site of the bite, films made from the sanious fluid which oozed out, and searched for spirilla, with negative results. The finger blood was examined daily for four days, with negative findings. Finally, on the 20th day after the bite, $\frac{1}{2}$ c.c. of blood was taken from the median basilic vein and injected subcutaneously into two white mice. One of these mice was killed 16 days later. Its spleen was found to be enormously enlarged. Smears from the cardiac blood showed typical *Spirillum minus*. The patient was not treated with salvarsan, and the case was subsequently lost sight of.

The above two cases were seen at Shillong. The remaining cases were all seen at Calcutta during the years 1924 to 1928.

CASE 3.

Name—Mr. J., European male.

night on a bamboo *machan* he was bitten by a rat. He applied cold compresses during the night, and the next morning had the bite cauterised with nitric acid at the Shillong Dispensary. This resulted in a local patch of necrosis, but the ulcer healed up in some ten days' time.

Two weeks after the bite he got fever with rigor, the fever lasting three or four days. The fever then subsided, only to recur a week later, with pain in almost all the joints of the body and enlargement of the glands in both axillae. When seen in this second attack of fever he was completely prostrated. (At the time we knew nothing of the technique for demonstrating the spirillum.) Blood films were searched for *Spirillum minus*, but none were found. He was diagnosed as a case of rat-bite fever on clinical grounds and three injections of novarsenobillon given, one a week for three weeks. The fever and joint pains completely disappeared after the first injection, and he made a complete recovery.

Case 2 (1928).—This case has previously been reported from Shillong in this journal by the junior author (Das Gupta, 1922), but for the sake of completeness, notes on the case may be included here.

Mrs. G., a Hindu lady, about 20 years of age, was bitten by a rat on the forehead on the night of the 19th December, 1921. The wound healed up in two days' time. On the 9th day after the bite the site of the bite became oedematous; fever set in, with a temperature varying from 101° to 102.8°F. and severe pain was felt at the site of the bite. On the 12th day the temperature dropped to normal and the pain disappeared, but the oedema persisted. Four days later fever recurred and lasted for six days. Severe pain was felt at the site of the bite and the glands on both sides of the neck, the parotid and submaxillary glands became

Case 3 (1924).—This case was a most interesting one. The patient, Mr. J., a European police officer, lived with three other bachelors in a large 'chummary' in Alipore, close to Kidderpore (in which area, as we shall describe later, a considerable proportion of the local rats are infected). Despite the fact that three Irish terriers were kept in the house, it was overrun with rats.

Mr. J. took ill with high fever and pain in the back on the 15th August, 1924 and went to bed. The fever dropped to normal on the 24th August. That night the patient was suddenly awakened from his sleep by a rather severe bite on the right forearm; he did not see the animal that bit him, but thought that it was probably a rat. The next day the temperature rose to 104°F., and the patient was admitted to the Presidency General Hospital, Calcutta.

On admission, there was a small swelling with a central vesicle in the middle of the front of the right forearm, with swelling and tenderness of the right supratrochlear gland. The oedematous part was incised, films prepared and searched for spirilla, but none were found. The subsequent temperature was as shown in the chart. On the 7th September the temperature dropped to normal and the local swelling subsided. On the 11th, the patient had his fourth attack of fever, but without local symptoms. On the 12th—nineteen days after the bite—a purplish blotchy rash appeared on the left forearm, and on the following day spread all over the body and limbs. It consisted of mulberry-coloured spots, varying in size from that of a pea to that of a two-anna bit, the spots being discrete and scattered all over, but tending to run together on the back. On the morning of the 14th the temperature again dropped to normal and the eruption faded away almost completely.

Case 5 (1926).—P. P., Hindu male, a cook, aged 40. The patient was sleeping on the verandah of his house one night when he was suddenly wakened up by being

bitten on the leg. He got up and lit a lamp and saw a rat sitting on the floor beside his bed. There was considerable bleeding from the bite and he applied cold compresses. Five days later the leg was considerably swollen, and fever with rigor set in on the 10th day after the bite. The patient states that the fever was so high that he became unconscious. The fever then dropped, but not quite to normal, and a low fever persisted for a week. A second attack of high fever now set in and a rash came out all over the body and neck. He was admitted to hospital on 29th May, 1926, about fourteen days after the bite. The subsequent course of the fever was as shown in the chart. The laboratory findings were as follows:—

29th May.—Mouse inoculated with the patient's blood showed *Spirillum minus* on the 14th June.

31st May.—Stool shows hookworm ova, but no protozoa.

30th May.—Urine normal, no albumin or sugar.

11th June.—Wassermann reaction: moderately positive.

The patient was treated with four injections of novarsenobillon, as shown in the chart, and made a sound recovery. He put on 6½ lbs. whilst in hospital.

Case 6 (1927).—(This was a case under the care of Dr. M. N. Mullick, Registrar to the Carmichael Hospital for Tropical Diseases, seen by the junior author in consultation. We are indebted to Dr. Mullick for the notes on the case and for his kind permission to publish them.)

G. G., Hindu male child, 6 years of age, was bitten by a rat on the 2nd April, 1927. The wound healed up a few days later. His first attack of fever set in on the 17th April and lasted till the 23rd April, the temperature varying between 101° to 104°F. He was then afebrile until 2nd May, when the second attack of fever set in and lasted for three days. A third attack of fever set in on the 11th May and lasted till the 13th May. A fourth attack occurred from the 13th June till the 16th June. A fifth attack occurred on the 1st August.

Two mice were inoculated with the patient's blood on the 22nd April—the 20th day after the bite—and both showed *Spirillum minus* on the 5th May, thirteen days later. The other laboratory findings in the case were as follows:—

8th May.—Total R.B.Cs. 4,570,000 per c.mm. Total leucocytes 6,600 per c.mm. Differential leucocyte count: eosinophiles 8 per cent.; polymorphonuclears 43 per cent.; small mononuclears and lymphocytes 45 per cent.; large mononuclears 4 per cent.

20th May.—The urine shows a trace of albumin, hyaline and granular casts, a few pus cells and scanty red blood corpuscles.

The patient was treated as follows:—

14th May.—Novarsenobillon 0.1 gm. intravenously. Novarsenobillon was afterwards discontinued, when albumin was found in the urine.

8th June. Sulfarsenol 0.015 gm. intramuscularly.

15th June. " 0.04 " "

21st June. " 0.06 " "

28th June. " 0.12 " "

17th July. " 0.12 " "

1st August. " 0.12 " "

17th August. " 0.12 " "

3rd September. " 0.18 " "

9th September. " 0.18 " "

20th September. " 0.18 " "

The child made a gradual recovery under this line of treatment and finally recovered. The case is of special interest, as showing how protracted cases of rat-bite fever can be. (An even better instance of this, however, is Case 15.)

Case 7 (1927).—K. R., Hindu male, aged 40, was admitted to hospital on the 1st August, 1927. He gave a history that a rat had bitten him on the right arm about two months previously, that fever had set in a week later and that since then he had had repeated attacks of fever off and on, each febrile attack being attended with pain and swelling at the site of the bite, with generalised

pain in the hands and legs. The course of the fever and treatment after admission to hospital were as shown in the temperature chart.

The laboratory findings in this case were as follows:—
30th July (when first seen as an outpatient). Thick and thin blood films: no parasites seen.

1st August.—Ditto.

CASE 7.

Name—K. R., Hindu male, age 40 years.

2nd August.—A guinea-pig and a mouse were inoculated with the patient's blood. Both showed *Spirillum minus* twelve days later.

2nd August.—Sputum for tubercle bacilli; none found.

4th August.—Hookworm ova in the stool; no protozoa or pathogenic bacteria found.

The patient received two injections of novarsenobillon, 0.3 gm. and 0.45 gm. respectively, and made a rapid recovery.

CASE 8.

Name—M. A., Mahommedan male, age 30 years.

Case 8 (1927).—M. A., Mahommedan male, aged 30. The patient was bitten on the left thigh by a rat. Next morning the wound was touched with silver nitrate solution. Ten days later a swelling appeared at the site of the bite and fever set in with rigor. This lasted for three or four days and then subsided. Two further

febrile relapses occurred, each attended with pain and swelling at the site of the bite, and he was admitted to hospital on the 18th August, 1927, on the 22nd day after the bite. The subsequent course of the fever and the treatment were as shown in the chart. On the day of admission the patient had a rash, and serum was obtained from one of the measles-like spots and examined, but no spirilla were found. The other laboratory findings were as follows:—

18th August.—A guinea-pig was inoculated with the patient's blood and ten days later showed *Spirillum minus*.

18th August.—Thin and thick blood films: no parasites seen.

20th August.—Hookworm ova in the stool; no protozoa seen; no pathogenic bacteria on plating.

guinea-pig was inoculated with the patient's blood and never showed any *Spirillum minus*. The subsequent course of the fever was as shown in the chart. The stools were examined on fifteen occasions. No protozoa were seen at any time, and no dysentery bacilli isolated nor were tubercle bacilli demonstrated in the sputum. *Ascaris* ova were present, however, and this infection was treated. A haemolytic streptococcus was isolated from the stools, and the patient received injections of an autogenous vaccine prepared from this source.

The blood was repeatedly examined for malaria, but with negative findings. The total leucocyte count was 5,600 per c.mm. The night blood was examined for filaria with negative results. The Wassermann reaction was moderately positive on 18th September. Intravenous iodine was tried, but did not control the fever.

CASE 9.

Name—S. D., Hindu female, age 60 years.

20th August.—Night blood for microfilaria: negative.

Case 9 (1927).—S. D., Hindu female, aged 60. Was bitten by a rat about two and a half months prior to admission to hospital, and gave a history of eruptions and fever subsequently. On admission, on the 22nd August, 1927, she was very weak and emaciated and also gave a history of an attack of dysentery about five

Finally, it was decided that the case must be one of rat-bite fever, despite the negative finding in the inoculated guinea-pig. A dose of 0.3 gm. novarsenobillon was given on 24th September, followed by a second similar dose on 1st October. The temperature finally subsided to normal on 6th October and the patient left hospital on 10th October.

CASE 10.

Name—Mr. D. I. H., European male, age 43 years.

months previously. The bite had been on the right foot, and on admission the right inguinal glands were found to be enlarged and tender. On admission there was daily intermittent fever, with a history of rigors. The diagnosis in this case presented some difficulty. The history was typical of rat-bite fever, but a

Case 10 (1928).—This was one of the most interesting cases of the series, as the infection was contracted at sea. [A previous case of rat-bite fever contracted at sea has been recorded by King (1914).] The patient, Mr. D. I. H., European male, aged 43, is a member of the Hughli Pilot Service.

On 6th April, sudden fever set in with rigor, swelling in the bitten foot and calf, and intense joint pains. The patient was admitted to hospital on the 9th April. On admission, he was in a drowsy state, complained of

Presumably, the rats on board the "Fraser" had become infected during the vessel's previous stay in the river at Calcutta, when the boat was coaling in Kiddernpore docks.

Name—S. P. S., Hindu male, age 35 years.

Despite the failure to demonstrate *Spirillum minus* in the inoculated guinea-pig, the diagnosis was fairly certain. The patient was given 0.3 gm. novarsenobillon on

29th February.—A guinea-pig and a mouse were inoculated with the patient's blood. The mouse died on the second day from septic peritonitis, but *Spirillum minus* was found in the guinea-pig's blood on the 12th day. The night blood showed microfilariae present. No protozoa, ova or pathogenic bacteria were found in the stools.

Fig. 1. The local lesion in Case 13; fifteenth day after the bite.
S. minus isolated in the exudate from the local lesion.

Fig. 2. The local lesion in Case 27; twentieth day after the bite.
S. minus isolated from the exudate from the local lesion.

The patient was treated with three injections of novarsenobillon, and left hospital on the 15th March, 1928.

standard guinea-pig strain of *Spirillum minus*, and caused immobilization of the spirochaetes within fifteen minutes. This was repeated on three other occasions and the result

CASE 12.

Name—N. B., Mahommedan female, age 52 years.

Case 12 (1928).—N. B., Mahommedan female, aged 52, was bitten on the dorsal and inner aspect of the left foot by a rat whilst she was asleep. She stated that she had fever for about five days after the bite, with enlargement of the left inguinal glands. The fever came on with a chill and was of intermittent character. There was a distinct periodicity, each attack of fever lasting for four or five days, with apyrexial intervals of about the same length between them.

This patient was first seen on the 20th day after the bite, and had slight fever on her admission, whilst there was a definite rash on the face and upper extremities. A guinea-pig was inoculated with her blood on the day of admission (5th May, 1928) and showed

was always positive. The further laboratory findings in the case were as follows:—

Thin and thick blood films taken at night for filaria on three occasions: negative.

5th May.—Wassermann reaction: completely negative.

7th May.—Stool showed hookworm and ascaris ova, and *Endolimax nana* cysts.

7th May.—Urine clear, no albumin or sugar.

25th May.—Thin and thick blood films: no parasites seen. Haemoglobin 60 per cent. Total leucocytes 15,200 per c.mm. Differential leucocyte count: eosinophiles 1 per cent.; polymorphonuclears 78 per cent.; small mononuclears 19 per cent.; large mononuclears 2 per cent.

The patient received two injections of novarsenobillon, which effected a rapid cure.

CASE 13.

Name—S. L., Hindu male, age 40 years.

Case 13 (1928).—S. L., Hindu male, aged about 40, was bitten at night by a rat on the third toe of the left foot. The wound healed up, but 13 days later he had a high rise of temperature with rigor, and came to hospital on the 15th day, when fever was still present. He was admitted on the 7th June, 1928.

On admission the site of the bite was found to be red and swollen and extremely painful; the inguinal glands were enlarged and tender. Serous exudate was obtained from the oedematous area around the site of the bite and showed *Spirillum minus* when examined under dark ground illumination.

The subsequent course of the fever and treatment were as shown in the temperature chart. The other laboratory findings were as follows:—

8th June.—Thin and thick blood films for malaria: no parasites seen.

8th June.—Urine clear, no albumin, no casts, no sugar.

9th June.—Wassermann reaction: negative.

11th June.—Serum test for immobilization of standard laboratory strain of *Spirillum minus*: negative, no immobilization occurred.

Case 14 (1928).—M. K., Mahommedan male, aged 32. The patient was bitten at night by a rat on the right foot. There was a good deal of haemorrhage from the site of the bite. The wound healed up, but on the 6th day it became red and inflamed and exquisitely tender, whilst high fever set in. He was first seen on the 14th June, 1928, the 15th day after having been bitten. He was admitted to hospital, and is still in hospital at the time of writing. The laboratory findings to date were as follows:—

14th June.—Serous exudate from the site of the bite shows *Spirillum minus* present. Night blood for filaria: negative.

Spirillum minus 15 days later. The rash spot on the dorsum of the hand was pricked in three or four places with a sharp needle and about ¼ c.c. of the exuding blood and serum, mixed with an equal volume of citrated saline, was inoculated into a white mouse intraperitoneally. This mouse showed *Spirillum minus* in its blood ten days later. The patient's serum was also tested against a

15th June.—Stool shows no helminthic ova, protozoa or pathogenic bacteria.

16th June.—Wassermann reaction: negative.

Case 15 (1928).—K. K. D., Hindu female, aged about 55 years; was bitten on the left shoulder about a month before she came under observation. The wound healed up, but three weeks later a very painful swelling developed at the site of the bite, also fever. She consulted a doctor, who cauterised the area (probably with fuming nitric acid).

When first seen—25th June, 1928—there was a big spherical ulcer about 2 inches in diameter on the shoulder, with raised margins, covered by a black necrotic slough. The glands of the axillæ and neck were enlarged and very tender. There was a profuse rash, which was most pronounced on the thighs, mammae, and forearms, where it was rather of an urticarial character. Pain was present in most of the joints, and diarrhoea was also a feature of the case. The patient was admitted to hospital the same day, and is still in hospital at the time of writing this report.

The laboratory findings in this case were as follows:—

25th June.—Serous exudate from a rash area examined under the dark ground: no spirilla found. (The site of the bite itself was not examined, as it was covered by a large black slough.)

26th June.—Patient's blood inoculated into two mice. These showed *Spirillum minus* 9 days later.

With the exception of Nos. 1, 2, 3 and 6, the above cases were treated in the Carmichael Hospital for Tropical Diseases, attached to the Calcutta School of Tropical Medicine. The next three cases to be described were under the treatment of Dr. S. P. Bhattacharjee, M.D. (Cal.), Assistant Professor of Tropical Medicine at the School, and the junior author was called in, in consultation in connection with them. We are much indebted to Dr. Bhattacharjee for his kind permission to publish the notes on these cases.

minus nine days later. The patient was now treated with novarsenobillon, as shown on the chart, and recovered.

The interesting feature in this case is the very trivial character of the initial lesion, also the somewhat erratic character of the temperature chart.

Case 17.—This case was the most prolonged one that we have yet seen, and the patient did not become finally afebrile until the 128th day of illness.

Mr. N., Indian Christian, aged 65, was bitten at night by a rat on the right foot. He was sleeping on the second floor of a house in Calcutta. Mrs. N., who was sleeping in the same room, was also bitten by the same rat at the same time, but subsequently showed no symptoms. Mr. N. was bitten just before Mrs. N.

The local sore healed up promptly, but on the 17th day inflammation set in at the site of the bite, the right inguinal glands became enlarged and tender, and high fever set in with rigor. The patient complained of intense pain in all the muscles of the extremities.

The subsequent course of the fever was as shown in the temperature chart. Between the 21st and 61st days of illness, nine injections of sulfarsenol were given subcutaneously, without in any way influencing the temperature. The fever ran a perfectly typical course, the pyrexial intervals being about three days each time, and the apyrexial periods four to five days; the chart in fact might serve very well as a standard chart of the course of the fever in rat-bite disease.

The patient now passed into the hands of the kavaraj on the 63rd day, but still continued to record his temperature. On the 77th day the patient was again seen by Dr. Bhattacharjee, who called in the junior author in consultation. Two guinea-pigs were inoculated with the patient's blood and both showed *Spirillum minus* eleven days later. In the meantime the patient had been put on to stavarsol and had gone to the hills for a change. This, however, did not check the fever, which continued as systematically as ever.

By the 82nd day the patient was in a pitiable condition. He was completely prostrated and very much emaciated.

CASE 16.

Name—Miss M., Anglo-Indian, age 8 years.

Case 16.—Miss M., Anglo-Indian, aged 8. This patient came for treatment for fever and swelling of the left inguinal glands. She mentioned that ten days previously she had had a slight scratch on the left great toe, while in bed at night which she attributed to a cockroach-bite, and of which she had taken no notice. There had been no local sore or tenderness. The case was taken to be one of filariasis—a disease which is very prevalent among the Anglo-Indian community in Calcutta—and she was treated with a mixed staphylococcus-streptococcus vaccine, then given a course of soamin injections, and then cytoselum.

The temperature chart in the meantime had assumed the form shown. Malaria being suspected, quinine was given, but had no effect on the fever. The temperature chart being very suspicious, and with the history of a previous "scratch" ten days before the onset of the fever, the suspicion of rat-bite fever now arose, and the junior author was called in. Blood was taken from the patient on the 72nd day of illness and injected into a guinea-pig and a mouse, both of which showed *Spirillum*

There was marked wasting of the muscles of the extremities. Pain in the muscles of the extremities, indeed, was a marked feature of the case throughout. The anemia was very severe; the blood picture was: haemoglobin 35 per cent., R.B.Cs. 2,000,000 per c.mm., and total leucocytes 10,600 per c.mm.

On the 91st day the pulse became slow and irregular, at a rate of 45 to 55 to the minute, and the urine became scanty. Examination of the urine showed abundant albumin present and a few hyaline casts. The pulse continued to be slow and irregular, and the amount of urine passed diminished, though there was less albumin in it than previously.

Novarsenobillon treatment was commenced on the 90th day of illness. On account of the albuminuria and tendency to suppression of urine, however, it was necessary to go slow. The doses were given intravenously, and the course was as follows:—

90th day N.A.B. 0.2 grm.

91st day. Patient put on full doses of alkalis and glucoso by the mouth.

Fig. 3. The rash in Case 12; twentieth day after the bite. *S. minus* isolated in guinea-pig inoculated with the patient's blood. Patient's serum

Fig. 4. Case 15; bitten one month previously. The local lesion on the left shoulder was cauterised with nitric acid and an ulcer has formed

99th day. 0.1 grm.
103rd day. 0.15 grm.
107th day. 0.2 grm.
111th day. 0.2 grm.
116th day. 0.2 grm.

CASE 17.
Name—Mr. N., Indian Christian, age 65 years.

120th day. 0.2 grm.
124th day. 0.2 grm.
127th day. 0.2 grm.
130th day. 0.2 grm.
The temperature finally fell to normal on the 128th day, and the patient was by then well into convalescence.

The case is of interest from the severity of the symptoms, the long duration of the fever, the emaciation, the severe pains in the limbs, the failure of sulfarsenol and stovarsol, and the final cure with repeated small doses of novarsenobillon, administered cautiously.

CASE 18.
Name—Mrs. S.

Case 18.—Mrs. S., was bitten by a rat and subsequently had an ulcer at the site of the bite, with lymphangitis and lymphadenitis in the glands draining the site of the bite. With antiseptic dressings however the ulcer soon healed up.

Fever with rigor set in on the 22nd day after the bite, and an erythematous rash broke out on the affected extremity and on the front of the body. The subsequent course of the fever was as shown in the chart.

With the continuance of the fever rapidly progressive anaemia set in and general anasarca. On account of the latter it was necessary to proceed cautiously with the novarsenobillon treatment. The following blood examinations were carried out.

First week.—Hæmoglobin 80 per cent. R.B.Cs. 4,000,000 per c.mm. Total leucocytes 7,500 per c.mm.

Second week.—Hæmoglobin 60 per cent. R.B.Cs. 3,200,000 per c.mm. Total leucocytes 14,000 per c.mm.
Third week.—Hæmoglobin 40 per cent. R.B.Cs. 2,300,000 per c.mm. Total leucocytes 6,750 per c.mm.
Fourth week.—Hæmoglobin 25 per cent. R.B.Cs. 2,000,000 per c.mm. Total leucocytes 10,450 per c.mm.
 The Wassermann reaction gave completely negative results.

A guinea-pig was inoculated with the patient's blood (unfortunately at a time when she was afebrile.) No *Spirillum minus* could be found in this animal subsequently.

The course of treatment was as follows:—

30th day. N.A.B. 0.2 grm.

38th day. N.A.B. 0.2 grm.

45th day. N.A.B. 0.25 grm.

55th day. N.A.B. 0.3 grm.

62nd day. N.A.B. 0.3 grm.

71st day. N.A.B. 0.3 grm.

79th day. N.A.B. 0.4 grm.

88th day. N.A.B. 0.45 grm.

On the 91st day the temperature fell to normal, and thereafter remained steadily normal.

96th day. N.A.B. 0.45 grm.

104th day. N.A.B. 0.45 grm.

The patient was now cured and in a generally satisfactory state of health.

OUTPATIENT CASES.

In addition to the above 18 cases, we have details of 10 further cases seen in the outpatient department. These were not admitted to hospital—usually because the patient refused to come into hospital, sometimes because no beds were available.

Case 19 (1924).—Chitra, a Hindu female child, aged 2 years, was bitten on the 4th February, 1924 on the forehead by an unknown animal. The child's mother was busy in an adjacent room at the time, but ran to the child on hearing her cry, stopped the bleeding by pressure with a cloth, and applied tincture of iodine. The wound healed up and the accident was forgotten. On the 25th day, however, fever set in. On examination the cervical, submaxillary, parotid and axillary glands were found to be enlarged and tender, and saliva was dribbling from the angles of the mouth. A dose of soamin had been administered by an outside practitioner. The liver was enlarged, and the patient had diarrhoea.

A mouse was inoculated with the patient's blood and showed *Spirillum minus* a week later. The child was seen a second time a week later, when the symptoms were to some extent ameliorated. When seen a third time there had again been fever with glandular enlargements. The parents refused to have the child taken into hospital.

Case 20 (1925).—P. D., Hindu male, aged 35, was referred to the Department from the Pasteur Institute, Calcutta. He had been bitten on the finger by a rat two weeks before. When first seen there was great swelling of the hand and forearm with much pain, and the axillary glands were also swollen and tender.

A mouse and a guinea-pig were inoculated. The mouse died the next day (owing to septic peritonitis from accidental wounding of the gut when giving the injection), but the guinea-pig's blood showed fairly numerous *Spirillum minus* ten days later. No beds being available, an alkaline mixture was prescribed and the patient told to return later.

He came back a month later and stated that during the interval he had had attacks of fever, each time with rigors. During the febrile attacks the site of the bite became red and tender. A week previously he stated that he had had a profuse rash on the face and chest, which had faded. Treatment with injections of novarsenobillon was advised, but the patient was not seen a third time.

Case 21 (1926).—Sudhamayee, a Hindu female child, aged 8, was bitten by some animal which was not identified on the right great toe on the night of the 8th July, 1926. On the 12th, swelling of the foot set

in with high fever. Next day vesicles appeared in the neighbourhood of the bite on the swollen area and she was brought to the outpatient department. The vesicles were punctured and stained films from the exudate examined, but no spirilla were seen; a few short chains of streptococci were present. No animal was inoculated at this stage, as the fever was thought to be due to sepsis. The swelling subsided soon afterwards on treating the part with baths of hot iodine lotion.

A week later, however, fever recurred and the child was again brought to the outpatient department. This time she looked very ill and complained of severe pain in all the limbs. The wound had completely healed, but there was pain and tenderness in the glands in the groin. Two young guinea-pigs were inoculated with the patient's blood and both showed *Spirillum minus* when examined on the tenth day.

The parents were advised to have the child treated by injections of sulfarsenol. The patient was not seen again.

Case 22 (1927).—N., a Mahomedan male, aged about 40, a tailor by profession, and resident in Kidderpore. The patient stated that he had been bitten by a mouse about six months before and that he had been getting fever off and on subsequently. Blood films were examined for malarial parasites, but none were found. Cinchona febrifuge was prescribed, and he was told to return when the fever recurred. A week later, he attended the laboratory, and at the time had high fever with rigor. Malaria was suspected and thin and thick blood films examined, but no parasites were found. A mouse was inoculated with the patient's blood and showed *Spirillum minus* on the 7th day.

The patient did not attend the department subsequently, though asked to do so.

Case 23 (1927).—Tegbahadin, male Gurkha, 28 years of age, was referred to the department from the Pasteur Institute, Calcutta, suffering from rat-bite. He stated that he had been bitten on the great toe by a rat seven days previously. The wound had healed, but oedema of the foot and leg had developed and the glands in the groin were swollen and tender. He had high fever when seen.

Blood films were taken and showed trophozoites and gametocytes of *Plasmodium vivax*. In view of the history, however, a mouse was inoculated to test for the possibility of a mixed infection, and showed *Spirillum minus* on the 9th day. At the time of his visit, cinchona febrifuge mixture was prescribed for the patient and he was instructed to return a week later, but failed to do so. (One wonders what happens to those untreated cases of rat-bite fever. Do they linger on and gradually die of the disease, or is the correct diagnosis made again in some other hospital and the patient properly treated?)

Case 24 (1927). This was a most unusual case, for the patient absolutely denied all history of a bite.

N. McG., Anglo-Indian male child, 5 years of age, the nephew of a member of the staff of the School, was suffering from fever in September 1927, with a temperature running between 102° and 103°F. His uncle took a blood film from the child, stained it, and asked the junior author of this paper to examine it for malaria parasites. No malaria parasites were seen, but—to his amazement—the junior author came across an undoubted *Spirillum minus* in the film. The film was seen by both authors and the organism was an undoubted *Spirillum minus*. The child was closely interrogated by his parents, but denied all history of a bite, nor could the parents remember that he had complained of having been bitten. He was thoroughly examined, but no scar of a bite could be found. He was treated with an alkaline mixture and made a spontaneous recovery; no quinine or arsenicals were given.

The slide on which the blood film was taken came from the Pathology Department of the School, where no work on *Spirillum minus* infection was going on at the time. It was stained in the Pathology Department, brought to the Protozoology Department, immediately put under the microscope and examined. These facts seem to exclude the possibility that the film had been

made on a slide on which a blood film from an inoculated animal might have been made previously.

Case 25 (1928). G. D., Hindu female, aged 28, came to the department on the 15th May, 1928, stating that she had been bitten at night on the left hand by a rat seventeen days previously. The wound healed up in three or four days' time, but a fortnight later the hand became red, swollen and very painful. With the onset of the local oedema, violent fever set in with rigors and vomiting. The left epitrochlear and axillary glands were tender and swollen, and there was a measles-like eruption present on the chest and arms.

The case was fairly thoroughly examined in the laboratory, and the laboratory findings were as follows:—

Thick and thin blood films: no malaria parasites or spirilla seen.

Direct examination of the blood under the dark ground: no parasites seen.

Half a c.c. of the patient's blood was inoculated intraperitoneally into a mouse: *Spirillum minus* was present in the mouse's blood on the 11th day.

Two c.c. of blood was inoculated intraperitoneally into a guinea-pig. This animal's blood was searched on the 15th day, but no spirilla found. It died on the night of the 16th to 17th day, but the body was too decomposed the next day to examine.

The urine was clear and showed no albumin. The centrifuged deposit showed no casts. The deposit was also examined under the dark ground, but no spirilla were detected.

Case 26 (1928).—I. S., Mahommedan adult male, aged about 50 years, a resident in Calcutta since birth, was bitten during his sleep at night on the right index finger. He woke up and saw the rat which had bitten him. There was only slight pain at the time, and the wound healed up in four or five days' time. On the 10th day after the bite the bitten area became red and painful and the wound broke down and suppurated. There was a streak of acute lymphangitis running up the arm and the glands in the axilla of the same side became tender to pressure. Fever did not set in, however, until five days after the re-appearance of local pain and swelling. (The patient denied all previous history of filariasis or lymphangitis, though he admitted to syphilis some twenty years previously and to gonorrhoea some fifteen years previously.)

When the fever set in, the temperature rose to 101°F., but without any rigor. Remittent continued fever persisted for four days, ranging between 99° and 101°F., the remissions being accompanied by sweating.

The patient was treated by a medical practitioner in Calcutta, who gave him two subcutaneous injections of sulfarsenol: one seven days before, and one three days before sending him to the laboratory for examination. He attended the laboratory on the 2nd June, 1928, the 20th day after the bite. The laboratory findings were as follows:—

Exudate from the local lesion examined under the dark ground: no spirilla seen.

Immobilization test: the patient's serum failed to immobilise a standard laboratory strain of *Spirillum minus* in 30 minutes.

A guinea-pig inoculated with the patient's blood on 2nd June, 1928, showed *Spirillum minus* in the blood on 15th June.

The patient was not seen again.

Case 27 (1928).—M. S., Hindu male, aged 28, was bitten by a rat on the inner side of the right arm a little above the elbow. The site of the bite healed up within a few days, but ten or twelve days after the bite the area became red, swollen and indurated. Fever set in on the 14th day after the bite and was present when the patient was seen, on the 20th day after the bite (6th June, 1928).

On examination, there was a big area of red, swollen induration about 5 inches long and 3 inches broad at the site of the bite, and the patient complained of excruciating pain in the arm and axilla. The axillary glands on the same side were much swollen and tender.

The laboratory findings in this case were as follows:—

Serum from the site of the bite showed *Spirillum minus* under the dark ground.

Two guinea-pigs inoculated with the patient's blood: both showed *Spirillum minus* in their blood on the 11th day.

Immobilization test: the patient's serum failed to immobilise a standard laboratory strain of *Spirillum minus* within 15 minutes.

Hæmoglobin: 90 per cent.

Total R.B.Cs.: 4,850,000 per c.mm.

Total leucocytes: 16,200 per c.mm.

Urine: a trace of albumin present, very numerous pus cells; no casts.

Thin and thick blood films: no parasites seen.

9th June. Wassermann reaction: complete negative.

Case 28 (1928).—Mr. D., Hindu male, aged 30 years, was bitten on the foot by a rat on the 30th March 1928, at night. Next morning he applied tincture of iodine and antiseptic dressings. The wound healed up completely in four or five days' time. Twenty days after the bite, however, severe pain, tenderness and swelling set in at the site of the bite, with enlargement and tenderness of the inguinal glands of the same side, pains in the limbs and joints, and fever attended with rigor.

Two days later he developed a rash on the forearm, elbow and leg.

The patient states that his mother was also bitten by a rat in the same house more than a month previously, but had shown no symptoms up to the end of June 1928.

The patient was seen as an outpatient on the 22nd June 1928, when the laboratory findings were as follows:—

Serous exudate from the site of the lesions examined under the dark ground: no spirilla seen.

Two mice inoculated intraperitoneally with the patient's blood: both showed *Spirillum minus* in their blood 10 days later.

The urine shows a trace of albumin, but no casts.

The case is still under observation at the time of writing this report.

In addition to the above 28 cases of rat-bite fever, we have seen several other cases—chiefly during the earlier years of work at the School, 1921-1924—of which unfortunately no detailed records have been kept. In all, we should think that we have seen at least 35, if not 40 cases of the disease during the last eight years. The disease therefore must be a relatively common one in India. It will be seen that it has been described from Bombay, Calcutta, Shillong, Goa, Central India and Colombo, and therefore must have a wide geographical distribution in this country.

Case 29.—One case in particular deserves mention, and occurred in 1926. It is mentioned on p. 55 of the Annual Report of the Calcutta School of Tropical Medicine and Hygiene for 1926. In this case, the blood of a white mouse inoculated with the blood of a patient suffering from rat-bite fever showed not only *Spirillum minus*, but also a streptothrix. On sub-passage of its blood into a second mouse, the *Spirillum minus* infection took, but not the streptothrix one. (Unfortunately no details were noted with regard to this patient).

Now Tunncliffe (1916, 1916a) has recorded a broncho-pneumonia in rats due to a streptothrix, and streptothrix infection in cases of rat-bite fever has been recorded by Schottmüller (1914), Blake (1916), Tiletson (1916), Litterer (1917), and Tunncliffe and Mayer (1918). Other observers have recorded secondary infections with septic cocci, bacilli and the like.

In our case, the streptothrix infection was clearly a secondary one, and the same is likely to be true of the other recorded cases. Secondary streptothrix infections of ulcers are not uncommon in the tropics, and we have seen such infection occurring in cases of inguinal granuloma and the like, so that possibly this contamination is air-borne. On the other hand, McDermott (1928) notes that in cases where a secondary streptothrix infection occurs, there is apparently almost always suppuration at the site of the bite; whereas in pure strain infections with *Spirillum minus* suppuration does not occur at the site of the bite. "It is not unreasonable to presume," he writes, "that a streptothrix or leptothrix infection may be transmitted to man by the bite of a rat. The further inference may also be drawn that in every case of intermittent fever following a rat-bite, the possibility of a streptothrix infection being present, either alone or with spirillosis, must be borne in mind, especially if salvarsan treatment is not proving satisfactory." He comments on the fact that in some of these cases it is distinctly mentioned that the rat was mangy or looked ill, and concludes that in such cases possibly the rat is infected with bronchopneumonia due to a streptothrix, and that its saliva is infected from the coughed-up sputum.

COMMENTS ON OUR SERIES OF CASES.

The case histories recorded above, we believe, are sufficiently numerous to give a clear clinical account of the chief features of rat-bite fever as seen in India, but there are a few special points on which we may here comment.

Diagnosis by inoculation of the blood into susceptible animals. In our experience, this is far and away the most certain method of diagnosis. The white mouse is definitely more susceptible to infection than the guinea-pig, and young guinea-pigs more susceptible than older ones. Row (1922) mentions that he had failed to isolate the spirillum by this method in any of his patients. On the other hand, we have but rarely failed to do so, provided the blood is taken at a time when the patient has fever. In our series of cases the following gave negative results on inoculation of the patient's blood into susceptible animals:—Nos. 9, 10 and 18—the last of whom was afebrile at the time when the blood was taken. Three in all. The following gave positive results on animal inoculation:—Nos. 2, 3, 4, 5, 6, 7, 8, 11, 12, 14, 15, 16, 17, 19, 20, 21, 22, 23, 24, 25, 26, 27, 28 and 29. Twenty-four in all.

The technique for this method will be described later.

Diagnosis by examination of serous exudate from the local lesion. This is regarded by Row as the best method of establishing the diagnosis. Powell and Bana's case was also diagnosed by this method, whilst Row and Parmanand both infected their animals by inoculation of expressed

fluid from the local lesion. McDermott* infected his guinea-pigs by inoculation with an emulsion prepared from the excised inflamed lymphatic glands.

In our earlier cases we had very little success with this method, but this was probably due to faulty technique, for we prepared, stained, and examined thin films from the serous exudate. Thus we failed to find spirilla in serous exudate from the local lesions in Cases 2, 4, 15 (from the rash), 26 and 28. Cases 13, 14, and 27 however yielded positive findings. On the other hand, we have lately realised that our earlier technique was faulty, and that the best method of examining the serous exudate is to examine it in the fresh state under the dark ground.

We have examined thin and thick films of the peripheral blood of most of the patients, but in only one—Case 24—have we seen the spirillum in such films. Examination of stained thin or thick films of the patient's blood appears to be a waste of time. On the other hand, it may be necessary, to exclude malaria. In Case 23 a mixed infection of rat-bite fever and benign tertian malaria was present.

McDermott lays stress on the value of the immobilization test with the patient's serum. The technique for this test will be described later, but we regard it as of value only when a positive result is obtained. The serum of patient No. 12 immobilised a standard laboratory strain of *Spirillum minus* within 15 minutes, but the test gave negative results in Cases 13, 26 and 27.

McDermott considers that "if syphilis can be excluded, a positive Wassermann reaction would be significant," whilst Briggs clearly regards the positive Wassermann reaction in his case as being due to rat-bite fever and not to syphilis. He does not state the laboratory in which this test was carried out, unfortunately. Surveyor records a negative Wassermann reaction in his patient, and Row remarks that his patients gave negative Wassermann reactions. The Wassermann reaction was tested in seven of our cases by the Imperial Serologist to the Government of India, Lieut.-Col. R. B. Lloyd, I.M.S., to whom we are very much indebted for carrying out these tests. It was completely negative in Cases 3, 12, 13, 14, 18 and 27; doubtful in Case 4; moderately positive in Case 5—a Mahomedan cook—and Case 9—a Hindu female, aged 60. Previous syphilis cannot always be ruled out, and in no case was the reaction strongly positive. We doubt very much whether the Wassermann test has any diagnostic value with regard to rat-bite fever, but further investigation of this point is wanted.

McDermott writes that "in mild cases there may be no involvement of the kidney, but in cases of any severity a toxic nephritis is common, the urine being diminished in amount and containing albumin and casts." This is well

*The references given throughout this paper to McDermott refer to his 1928 paper.

exemplified in our series in Cases 6 and 17; in Cases 27 and 28 a trace of albumin was present, but no casts; in Cases 4, 5, 10, 12, 13 and 25, however, the urine was perfectly clear and free from albumin and casts.

In estimating the incubation period of the disease, up to the time of onset of the high fever and local oedema and inflammation of the site of the bite, we have had to rely chiefly on the patient's own statements, but the following figures may be quoted:—

Case 1. 14 days.	Case 15. 21 days.
Case 2. 12 days.	Case 16. 10 days.
Case 3. (Febrile at the time when bitten.)	Case 17. 17 days.
Case 4. 16 days.	Case 18. 22 days.
Case 5. 10 days.	Case 19. 25 days.
Case 6. 15 days.	Case 20. (Uncertain).
Case 7. 7 days.	Case 21. 4 days. (A young child).
Case 8. 10 days.	Case 22. (Uncertain).
Case 9. (Uncertain).	Case 23. 7 days.
Case 10. 15 days.	Case 24. (Denied all history of bite).
Case 11. 12 days.	Case 25. 14 days.
Case 12. (Uncertain).	Case 26. 10 days.
Case 13. 13 days.	Case 27. 11 days.
Case 14. 6 days.	Case 28. 20 days.

This which gives an average incubation period of 13.2 days. The actual figures, however, are very variable.

In some cases of rat-bite fever, the initial lesion may be of the most trivial description. This is well exemplified by Case 16, where the patient attributed the bite to a cockroach; whilst Case 24 denied all history of any bite at all. McDermott quotes an extraordinary case recorded by Boidin (1922) where the infection was acquired by eating a raw rat; also others in which "transmission was probably due to mechanical transfer." The disease has also been transmitted by the bite and even by a scratch from the claws of an infected cat; also by weasels and ferrets; and in one case by the bite of a dog.

In only three cases in our series—Nos. 13, 14 and 27—was the diagnosis established by finding the spirillum in the serous exudate from the local lesion. We believe, however, that we have not paid sufficient attention to this method of diagnosis, and hope to pay more attention to it in the future.

The severe and progressive anæmia of rat-bite fever is well illustrated by Cases 17 and 18.

THE DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS OF RAT-BITE FEVER.

The diagnosis of rat-bite fever is usually quite straightforward. There is a definite history of a bite (usually at night), either by a rat or some animal which has not been seen. The temperature chart is very characteristic, so also is the acute local oedema, induration and pain at the site of the lesion (which has usually healed up). Headache, vertigo, and sometimes vomiting accompany the onset of fever, which usually takes place with rigor. Acute pains in the limbs are complained of. A rash may or may not be present, and may be easily overlooked in dark-skinned patients. The lymphadenitis is usually

marked, and may affect only the glands draining the site of the bite or may be generalised.

Laboratory Diagnosis. In order to confirm the diagnosis, the following procedures may be resorted to in the laboratory:—

(i) *Examination of the Local Lesion.* A prick is made with a sharp stout needle into the oedematous area around the site of the bite, and the fluid that oozes out is examined under dark ground illumination. The movements of the spirillum at first are extremely active; it flashes across the field like a streak of light. After the preparation has been put up for some little time, however, the movements slow down and the spirilla become clearly visible. The preparation should therefore be vaselined and allowed to settle for some little time before it is examined.

In the absence of dark ground illumination, films may be stained for diagnostic purposes by either Leishman's or Giemsa's stain. The best method of demonstrating *Spirillum minus*, however, and the one which brings out the terminal flagella best—in our experience—is Tribondeau's modification of Fontana's stain. For the sake of completeness we may here give details of this method.

(1) Prepare a thin film of the clear serous exudate from the lesion on a slide. Allow it to dry in air.

(2) Lay the slide on a staining rack and flood the dry film with Ruge's solution, which has the following composition:—

Pure glacial acetic acid	1 c.c.
Formalin (40 per cent.)	2 c.c.
Distilled water	100 c.c.

Pour the fixative on, drain off, and repeat two or three times for about a minute.

(3) Drain the fixative off the slide. Cover the slide with methyl alcohol and flame by applying a lighted match to the slide. This completes fixation.

(4) Lay the slide on the staining rack, and flood with the following mordant:—

Fresh tannic acid, powder	..	5 grammes.
Distilled water	..	100 c.c.

Warm gently till steam rises from the slide. The best and least messy way of doing this is to wrap a little cotton-wool round the end of a piece of wire, soak it in spirit, light it, and hold it under the slide. When steam rises from the slide, remove the flame and allow the mordant to act for 30 seconds longer, without further heating.

(5) Wash the slide with distilled water and then cover it with Fontana's silver solution. To prepare this, a 5 per cent. aqueous solution of silver nitrate is taken in a glass cylinder which has previously been very thoroughly washed with distilled water. With a capillary pipette add liquor ammoniæ fortis B.P. drop by drop. A sepia precipitate forms and then re-dissolves. To the now clear solution add more liquor ammoniæ fortis *very carefully*, and only drop by drop from a capillary pipette, until a solution results which is just opalescent (and no more) on shaking. Do not add a drop more of the ammonia solution than is necessary to produce slight opalescence.

Cover the slide with this solution and warm gently till steam arises, then remove the flame and allow the warm solution to act for a further 30 seconds.

(6) Wash the film in distilled water, and allow to dry in air. It should never be blotted.

Examine with the oil-immersion lens. The spirilla stain an intense brown-black against a faint yellow background. The appearance of

the spirillum by this method is illustrated in the text figure. Fontana-stained films fade very rapidly and permanent preparations cannot be obtained by this method. The tannic acid used must be fresh; old solutions of tannic acid which have been exposed to light are useless, and are also very apt to become contaminated with moulds.

The spirillum can also be stained with Leishman's stain or by prolonged staining with Giemsa's stain, but, in our experience, Fontana's stain is preferable to either of these methods and brings out the fine terminal flagellum of *Spirillum minus* with considerable constancy and clear definition. Several workers such as Wenyon (1926, p. 1286) and McDermott (1928) figure spirilla with more than one terminal flagellum at each end, but so far we have never seen more than one terminal flagellum at each end.

The number of spirilla in a film from the serous exudate is usually scanty and prolonged search may have to be made. On the other hand, it seems probable that this method is the one that is most likely to give immediate confirmation of the clinical diagnosis.

(ii) *Immobilization Test with the Patient's Serum.* For this test a guinea-pig or mouse previously infected with a standard strain of *Spirillum minus* is required.

The patient's serum is diluted 1 : 5 with normal saline, and one volume of the diluted serum mixed with an equal volume of the blood of the infected mouse or guinea-pig on a slide. A cover-slip is applied, and the preparation is vased and allowed to stand for one hour. It is then examined under the dark ground microscope. It is essential in all cases to put up a control preparation with normal serum from a person who has not been bitten. In the control preparation the spirilla are still actively motile at the end of an hour, in the patient's serum, if the result is positive, the spirilla are completely immobile at the end of one hour (or sometimes sooner).

The test is of value in diagnosis only if the result is positive. A positive result indicates that the patient is infected with *Spirillum minus*. On the other hand, in three of our cases in which the test gave negative results, *Spirillum minus* was demonstrated on inoculation of the blood into susceptible animals.

(iii) *Inoculation of Susceptible Animals.* In our experience this is the most certain and reliable method of demonstrating that the patient is infected with *Spirillum minus*. It succeeded in 23 out of the 26 cases in which we tried it. The blood however must be taken during the febrile period.

The most susceptible animals are in order of frequency:—(i) White mice—of which we used an English strain, imported in connection with kala-azar work at the School; (ii) young guinea-pigs; and (iii) adult guinea-pigs. McDermott found 13 out of 14 white rats susceptible, also rabbits and the *Macacus rhesus* monkey. The

animals can either be inoculated subcutaneously with a drop of serous exudate from the lesion, as has been successfully done by Row, Parmanand, McDermott, and others, or, as in our series, intraperitoneally with the patient's blood. The technique for the latter operation is as follows:—

At a time when the patient has fever 3 c.c. of blood is withdrawn from the median basilic vein with a hypodermic syringe and immediately inoculated into two animals: 2 c.c. being given intraperitoneally to a guinea-pig and $\frac{1}{2}$ c.c. intraperitoneally to a white mouse. The blood of these animals is then examined daily from the 8th day onwards under the dark ground microscope. A small drop of blood is obtained, either by snipping the nail of the guinea-pig with a fine sharp pair of scissors or snipping off the end of the tail of the mouse, and placed on a thin, perfectly clean slide, which should not be more than 1.2 mm. thick. A very thin and scrupulously clean cover-slip is then dropped on it, and the preparation vased. The preparation should be so thin that the red corpuscles do not overlap one another. It should be examined under the dark ground about half an hour after it has been made, by which time the spirilla have slowed down to some extent and their detection become easier.

It is very important not to mistake pseudo-spirochaetes, i.e., filaments from disintegrating red corpuscles, and hæmoconia particles for sluggish spirilla.

In the absence of the dark ground, blood films can be taken from the inoculated animals and stained with Fontana's stain, or with Leishman's or Giemsa's stain, or by the panoptic method. The spirilla, as a rule, are not numerous in the film, and it may have to be searched for some little time before they are found. Once seen, however, the laboratory worker can never fail to identify *Spirillum minus* again. Under the dark ground the spirillum appears as a very actively motile refractile wavy organism. It stains readily by any aniline dye, and also by Leishman's and Giemsa's stains. With Fontana's stain it shows up very prominently, the deposit of silver causing it to appear thicker and coarser than it really is, and the terminal flagella usually stain well by this method. Non-dividing forms measure from 1.5 μ to 10 μ (exclusive of the terminal flagellum), and each wave is about 1 μ in length.

Spirillum minus is a spirillum with a rigid structure. Whereas in a true spirochaete the coils are formed by the bending of the organism as it travels, the coils in *Spirillum minus* are pre-formed and the organism has a rigid structure, like that of a corkscrew. McDermott quotes Ruys (1926) as stating that the windings lie in one plane. The waves are very regular, and in a blood film the spirilla are frequently seen applied either by one end or along their length to the margin of a red blood corpuscle. (This may be an effect due to spreading, but it is rather a characteristic appearance of this spirillum).

Movement is rapid and in a straight line, as a rule. The ends of the spirillum may be blunt, but are usually sharply pointed, especially as seen in Fontana-stained preparations. There is not the lateral bending movements so characteristic of the true spirochaetes. Motility is retained in sealed blood preparations for several hours. Division appears to be always by transverse binary fission.

McDermott states that there may be from 1 to 7 flagella at each end of the spirillum, and advocates Adachi's method for demonstrating them. We have not tried this method, but have found Tribondeau's modification of Fontana's stain very reliable.

During the past five years we have made repeated attempts to cultivate *Spirillum minus* *in vitro*, using very many different methods, but have never once succeeded. Futaki and his colleagues (1917) claim to have cultivated this organism *in vitro*. Joekes (1925) also claims to have been successful. On the other hand, a most curious feature of Joekes' cultures was that all successful cultures contained a symbiotic coliform bacillus, from which he found it impossible to separate the spirillum. This sounds very suspicious. Noguchi (1928, Plate X) has recently drawn attention to the liability of mistaking detached bacillary flagella in a culture-medium for spirochaetes, and this may explain Joekes' findings. Our complete failure to cultivate *Spirillum minus in vitro* is in accordance with the equally complete failure of Robertson (1924) and McDermott (1928).

In practically every instance man is infected by the bite of an infective rat, and the exact mechanism has been much discussed. The spirillum has never so far been demonstrated in the saliva of infected rats, though McDermott considers that it may only have to be looked for further to be found. The rat occasionally bites sufficiently hard to break a tooth, and it is usually supposed that the spirilla escape from the blood through some lesion of the gums of the rat into the saliva at the moment of biting. McDermott notes the presence of keratitis with a profuse discharge from the eyes and nostrils, in which the spirillum may be present; spirilla from this source could easily come to contaminate the site of the bite when the rat bit. McDermott further draws attention to the general resemblance of rat-bite fever to syphilis. There is a primary lesion in both diseases: a secondary eruption, and tertiary lesions. The tertiary lesions in an infected rat take the form of white nodules in the lungs, which, on section are found to consist of necrotic matter, encapsuled by fibrosis. The presence of spirilla in these lesions was demonstrated by inoculating the matter into guinea-pigs, which became positive. These tertiary lesions may ulcerate into the bronchi; the infected sputum be coughed up, and so come to contaminate the rat's saliva. "These tertiary lesions," writes McDermott, "offer an easy explanation of the entry of spirilla into the bite wound: by secre-

tion from the eyes (or, in the cat at least, from the nose) streaming down the muzzle on to the wound or into the buccal cavity by way of the nose and naso-palatine duct, or by the passage of material from ulcerated lesions into the mouth the 'sick' appearance of rats in the tertiary stage of the experimental disease suggests that many of the infectious rats may have been in this stage of the disease, and that accordingly the usual mode of infection is by contamination of the wound with material from the eyes (or nose) or from internal granulomatous lesions."

Transmission of the infection from rat to rat presumably takes place by bites. It is also clear that it might occur by coitus if the mucosa of the genitalia were abraded. Dr. B. C. Basu, Entomologist to the Spirochaetosis Transmission Enquiry in our Department, under the Indian Research Fund Association has fed rat fleas on infected mice and guinea-pigs. He finds that *Spirillum minus* will survive in the gut of fed fleas for 24 hours or even longer. On the other hand, he could find no evidence of invasion of the coelomic cavity or of the salivary glands of the flea. It does not appear likely that fleas play any part in the transmission of the disease in Nature.

DIFFERENTIAL DIAGNOSIS.

Although the diagnosis of rat-bite fever is usually straightforward enough, yet in our experience of the disease it may occasionally present unexpected difficulties. The diseases which may be confused with true rat-bite fever due to *Spirillum minus* are chiefly as follows:—

(i) *Simple Septic Fever following after a Rat-bite.* Here there will be suppuration at the site of the wound, marked polymorphonuclear leucocytosis (to a much greater degree than is the case in true rat-bite fever), and an entirely different type of temperature chart. At first, however, we did not realise how often septic infection may be super-imposed on true rat-bite fever. Case 3 is a good example in point. The appearances of the lesion were very septic, the temperature chart very aberrant (at first), and simple septic fever was suspected. On the other hand, both the inoculated mouse and guinea-pig showed *Spirillum minus*. This case taught us the very necessary lesson that the presence of sepsis and an aberrant temperature chart may not exclude infection with *Spirillum minus* (though it renders any hope of finding the spirillum in exudate from the site of the lesion hopeless).

(ii) *Filariasis, and especially Filarial Lymphangitis.* Filarial infection is very common in Calcutta city, some 12 per cent. of the population being infected. It is especially prevalent in the Anglo-Indian community and among Indian clerks, artisans, and even in the professional classes. Hence rat-bite fever may be mistaken for filarial fever, and the acute swelling and oedema of the site of the bite be confused

with for filarial lymphangitis. The bite may have been forgotten, or it may have been so trivial as to have been overlooked. Cases 16 and 24 are instances in point. In Case 11 both infections were present simultaneously. Examination of the blood at night will usually disclose microfilariæ in cases of filarial fever, but in established filarial lymphangitis microfilariæ are frequently not found. The eosinophilia of filariasis is in marked contrast to the tendency for the eosinophile count to be low in rat-bite fever.

(iii) *Relapsing Fever*.—In areas in India where relapsing fever is prevalent, together with rat-bite fever, confusion may arise. The febrile period in rat-bite fever, however, rarely exceeds 48 hours, whereas in Indian relapsing fever it is usually five or six days. Examination of a fresh drop of blood taken from the patient during the febrile phase usually fails to show any spirilla in cases of rat-bite fever, whereas usually very numerous *Spirocheta recurrentis* are found in cases of relapsing fever.

(iv) The onset of the fever with acute malaise, headache, joint pains, and sometimes vomiting, and the defervescence with sweating may simulate malaria, though the temperature in rat-bite fever is usually elevated for a longer period than in malaria. Differentiation is readily established by examining a stained blood film. The two diseases may co-exist in the same patient (Case 23).

(v) It is possible that a case of rat-bite fever might be mistaken for one of dengue, during a dengue epidemic. The local lesion in rat-bite fever, and the entirely different types of temperature charts in the two diseases should serve to establish the differential diagnosis.

(vi) The acutely painful brawny red œdema at the site of the bite in rat-bite fever rather resembles the local condition present in erysipelas. On the other hand, in rat-bite fever there is no defined advancing margin to the area of acute inflammation; the leucocytosis is markedly greater in erysipelas; and the temperature chart will not show the periodic relapses of rat-bite fever.

TREATMENT.

The treatment of rat-bite fever is simplicity itself. One or two intravenous injections of novarsenobillon are frequently sufficient to cure the case (e.g., Case 9; also Briggs' (1922) case). On the other hand, it is advisable to give a second and even a third injection, in order to make sure that the infection has been eradicated. Sulfarsenol seems less effective than novarsenobillon (e.g., Case 17). Where there is much albumin in the urine, it is advisable to go slow and trust to repeated injections of small doses, rather than to two or three larger doses (e.g., Case 17).

The local inflammation and pain may call for hot fomentations, but with the destruction of the spirilla by novarsenobillon, the local symptoms clear up almost as rapidly as does the fever.

THE DISEASE IN EXPERIMENTAL ANIMALS.

McDermott gives a very thorough account of the disease as seen in inoculated mice, rats, guinea-pigs, rabbits, monkeys, cats and ferrets, so we need here give only some general observations on this subject. We have used animals chiefly for purposes of diagnosis, and during the last four years have inoculated 26 guinea-pigs and about the same number of white mice.

Guinea-pigs.—Twenty-six guinea-pigs were inoculated intraperitoneally, each with 2 c.c. of blood from the patient. Of these 26 guinea-pigs, 23 subsequently showed *Spirillum minus* in their blood, though one was not positive until the 38th day after inoculation. Two remained negative for more than two months after inoculation, after which period they were not further examined. On the other hand, in both these instances the mice inoculated from the same patients took. McDermott (p. 449) states that the reaction of guinea-pigs varies: some dying without ever having shown spirilla, others remaining negative. This is not our experience. Further, on sub-passage from guinea-pig to guinea-pig, the infection is invariably successfully transmitted, and a standard laboratory strain can be maintained very easily. In the case of guinea-pigs primarily inoculated with the patient's blood, spirilla may appear as early as the 8th day or as late as the 38th day, usually towards the end of the second week. In sub-passage animals spirilla usually appear in the blood on the 7th day.

The principal symptoms in the infected guinea-pigs are:—

- (i) Loss of weight.
- (ii) Marked emaciation.
- (iii) Thinning of the fur, especially on the front of the chest and abdomen.
- (iv) Œdema of the legs, leading to ulceration. A fairly large number of spirilla can be seen in the discharge from these ulcers.
- (v) Fever: the temperature rising to 102° to 104° F. or more.
- (vi) Blepharitis—a symptom which is not, however, invariably present.

The infected guinea-pigs usually die about two months after inoculation.

White Mice.—Spirilla appear earlier in inoculated mice than in inoculated guinea-pigs. The inoculated mice generally die within a month after inoculation, but it is difficult to say whether death is due to spirillosis or to other intercurrent infections. In one instance a mouse inoculated on the 22nd February, 1927, remained quite healthy until it was chloroformed on July 7th, 1927. At autopsy the spleen was found to be enormously enlarged, and smears from this organ and from the kidney showed scanty spirilla.

Mice do not seem to suffer from any symptoms when infected with *Spirillum minus*. The same point has been noted by McDermott. The

spirilla are not constantly present in the blood of infected mice; they appear, disappear, and reappear. At autopsy on infected mice a lesser or greater degree of splenic enlargement seems to be invariably present, and sometimes the spleen may be three or four times its normal size.

White Rats.—Two white rats were inoculated with the blood of an infected guinea-pig on the 24th May, 1928. Their blood was examined daily from the 9th day onwards, but did not become positive till the 30th June, 1928, when both showed scanty spirilla in their blood—an interval of 37 days.

Spirillum minus IN ITS NATURAL HOSTS.

Prior to 1928, our method of examination of rats for *Spirillum minus* and for *Trypanosoma lewisi* was to take thin blood films, stain them and examine them. More than 100 rats have been so examined from different areas in Calcutta during the last few years. One rat showed a mixed infection with both *Trypanosoma* and *Spirillum minus*. Two further rats, both of them caught at Kidderpore docks, showed *Spirillum minus* infection.

This year (1928), however, we have taken to examining the blood of rats by dark ground illumination. Twenty-three rats (all *Rattus norvegicus*) were thus examined. Results were as follows:—

	No. examined.	No positive for <i>Spirillum minus</i> .
From Kidderpore ..	7	3
From Princep Street area.	6	1
From sweepers' quarters at the Medi- cal College.	8	0
From Belgachia ..	2	1
TOTAL ..	23	5

This table shows the great superiority of the dark ground method of examination to simple examination of a stained blood film. It also shows how heavy is the percentage of infection with *Spirillum minus* in rats in certain areas of Calcutta city—especially the area around Kidderpore docks.

It is this fact that explains why rat-bite fever is a relatively frequent disease in Calcutta.

SUMMARY.

(1) We believe rat-bite fever to be quite a common disease in India. It is very prevalent in Calcutta, and some 30 to 35 cases have been seen by the authors during the last five years.

(2) Details are given in the present paper of 28 cases especially studied by laboratory methods; also a review of the previous literature on the disease as it occurs in India. Clinically these cases are typical of the disease as seen in other countries.

(3) The diagnosis is usually a straightforward matter, but the initial lesion may occasionally be of a trivial character and this may lead to confusion with filariasis, filarial lymphangitis, relapsing fever, malaria, and erysipelas.

(4) In the laboratory the best methods of establishing the diagnosis are (a) examination of the serous exudate from the local lesion under the dark ground microscope, and (b) inoculation of the patient's blood into white mice and guinea-pigs. The latter method was successful in our hands in 23 out of 26 cases in which it was tried.

(5) A description is given of the disease as it occurs in laboratory animals, and of the methods of examining them. Again, examination of the blood under the dark ground microscope gives much better results than the examination of stained thin blood films.

(6) The morphology of *Spirillum minus* is discussed. Tribondeau's modification of Fontana's stain is recommended for bringing out the terminal flagella of this organism.

(7) An examination of rats in Calcutta city (of species *Rattus norvegicus*) shows that a considerable proportion of them (5 out of 23 examined by the dark ground method) are infected, especially in the Kidderpore docks area.

We are much indebted to Mr. J. K. Mullick, artist to the Department, for copying out the temperature charts for publication, and for the colour plate which accompanies this paper.

ON ETHER BY THE OPEN METHOD AS THE ANÆSTHETIC OF CHOICE IN INDIAN CONDITIONS.

By J. B. HANCE, M.A., M.D. (Cantab.), F.R.C.S.E.,

MAJOR, I.M.S.,

Jodhpur,

and

JOTI PERSHAD, L.M.P.,

Late S. A. S. I/C Operation Room and Anaesthetist, Hewson Hospital, Jodhpur.

THE superiority of ether administered by the "open" method over chloroform or "mixtures" as an anæsthetic in temperate climates is unchallenged; but conversation with many sceptical colleagues has convinced one of the writers that its cause needs pleading with surgeons in the Indian mofussil. The writers have no experience of conditions prevailing in the large hospitals of the Presidency towns; and if surgeons there employed are inclined to retort that Queen Anne is dead, they can only agree; but they plead in extenuation that the fact does not seem to enjoy general acceptance in the mofussil.

For over ten years one of the writers has insisted on the administration of open ether in every case where it was practicable and not contraindicated by the nature of the operation to be performed, and in climates varying from the Persian Plateau at 6,000 ft. elevation to the plains of the Derajat and Rajputana; and for a similar period he has enthusiastically championed its cause in conversation with the sceptical colleagues referred to, with more or less success. Objections to it have been raised on the score of expense, on the score of technical difficulties, and on the score that at high temperatures evaporation is so rapid that induction of anæsthesia is impossible.

The writers, on the other hand, claim that induction is not only possible but regularly practised, that the technical difficulties are very much fewer than those which attend the administration of chloroform, and that the very much greater margin of safety more than overrules the extra expense, if any. At the risk of being accused of vain repetition they would emphasise the obvious advantages of an anæsthetic which in physiological doses is a cardiac and respiratory stimulant instead of a depressant, which is associated with no delayed poisoning and which produces, relatively speaking, no ketosis. An additional advantage from the surgeon's point of view, is the greatly superior muscular relaxation obtainable on deep anæsthesia, while from the anæsthetist's side there is the possibility of accommodating the surgeon without risk to his patient, which the margin of safety in ether provides.

In order to substantiate their contention they kept careful records over a period of time extending from 17th November, 1926 to 28th August, 1927 of all operations performed under open ether anæsthesia.

These observations were designed so as to include both the cold weather and the hot weather and thus provide a standard of comparison; and in each case the nature of the operation, duration of anæsthesia, the amount of ether expended, and the temperature of the operating theatre were recorded, and the results are given in the attached tables.

In such a catholic series, classification is not easy, and in the present case the classification of the official annual return has been followed as closely as possible. Thus Table I gives a series of 11 cases in which the appendix was the main object of attack, but includes one gastro-enterostomy and one colostomy and a combined cholecystostomy and appendicectomy; while Table II gives a series of operations for hernia, but includes two epiploplexies.

Study of these records will, it is felt, completely dispose of the myth that open ether anæsthesia is impossible during the Indian hot weather; especially when it be remembered that operations are, when possible, performed before the heat of the day, and that even in the height of the hot weather, when shade temperatures vary between 110°F. and 118°F. or even higher, the temperature of the operating theatre seldom

the cost estimated; the price of ether having been taken at Rs. 3 per pound of 16 ounces. It will not, we think, be seriously urged that Re. 1-14 is an exorbitant price to pay for the additional safety to the patient and comfort to the operator in an operation for appendicitis lasting 50 minutes, performed on 6th May with a theatre temperature of 95°F.

For the benefit of those of our readers who may be inclined to agree with our contention a few words on the subjects of preparation and administration will perhaps not be out of place.

Preparation.—Where possible a light aperient is administered 36 hours before operation, and unless operation on the large intestine is anticipated, no further interference with the alimentary tract takes place. During the day prior to operation the patient is kept on a low residue diet, and glucose combined with large doses of alkali is generously administered. On the morning of operation food is withheld, but water, or better, 5 per cent. glucose in orange or lime squash is permitted. Half to three-quarters of an hour before operation the patient, if adult, receives a hypodermic injection of $\frac{1}{4}$ gr. morphia and 1/100 gr. atropin, which lessens anxiety and controls salivation.

reaches and practically never exceeds 100°F. —fortunately for the surgeon in his gown and mask! In the hot weather the expenditure of ether is, of course, greater, but the writers, on studying their records, have been surprised how small the difference actually is; while exactly the same applies to chloroform, with the additional factor of deterioration, which, in our experience, does not occur with ether.

With regard to expense, the average expenditure of ether has been struck for each series and

Administration.—The anæsthetic is administered with the apparatus designed by Dr. F. E. Shipway, Senior Anæsthetist to Guy's Hospital, of which the details can be seen in the accompanying photograph. The apparatus can be used for the administration of chloroform, C. E. mixture or pure ether by altering the control lever on the dial. The ether bottle stands in a metal reservoir which contains, in the cold weather, warm water to facilitate evaporation, and in the hot weather, freezing mixture to control it.

From thence it is conducted through water in a "Thermos" container kept at 90°F., so that, cold weather or hot, the ether vapour reaches the patient moist and warm—an important consideration in the prophylaxis of post-anæsthetic lung trouble. In practised hands induction by ether from the start yields the best results from the point of view both of the patient and the surgeon; but those starting this method of anæsthesia may find it convenient, at first, to induce with C. E. The writers deprecate induction with chloroform and maintenance with ether; in fact, generally speaking, the less chloroform that reaches the patients the more comfortable they are, and in the great majority of cases they avoid its use altogether. In only one of the cases recorded (Table I, case 1) was induction carried out with other than pure ether, and in this case the drug used for the purpose was C. E.

The patient having been placed on the table, a gamgee tissue mask, cut to expose nose and mouth, is placed over his face, and the Schimmelbusch mask with rubber ether connection placed on it so as to fit snugly but not uncomfortably. Induction is then commenced with vigorous but regular compression of the bellows at about 2 per second, the patient meanwhile breathing deeply. With the onset of the second stage, the Schimmelbusch mask is covered by the "concentrating mask" similar in structure to the face pad, but with a smaller central aperture, and surgical anæsthesia is rapidly and easily produced. The average induction time is about 7 minutes in a patient of temperate habits. Surgical anæsthesia having been secured it is maintained by about one pressure of the bellows per second, deepened, as required by the surgeon, by increasing the frequency of the ventilation; and when the patient is comfortably "under," administration is much simplified by the insertion of the "anæsthetic airway" in use at the Mayo Clinic, and obtainable from Messrs. Down Bros. This instrument, which combines the functions of keeping the tongue forward and the airway clear, is seen attached with tape to the anæsthetic table in the accompanying photograph, which shows Shipway's apparatus and masks in use.

With experience, the depth of the anæsthesia can be gauged almost entirely by the respiration; and the corneal reflex is only consulted at most twice or thrice at long intervals. In these circumstances it is a reliable guide, and not, as is often the case with chloroform administration, "fatigued" out of existence. When morphine has been administered prior to operation the anæsthesia should never be pushed to dilatation, the pupil being maintained contracted, and the corneal reflex just coming and going. In severe operations a slow stream of oxygen may be administered by the nasal catheter with great advantage, or the oxygen cylinder may be connected to the ether bottle and oxygenated ether administered direct. In these conditions vomiting on "coming round" is the exception, rather than

the rule, and the patient leaves the table with good pulse and colour.

Finally, reference must be made to post-anæsthetic respiratory troubles. On first adoption of this method of anæsthesia, the anæsthetist will be chagrined and exercised by the fact that some of his patients develop a sharp cough and congestion at the bases of their lungs. In some cases definite patches of consolidation will occur, and he may even lose an enfeebled or elderly patient in consequence. But with practice he will find that these complications grow very much rarer, and, in all ordinary routine cases, cease altogether. On reflection he will realise that the secret lies in *steady* administration. The inexperienced anæsthetist is continually consulting the pupil, with the result that his ether dosage is spasmodic. He omits to put in the airway, and has to grope after the tongue; the patient becomes "lighter" and the surgeon expresses himself with pungency and point. Result:—a frenzied pumping in of ether to bring the patient and the surgeon into the desired condition; and the patient, whose lungs have been relatively free of ether, receives a concentrated and irritating dose. Should such a contretemps occur, the wise anæsthetist will unobtrusively turn on the oxygen, and invent replies to subsequent enquiries regarding excessive expenditure of cylinders. With experience, however, he will find that close observation of the breathing combined with *regular* administration will keep the patient satisfactorily anæsthetised and obviate the necessity for these subterfuges, and reduce his post-anæsthetic lung complications to a negligible percentage.

Since the foregoing was written, one of the writers has had the opportunity of seeing in use the extremely ingenious apparatus for open ether designed by Captain C. V. Thornton, R.A.M.C. (ret'd.), in Bombay. This apparatus consists of a pear-shaped graduated glass reservoir connected by flexible rubber tube to a metal tap which is carried upon a stirrup fixed to a Schimmelbusch mask. Ether is thus delivered on to the mask by gravity, and the rate of flow is regulated by the metal tap which ensures an absolutely even administration. The mask is applied over a face pad similar to, but thicker than that in use by the writers. In place of the concentrating pad used by the latter, Dr. Thornton's Schimmelbusch mask is fitted with a metal cover which exposes only a small central area, cruciform in shape, of the lint.

The apparatus has the great advantage of ensuring absolutely regular administration and therefore of reducing the risk of lung complications to a minimum, and carries an attachment for oxygen if required. The climate of Bombay supplies the necessary warmth and moisture, and the anæsthesia, produced from the surgeon's point of view, is most satisfactory. Its only drawback appeared to be that evaporation cannot be controlled, as in Shipway's apparatus, by a water-bath, which would seem to render it relatively

more wasteful of ether. This would probably be an obstacle to its general employment in the plains of the north of India.

CONCLUSIONS.

1. That the administration of open ether is perfectly practicable, even in the Indian hot weather.

2. That its properties make it the anæsthetic of choice in all surgical procedures where its exhibition is not contra-indicated.

3. That the contra-indications are identical with those in temperate climates.

APPENDIX.

TABLE I.

Operations on the Stomach and Intestines, including Appendix.

No.	Date.	Class and sex of patient.	Nature of operation.	Duration of anæsthesia.	Quantity of ether used.	Temperature of theatre.
1	17-11-26	H. F.	Appendicectomy. Division of ileal and sigmoid kinks.	2 hours	9 ozs.	76° F.
2	8-4-27	H. M.	Appendicectomy and cholecystostomy.	2 hours	15 ozs.	86° F.
3	15-4-27	H. M.	Appendicectomy. Division of ileal kink.	1 hour 20 minutes	10 ozs.	90° F.
4	2-5-27	H. M.	Appendicectomy. Division of ileal kink.	1½ hours	12 ozs.	88° F.
5	6-5-27	H. M.	Appendicectomy	50 minutes	10 ozs.	95° F.
6	15-7-27	H. M.	Appendicectomy. Division of ileal and sigmoid kinks.	1 hour 50 minutes	8 ozs.	92° F.
7	26-7-27	H. M.	Appendicectomy	40 minutes	8 ozs.	90° F.
8	2-8-27	H. M.	Appendicectomy	45 minutes	6 ozs.	80° F.
9	2-5-27	H. M.	Appendicectomy	1½ hours	12 ozs.	88° F.
10	12-3-27	H. M.	Colostomy for intestinal obstruction.	1 hour	4 ozs.	88° F.
11	30-12-26	H. M.	Gastro-enterostomy	2 hours	10 ozs.	72° F.

Average ether used per head; 9.4 ozs.

Cost per operation, Re. 1-12-2.

TABLE II.

Operations on the Abdominal Wall and Cavity, Operations for External Hernia.

No.	Date.	Class and sex of patient.	Nature of operation.	Duration of anæsthesia.	Quantity of ether used.	Temperature of theatre.
1	18-11-26	H. M.	Right inguinal hernia (for radical cure).	½ hour	1½ ozs.	78° F.
2	4-12-26	H. M.	Right inguinal hernia (for radical cure).	1 hour	4 ozs.	74° F.
3	14-12-26	H. M.	Right inguinal hernia (for radical cure).	1½ hours	5 ozs.	72° F.
4	30-11-26	H. M.	Oblique inguinal hernia (omental) for radical cure.	45 minutes	4 ozs.	76° F.
5	17-12-26	H. M.	Right inguinal hernia (for radical cure).	45 minutes	5 ozs.	70° F.
6	24-2-27	H. M.	Double inguinal hernia (for radical cure).	1½ hours	6 ozs.	62° F.
7	15-3-27	H. M.	Right inguinal hernia (for radical cure).	1½ hours	8 ozs.	83° F.
8	15-4-27	H. M.	Double bubonocoele (for radical cure).	1½ hours	6 ozs.	96° F.
9	22-4-27	H. M.	Ventral hernia (for radical cure).	1½ hours	6 ozs.	94° F.
10	28-4-27	H. M.	Inguinal hernia (for strangulation).	40 minutes	10 ozs.	96° F.
11	15-4-27	H. M.	Inguinal hernia (for strangulation).	45 minutes	2 ozs.	92° F.
12	31-7-27	H. M.	Inguinal hernia (for strangulation).	40 minutes	5 ozs.	92° F.

TABLE II.—*Contd.*

No.	Date.	Class and sex of patient.	Nature of operation.	Duration of anæsthesia.	Quantity of ether used.	Temperature of theatre.
13	20-8-27	H. M.	Herniotomy, appendicectomy and incision of tunica vaginalis for hydrocele.	2 hours	12 ozs.	82° F.
14	3-6-27	H. M.	Oblique inguinal hernia.	8 ozs.	96° F.
15	23-8-27	H. M.	Bubonocoe both sides (for radical cure).	1½ hours	10 ozs.	82° F.
16	6-7-27	H. M.	Bubonocoe (for radical cure).	½ hour	8 ozs.	93° F.
17	6-7-27	H. M.	Inguinal hernia (for radical cure).	2 hours	8 ozs.	84° F.
18	20-7-27	H. M.	Laparotomy (for peritonitis).	1½ hours	10 ozs.	90° F.
19	31-3-27	H. M.	Laparotomy (for intestinal obstruction).	1 hour 20 minutes	12 ozs.	94° F.
20	23-2-27	H. M.	Epiploxy	20 minutes	1½ ozs.	64° F.
21	26-4-27	H. M.	Epiploxy	30 minutes	3 ozs.	96° F.

Average ether used per head: 6.5 ozs.
Cost per operation, Re. 1-2.

TABLE III.
Operations on the Rectum and Anus.

No.	Date.	Class and sex of patient.	Nature of operation.	Duration of anæsthesia.	Quantity of ether used.	Temperature of theatre.
1	7-12-26	H. M.	Removal of hæmorrhoids	20 minutes	4 ozs.	71° F.
2	14-12-26	H. M.	Removal of hæmorrhoids	30 minutes	3 ozs.	72° F.
3	16-12-26	H. M.	Removal of hæmorrhoids	25 minutes	2 ozs.	73° F.

Average ether used per head; 3 ozs.
Cost per operation, annas twelve only.

TABLE IV.
Operations on the Bladder and Prostate.

No.	Date.	Class and sex of patient.	Nature of operation.	Duration of anæsthesia.	Quantity of ether used.	Temperature of theatre.
1	30-11-26	H. M.	Litholapaxy	½ hour	4 ozs.	76° F.
2	4-1-27	H. M.	Litholapaxy	20 minutes	1½ ozs.	70° F.
3	27-1-27	H. M.	Litholapaxy	1 hour	6 ozs.	68° F.
4	29-1-27	H. M.	Suprapubic lithotomy	25 minutes	4 ozs.	70° F.
5	1-2-27	H. M.	Suprapubic lithotomy	25 minutes	2 ozs.	70° F.
6	23-2-27	H. M.	Suprapubic lithotomy	1 hour	3 ozs.	64° F.
7	20-2-27	H. M.	Litholapaxy	½ hour	3 ozs.	92° F.
8	13-4-27	H. M.	Litholapaxy	½ hour	4 ozs.	96° F.
9	1-5-27	H. M.	Litholapaxy	45 minutes	8 ozs.	70° F.
10	10-5-27	H. M.	Suprapubic cystotomy	45 minutes	10 ozs.	96° F.
11	9-7-27	H. M.	Litholapaxy	½ hour	5 ozs.	84° F.

13	27-7-27	H. M.	Litholapaxy	½ hour	8 ozs.	94° F.
14	15-3-27	H. M.	Suprapubic cystotomy	½ hour	4 ozs.	82° F.
15	30-3-27	H. M.	Litholapaxy	½ hour	6 ozs.	80° F.
16	25-5-27	H. M.	Litholapaxy	45 minutes	6 ozs.	100° F.
17	10-3-27	H. M.	Prostatectomy (open operation).	1½ hours	10 ozs.	84° F.
18	16-7-27	H. M.	Prostatectomy (open operation).	1 hour 50 minutes	8 ozs.	92° F.

Average ether used per head; 5.15 ozs.
Cost per operation, annas fifteen and pies six.

TABLE V.
Operations on the Male Generative Organs.

No.	Date.	Class and sex of patient.	Nature of operation.	Duration of anæsthesia.	Quantity of ether used.	Temperature of theatre.
1	16-2-27	H. M.	Double radical cure of hydrocele.	$\frac{1}{2}$ hour	4 ozs.	74° F.
2	21-7-27	H. M.	Radical cure of hydrocele.	$\frac{1}{2}$ hour	4 ozs.	92° F.
3	27-6-27	H. M.	Radical cure of hydrocele.	$\frac{1}{2}$ hour	8 ozs.	96° F.
4	24-4-27	H. M.	Complete amputation of the penis for epithelioma.	$\frac{1}{2}$ hour	3 ozs.	94° F.

Average ether used per head: 4.7 ozs.
Cost per operation, annas fifteen.

TABLE VI.
Operations on the Veins.

No.	Date.	Class and sex of patient.	Nature of operation.	Duration of anæsthesia.	Quantity of ether used.	Temperature of theatre.
1	29-3-27	H. M.	Removal of varicose veins of leg by dissection.	1 hour 20 minutes	12 ozs.	94° F.

Cost per operation, Rs. 2-4.

TABLE VII.
Operations on Tumours.

No.	Date.	Class and sex of patient.	Nature of operation.	Duration of anæsthesia.	Quantity of ether used.	Temperature of theatre.
1	31-12-26	H. F.	Removal by enucleation (fibroma left thigh).	2½ hours	10 ozs.	72° F.
2	21-12-26	H. F.	Excision of cancerous glands from axilla.	$\frac{1}{2}$ hour	3 ozs.	69° F.
3	15-2-27	H. F.	Radical excision of breast.	1½ hours	5 ozs.	70° F.
4	27-3-27	H. M.	Radical excision of breast.	1½ hours	6 ozs.	64° F.
5	24-3-27	H. F.	Excision of fibroma, abdominal wall.	$\frac{1}{2}$ hour	3 ozs.	88° F.
6	15-4-27	H. F.	Excision of soft fibroma foot.	1 hour	6 ozs.	96° F.

Average ether used per head: 5.5 ozs.
Cost per operation, annas fifteen.

TABLE VIII.
Operations on Lymphatics.

No.	Date.	Class and sex of patient.	Nature of operation.	Duration of anæsthesia.	Quantity of ether used.	Temperature of theatre.
1	21-7-27	H. M.	Excision of cancerous glands, both groins.	1½ hours	10 ozs.	92° F.
2	9-4-27	H. M.	Excision of cancerous glands.	$\frac{1}{2}$ hour	2 ozs.	83° F.
3	12-5-27	H. M.	Excision of cancerous glands, both groins and iliac fossa.	2 hours 10 minutes	14 ozs.	96° F.
4	6-5-27	H. M.	Removal of tuberculous glands, axilla.	$\frac{1}{2}$ hour	4 ozs.	90° F.
5	25-3-27	H. M.	Removal of tuberculous glands, axilla.	1 hour	6 ozs.	82° F.

Average ether used per head: 7.2 ozs.
Cost per operation, Re. 1-5.

TABLE IX.
Operations on Bones.

No.	Date.	Class and sex of patient.	Nature of operation.	Duration of anæsthesia.	Quantity of ether used.	Temperature of theatre.
1	22-12-26	H. M.	Sequestrotomy, for necrosed radius.	$\frac{1}{2}$ hour	3 ozs.	69° F.
2	18-2-27	H. M.	Plating of fractured clavicle.	1½ hours	7 ozs.	74° F.
3	8-3-27	H. M.	Plating of ununited fracture, left humerus.	1½ hours	10 ozs.	93° F.
4	4-7-27	H. M.	Plating of fractured radius.	1 hour	5 ozs.	93° F.
5	9-8-27	H. M.	Sequestrotomy. Right ulna for osteomyelitis.	$\frac{1}{2}$ hour	3 ozs.	93° F.

THE THERAPEUTIC ACTIVITY OF LIQUID PREPARATIONS OF ERGOT ON THE CALCUTTA MARKET.

By R. N. CHOPRA, M.A., M.D. (Cantab.),
LIEUTENANT-COLONEL, I.M.S.,
and

PREMANKUR DE, B.Sc., M.B. (Cal.), M.R.C.P. (Edin.).
(From the Department of Pharmacology, School of Tropical Medicine, Calcutta.)

As early as 1859 Büchheim stated that the activity of ergot varied a great deal. He said

that ergot from wet places is inactive, while preparations made from active ergot lose their activity and that no method of producing a staple preparation was known. He, therefore, preferred to administer the drug in the form of a powder and gave it in 15 to 20 grain doses every 15 to 20 minutes, until the desired action occurred. The position to-day is similar and many liquid preparations of ergot on the market are pharmacologically and therapeutically quite inert. Last year Prof. A. J. Clark(1) in a paper entitled "Do the pharmacopœial preparations of

ergot contain any active principles?" pointed out that the preparations of ergot, described in the *British Pharmacopæia*, cannot contain more than traces of the active principles. It is well known that the active principles of ergot can be divided into two main groups:—

- (1) The specific alkaloids, ergotoxin and ergotamin, which have the same action.
- (2) A number of non-specific substances which are mostly products of protein break-down, etc. These include bodies like tyramin, histamin, agmatin, cholin, acetyl-cholin, methylamin, ethylamin, etc.

It is an established fact that the therapeutic action of ergot, when given by the mouth, depends on the specific alkaloids present in it and not on the large number of non-specific amines. These latter bodies are not absorbed into the circulation and produce little or no systemic action when given in ordinary doses by the oral route. Clark has shown that while 15 mgm. of

ergot in a human being produced a marked fall of blood pressure, considerably larger doses would be required to produce the same effect when given orally. The reason is that the liver can break down tyramin and can store histamin. They fail, therefore, to get into the circulation.

It has been definitely proved that the method of preparation of both the solid and liquid extracts laid down in the *British Pharmacopæia* precludes there being anything but mere traces of these alkaloids. It is for this reason that the clinicians in this country have doubted the efficacy of these preparations and have shown a distinct preference for some of the preparations in the market manufactured by specially devised methods; extract of ergot prepared by the *United States Pharmacopæia* method are not generally easily available. As we have often been asked to express our opinion regarding the relative merits of these preparations, we undertook to determine the alkaloid content of a number of them bought at random from the Calcutta market. For the assay of the alkaloidal content we used the method described

Table showing the Alkaloid Content of Ergot Preparations on the Market.

Number.	Description of the sample assayed.	Amount of ergot preparation required to reverse the action of 0.1 c.c. of 1 in 1,000 solution of adrenalin.	Ergotoxin content.	REMARKS.
1	Sample prepared by <i>British Pharmacopæia</i> method.	1 c.c. of extract did not reverse.	Practically nil ..	
2	Do.	1 c.c. had a tendency to reverse.	Only traces of alkaloids	
3	Do.	1 c.c. did not reverse ..	Practically nil ..	
4	Do.	0.5 c.c. did not reverse	Do. ..	
5	Do.	0.5 c.c. did not reverse, but had a tendency to reverse.	Traces	
6	Sample prepared by a well-known Indian firm—not by <i>B. P.</i> method.	0.5 c.c. did not reverse, but had a tendency to reverse.	Do.	
7	Sample prepared by a well-known American firm—not by <i>B. P.</i> method.	0.075 reversed ..	0.0022 mgm. per c.c. ..	This preparation is one of those preferred by Calcutta practitioners.
8	Sample prepared by a well-known English firm by special method.	0.025 c.c. reversed ..	0.00664 mgm. per c.c. ..	Do.
9	Sample prepared by <i>U. S. P.</i> method.	0.015 c.c. reversed ..	0.01101 mgm. per c.c. ..	Specially prepared by Bengal Chemical & Pharmaceutical Works from Spanish ergot for our tests.
10	<i>Liq. Ergot Fortis</i> ..	0.02 c.c. reversed ..	0.0083 mgm. per c.c. ..	Prepared by Bengal Chemical & Pharmaceutical Works by the method described in this paper.
11	Do. ..	0.02 c.c. reversed ..	0.0083 mgm. per c.c. ..	Do.
	Do. ..	0.0225 c.c. reversed ..	0.00734 mgm. per c.c. ..	Do.

tyramin produce a distinct rise of blood pressure when injected subcutaneously in man, 200 mgm. by the mouth cause little or no action. Similarly, while 0.5 mgm. of histamin given intravenously in a cat or 2 to 4 mgm. subcutane-

ously in a human being produced a marked fall of blood pressure, considerably larger doses would be required to produce the same effect when given orally. The reason is that the liver can break down tyramin and can store histamin. They fail, therefore, to get into the circulation.

by Broom and Clark.(2) As many samples of different preparations as possible were assayed with different pieces of the same rabbit's uterus under similar conditions, so that the results obtained were comparable. The alkaloid content

was calculated from the amount of ergotoxin phosphate required to reverse completely the action of 0.1 c.c. of 1 in 1,000 solution of adrenalin. It is worthy of note here that both ergotoxin and ergotamin are effective in reversing the action of adrenalin on the rabbit's uterus, the latter being somewhat less powerful. The total alkaloids by this method are determined in terms of ergotoxin.

We further asked the Bengal Chemical and Pharmaceutical Works, Ltd. to prepare for us fresh extracts of ergot by the method laid down in the *United States Pharmacopæia* and, if possible, to devise a suitable method by which the alkaloidal contents could be increased in preparations. This they very kindly did, and we are greatly obliged to their head chemist, Mr. J. Lahiri, M.Sc., for his help and co-operation. This preparation was named *Liq. Ergot Fortis* and was prepared in the following way:—

"Ergot in 20 mesh powder is kept moistened with a sufficient quantity of 50 per cent. w/v alcohol and hydrochloric acid (the acid taken should be 0.5 per cent. HCl of the weight of ergot taken) for 48 hours, with occasional stirring and afterwards pressed. The liquor is set aside to be used afterwards.

The marc is repeatedly moistened with 50 per cent. w/v alcohol and pressed until exhausted. The pressed liquors from the repeated macerations are mixed together and distilled *in vacuo*. The thick magma left in the vacuum pan is mixed with the liquor that was kept aside and afterwards the whole of it is mixed with the requisite quantity of rectified alcohol and water, so as to bring the product 1 to 1 containing 82 per cent. proof-spirit as the spirit strength."

A perusal of the table will show that the extract of ergot, prepared by the method laid down in the *British Pharmacopæia* and offered for sale in Calcutta, contains little or no active alkaloid. The method laid down by the *United States Pharmacopæia* and some of the special methods, including that devised by the Bengal Chemical and Pharmaceutical Works Ltd. for *Liq. Ergot Fortis*, give a reasonable alkaloid content and should be therapeutically active.

EXPERIMENTS ON THE DIGESTIBILITY OF DIFFERENT KINDS OF RICE AND RICE PREPARATIONS.

By SHIAM NARAIN MATHUR, M.B., B.S.,

Lecturer in Physiology.

(From the Physiological Laboratory of the Medical College, Lucknow.)

For many centuries rice has been the staple article of food of most Indians. Very many improvements must have been made in the mode of its cultivation from time to time, so that to-day

such fine specimens of it are found, that no grain in the country can rival it in the dearness of its price. Its ancestral forms are also flourishing, which offer the cheapest food grain for the poorer classes. Some time ago, I carried on experiments on some 30 different kinds of rice available in the local market, and found that they vary very much in their digestibilities.

Experiments must also have been done in the past to determine the best method of preparing it for use at table from the economical, physiological and aesthetic points of view. Out of the various methods that must have been followed in the past, two of them are still prevalent, and have become more or less standardised. These are boiling and parching. The object of the present work was to determine which of these two methods is better suited to digestion. These experiments have been carried out with saliva in test-tubes, and it has been concluded that what is true of saliva is probably also true of other digestive enzymes.

Parched rice is the favourite food of the poorer classes, and for this reason only the cheapest kind of grain enters into its preparation. There are two chief ways in which it is parched. The product of one is the preparation called *kheel* or *lava*, and of the other *parmal* or *murmura*.

The method of experiment in brief is to take measured quantities of these substances, subject them to salivary digestion in test-tubes, and subsequently determine their sugar-content. I give below short reviews of some of the more important concluding experiments that I performed.

Experiment I.

Took 0.2 gms. each of

1. *Kheel*.
2. The same whole rice that is used in the preparation of *kheel*.

Rice was boiled in 4 c.c. of water over a water-bath for $3\frac{1}{4}$ of an hour. This time in the water-bath was found to be just more than sufficient to bring even the cheapest rice to the full boil (superior qualities take much less time). The water-bath was used for various reasons which need not be given. By the term "full" boil I mean the state when even the deepest interior of the grain becomes soft. When rice had been boiled it was cooled down to 40°C. In another tube was placed the weighed amount of *kheel*. Water was added to it, and it was made up to the same level as in the other tube. Half a c.c. of saliva was added to each tube. In this, as well as in other experiments, saliva was taken from the same person; no sialogogues were used. It was collected as it dribbled out from the mouth hanging low. As saliva is apt to differ in the content of its ptyalin, the active principle—at different times of the day it was, as far as possible, always taken at the same fixed hour every time. By the way, it was also noticed that it differed very little in its content of ptyalin from day to day when taken at the same fixed hour. The tubes were kept on a water-bath at 40°C.

and digestion was allowed to continue for half an hour. They were then taken out, and boiled to stop further action. Their contents were subsequently thoroughly ground in a mortar and more water added. The amount of reducing sugar formed was determined by the number of c.c. of Benedict's solution reduced. This was taken as the measure of the amount of digestion. The results were as follows:—

NUMBER OF C.C. OF BENEDICT'S SOLUTION REDUCED.

<i>Kheel.</i>	Rice.
41 c.c.	15.5 c.c.

Experiment II.

This experiment was carried out to determine whether boiling has any further effect on the velocity of digestion of *kheel*. It was observed that boiling did not enhance its digestibility any further.

Experiment III.

This experiment was carried out on *kheel*, and rice prepared from the same stock of rice with its husk intact. This time three substances were compared.

NUMBER OF C.C. OF BENEDICT'S SOLUTION REDUCED.

	5 min.	10 min.	15 min.	20 min.	25 min.	30 min.
Bazaar <i>Kheel</i>	26	36	39	40	40	40
<i>Kheel</i> rice (only husk removed) ..	1	1½	2	2½	3	4½
<i>Kheel</i> rice (broken into pieces) ..	7	15	18	19	20	21
Best market rice	9	18	23	24	24½	24½

- (1) *Kheel*.
- (2) Rice (only husk removed).
- (3) Rice (husk removed and broken into pieces before boiling).

six tubes of each substance were taken out during the course of half an hour. Their contents were thoroughly ground in a mortar and their sugar content determined as usual.

NUMBER OF C.C. OF BENEDICT'S SOLUTION REDUCED.

	5 min.	10 min.	15 min.	20 min.	25 min.	30 min.
<i>Kheel</i>	29	38	39	41	41	41
<i>Parmal</i>	27	37	39	40	41	41½

The results were:—

NUMBER OF C.C. OF BENEDICT'S SOLUTION REDUCED.

<i>Kheel.</i>	Rice (only husk removed).	Rice (broken into pieces).
35 c.c.	5 c.c.	19.5 c.c.

It may be mentioned here that *kheel* prepared in the laboratory was not as good as the bazaar substance. It did not puff to the same extent. Again rice No. 2 had its outer coat intact whereas during the usual husking process this outer coat

is broken at several places which exposes the more digestible interior. This probably is the reason for the discrepancy in the results. For a similar reason rice No. 3, which was broken into pieces, reduced a greater quantity of Benedict's solution.

Experiment IV.

This time comparison was made between the best market rice and bazaar *kheel*.

NUMBER OF C.C. OF BENEDICT'S SOLUTION REDUCED.

Best market rice.	Bazaar <i>Kheel</i> .
22 c.c.	41 c.c.

Experiment V.

Up to now all the digestions had been carried on for half an hour. A second series of experiments was now carried out to determine the velocity of digestion at different times during the course of half an hour. For each substance six tubes were taken and up to the stage of putting saliva into them were treated as those in the previous experiments. Afterwards, after every five minutes, one tube from each lot was taken out, boiled and put aside. In this way all the

Experiment VI.

This time an experiment was carried out to compare *kheel* and *parmal*, the two main preparations of parched rice.

Experiment VII.

As all the above experiments were carried out on different occasions, naturally every time different saliva was used. In spite of all these differences the results have been markedly uniform. However, to be doubly sure, some of the above experiments were repeated on one day on saliva taken from the same source.

The following substances were selected:—

NUMBER OF C.C. OF BENEDICT'S SOLUTION REDUCED.

	5 min.	10 min.	15 min.	20 min.	25 min.	30 min.
Bazaar <i>Kheel</i> ..	30	37	39	41	41	41
<i>Parmal</i>	26	35	37	38½	40½	41
<i>Kheel</i> (husk only removed) ..	1	1½	2	4	4½	5
<i>Kheel</i> rice (broken into pieces) ..	8	15	18	19	21	21½
Best market rice	7	18	18	24	24½	25

The above results can be seen at a glance by looking at the graph.

Curve A is that of *kheel*. It is at once evident that within the short space of 5 minutes its digestion has advanced remarkably. It has reduced as much as 30 c.c. Benedict's solution or, in other words, half of the total weight of *kheel* has been converted into sugar which came from its carbohydrate store (25 c.c. of Benedict's solution require 0.074 gms. of maltose, the sugar formed during salivary digestion, for its reduction); during the course of the next 25 minutes only 11 c.c. more of the solution will be reduced. In fact this number had been reached as early as 20 minutes and during the remaining 10 minutes

there was no further digestion. As will be remembered, we took only 0.2 gms. of *kheel* for our experiment and nearly 0.12 gms. have been already converted into maltose, the amount required for the number of c.c. of Benedict's solution reduced. This leaves us only 0.08 gms. more of the weight of *kheel* which has not been converted into sugar. Out of this nearly 0.04 gms. is non-carbohydrate material, water included. This leaves us 0.04 gms. of carbohydrate not acted upon by ptyalin of saliva. Has ptyalin become inactive, or is there no more available digestible carbohydrate material left? Boiling had no effect as will be remembered from experiment II. Possibly the ptyalin had become inactive. To test this a further experiment was carried out. Some more weight of *kheel* was added to the already digested material in the tube. Ptyalin was found to be still active as more reducing sugar was formed: 0.04 gms. out of 0.02 gms., or in other words 25 per cent. of the weight of *kheel* probably represents its indigestible fibrous or cellulose material. Possibly some of this indigestible material may be acted upon by the more active pancreatic ferment. Curve B shows the velocity of digestion of *parmal*. It closely follows the curve A. It is slightly lower in the beginning, reaching the same height as A after half an hour. It has a tendency to go still higher after that time. This indicates that it contains a higher percentage of digestible carbohydrate material than *kheel*. This point will be further discussed.

Curve C is from the best available market rice. Its curve is much lower than either of the above two curves. This contrast becomes much more evident when we come to the lowest curve E, the rice from which *kheel* and *parmal* are prepared. Curve D is from the same rice as E, but broken into pieces before boiling. This nearly follows C, the curve from the best available rice. This points to the desirability of breaking inferior kinds of rice into small particles if its digestibility is to be increased. The same advantage to some extent can also be

obtained by breaking the outermost fibrous coat at several places, and exposing the digestible interior to the action of digestive ferments. This also indicates that it is chiefly the outer fibrous coat which mostly obstructs the passage of ferments, and when it is broken up, even the most inferior kind of rice reaches the level of digestibility of the best market rice.

There is a belief prevalent amongst Indians, specially the *hakim* class, that *murmura* or *parmal* is an easily digestible food for patients with weak digestions. *Hakims* generally allow *murmura* to their patients when they will deny every other kind of food. This is particularly the case with children who are always found to be very fond of such things. This belief appears to be well founded. The above findings are only test-tube results. Results may be different when carried out in the tube of the alimentary canal. They will, however, be far more favourable for *kheel* and *parmal* and equally less favourable for boiled rice. *Kheel* and *parmal* being the most dry foods excite the largest amount of saliva, and being also the most starchy excite the largest amount of ferment secretion. Again psychical factors, not to be neglected, specially in salivary digestion, are also more favourable for parched rice than for inferior grades of boiled rice. During parching a special kind of agreeable flavour is developed in rice which is not originally present. This also is a greater factor in exciting a psychical flow. Boiled rice on the other hand is not only very insipid when it comes from cheap rice, but also being already semi-solid and taken in the form of a formed bolus is so easily and readily gulped down the oesophagus that saliva need not be secreted to make it moist, and the teeth and tongue come to help in mixing it with saliva and forming a bolus. This should give undue rest to the teeth which, from the lack of exercise and cleansing action of the large amount of watery saliva, should tend easily to become carious and fall out. *Kheel* and *parmal* not only excite large quantities of saliva, but are also thoroughly mixed with it by the grinding action of the teeth; this process being not only of great advantage in digestion, but also of great benefit to the teeth themselves.

In this connection I may also mention that a prejudice exists amongst *hakims* that whereas *parmal* or *murmura* are considered good for the patients, *kheel* is regarded otherwise. It is said to cause vague bowel troubles. As far as the digestibility is concerned, *kheel* is the most easily digestible of all the rice preparations. Its very rapid digestibility cannot be a factor in causing bowel troubles. Even if it were, it can be easily dismissed when we see that the favourite *murmura* is not far behind it. Both *kheel* and *parmal* are prepared from the same kind of inferior grain. The difference probably lies in the mode of their preparation. If we peel off the outer husk from the grain, rice is still found to be covered by a fibrous coat which is nominal in the

case of the superior grades, and tough in case of the inferior. This tough covering is much broken during the husking process. During the parching of *kheel*, although the starch granules are thoroughly exposed, the tough outer covering remains adhering to them. This becomes tougher still during parching, probably on account of the larger percentage of proteins in it which get coagulated inside the tough cellulose covering, and glue the fibres closer still. These proteins get less digestible after boiling. For a similar reason they should get even less digestible after parching. For all these reasons the fibrous outer covering which remains adhering to *kheel* may be found irritating to the stomach of patients with a delicate digestion. As will be remembered, quite a large percentage of the total weight of *kheel* is, or is rendered, indigestible with saliva during parching. This possibly may set up the irritation which is alleged to follow its use. This tough covering is wanting in *murmura* which for this reason is not found irritating. This also is the reason for its containing a higher percentage of digestible carbohydrate material. If *kheel* were prepared from better kinds of rice, or with an improved method of parching which would remove its tough covering, it should be considered the most easily digestible of rice preparations, and could safely be recommended to patients with weak digestions in preference to even *parmal* which, in the meantime, should be considered a very desirable food for patients with weak digestions.

Why is parched grain so easily digested? I give the following reasons for this fact:—

(1) In parched rice the starch grains are completely exposed from their cellulose coverings and are lying completely outside as evidenced under the microscope.

(2) In *kheel* all the starch is converted into dextrin, an intermediate product of digestion of starch. In *parmal* also the greater part of the starch is converted into dextrin, and the remainder into soluble starch. This can be easily demonstrated by staining the granules with iodine and examining under the microscope. Parched rice thus gets a big start beforehand. This is not the case with boiled rice. There is a third factor also which, when present, should still further turn the scales in favour of parched grain and this is its dry nature. As mentioned previously, this provokes a large flow of active saliva and, on account of its containing in its meshes no water but only air, ferments should reach in no time to its deepest interior. This is not possible with boiled rice, where ferments not only will take much time to displace water, but will also be diluted by it. In my test-tube experiments this factor was not present as I had intentionally added water, for comparison was required between parched rice and boiled rice under exactly similar conditions. This factor, however, is prominently present in the mouth.

Similar experiments were carried out with other parched grains such as gram and maize, and in every case the starch contents were rendered much more rapidly digestible.

At the advice of Dr. Burrige to whom I am extremely grateful I carried on some feeding experiments on healthy people to see which of the two preparations of parched rice, *kheel* and *parmal*, leaves the greater residue in fæces.

Before starting the experiments, the fæces of the subjects on whom feeding experiments were to be done were examined both macroscopically and microscopically. Their insoluble residues were identified, which consisted mostly of wheat bran and green vegetable and fruit fibres. They were then fed on *murmura* and *kheel* alternately and their fæces examined on subsequent days. Milk was allowed to them but no other food was given. During their feeds they were also made to swallow small muslin bags containing measured quantities of *kheel* and *parmal*. The contents of the bags as they passed out were separately examined and the weights of the residue determined. The results were more or less uniform and confirmed my findings in the test-tube experiments. In every case a much larger and also coarser residue came out after feeding with *kheel*. In the case of *parmal* the residue was much less and finer. None of the subjects' staple diet was rice. The residue after *parmal* was much finer than the residue of wheat on their ordinary diet; but the residue of *kheel* was even coarser than that of wheat. In the case of *kheel* about 8 per cent. of the weight came out as insoluble fibrous matter, whereas it was only a little over 1 per cent. in the case of *parmal*. This points to the superiority of *parmal* over *kheel*, but if the latter were prepared from better grain and with improved technique this drawback should completely disappear, and *kheel* should be counted even better than *parmal*.

These preparations should form a very good diet for the patient who is allowed only small quantities of easily digestible food at a time. These articles being very bulky only small quantities should be easily satisfying and filling.

SUMMARY.

1. Experiments have been carried out on the digestibility of rice and its different preparations in saliva.
2. Parched rice has been compared with boiled rice.
3. Parched rice has been shown to be an easily digestible food.
4. Of the two main preparations of parched rice, *kheel* is more easily digestible than *parmal*, but contains a larger proportion of indigestible material which may cause some trouble if the digestive system is not properly working.
5. Other parched grains are also rendered easily digestible as far as their starch is concerned.

6. It is conjectured that protein is rendered less digestible after parching.

CONCLUSION.

Murmura is a good food for weak digestions more especially when prepared from better kinds of grain.

In conclusion I have again to tender my grateful thanks to Dr. Burrige for his invaluable advice, suggestions and criticism.

RADIOGRAPHY AS A HELP TO CORRECT DIAGNOSIS IN TRAUMATIC LESIONS.

By NISANATH GHOSH,

Teacher and Radiologist, Medical School, Dibrugarh, Assam.

RADIOGRAPHY is a valuable aid to diagnosis, both positive and negative, by rendering visible invisible parts. It is especially useful to the general practitioner in the correct diagnosis of such traumatic lesions as fractures and dislocations. Such lesions may and often do exist where they are least suspected. On the other hand, they may not exist at all when strongly suspected. Fractures without crepitus, without obvious deformity or change in measurements, are not uncommon.

Four such confusing cases came to my notice within nine months out of a total of 89 cases of fractures and dislocations examined by X-rays. This works out at 3.37 per cent. Short notes of these cases with X-ray prints are as follows:—

No. I.

Case 1.—The patient, K. B., male, aged about 40 years, was admitted on 19th December, 1927, with a history of a fall from a height of about 15 feet and pain in his left ankle. Clinical examination showed no crepitus, no change in the length of the limb and no deformity. There was slight swelling on the medial aspect of the ankle-joint. Some trouble in the joint itself was suspected and he was sent for X-ray examination. This revealed fracture lines running through the calcaneus (*vide* Skiagram No. I).

No. II.

Case 2.—Patient, K. G., Hindu female, aged about 40 years, was admitted on 27th February, 1928,

flexion and inversion—the patient being able to move about though complaining of pain. There was no swelling, but slight tenderness on the back of the thigh. Two possibilities were suggested:—dorsal dislocation of the hip-joint and sciatica. But X-ray examination disproved both and disclosed impacted fracture of the neck of the femur (*vide* Skiagram No. II).

Case 3.—This case is the reverse of the first two. About five months ago, a policeman was sent in with a history of injury in his right thumb and deformity highly suggestive of dislocation. Reduction under chloroform was decided upon after X-ray examination, when, to the surprise of all, the bones and joints were found normal.

Case 4.—Patient, a young man of 24, a football player, had a fall in a football match, but went on playing for about five minutes more and then retired from the field owing to intense pain in the knee (right). He was unable to walk for about a week and was treated as a case of sprained knee. After that he was limping about and sometimes rode a bicycle even. The pain, however, persisted. About three weeks after the injury he sought X-ray-aid and two fracture-lines in the upper end of the tibia (right) without displacement of fragments, and without deformity or change in the length of the limb were revealed (*vide* Skiagram No. III).

These cases point to the absolute necessity of X-ray examination, where facilities exist, as a routine method of diagnosis. It must be admitted, however, that such facilities exist in very few towns of India not to speak of villages where

No. III.

with a history of a fall about three weeks before, with pain in the left hip-joint. Clinical examination showed slight shortening ($\frac{1}{2}$ inch) of the limb with a little

even a microscope is a rare curiosity for miles around.

Indian Medical Gazette.

SEPTEMBER.

LIVER TREATMENT OF PERNICIOUS ANÆMIA.

THE study of tropical diseases is a comparatively young branch of Western medical science, it is, therefore, not surprising that almost yearly some definite advance is made in the treatment of these diseases. With diseases of the temperate zones, however, the position is different; the study of these diseases was placed on a scientific basis many years ago and, whenever new scientific methods have been introduced, they have been applied to the study of medicine. It cannot be said that during these years no stones have been left unturned, but certainly all the largest and most promising stones have been turned. It is to be expected, therefore, that dramatic discoveries, which place in the hands of the medical profession a means of treating a disease for which previously there was no treatment, or only very unsatisfactory treatment, are made only at long intervals. There are, of course, the "great discoveries" which are boomed in the public press but of which, after a month or so, one hears no more. There are the fads and fashions of medicine which run their natural course and either fade away or take a very humble place in the textbooks, but genuine advances are few and far between. In recent years, the discovery of insulin constitutes a definite advance in our knowledge of the treatment of disease. It is not suggested that with its introduction the problem of the treatment of diabetes was settled, but many diabetics have been cured who would otherwise not have been cured, and the lives of others have been prolonged and made comparatively comfortable as a consequence of this discovery.

The introduction of liver in the treatment of pernicious anæmia must, we think, be looked upon as a definite advance. Minot and Murphy, who are mainly responsible for the introduction of this treatment, published their first paper about two years ago. The treatment has been used by a very large number of the leading physicians in Britain, America and the Continent. Opinions as to its value appear to be unanimous. In almost every case of the disease in which sufficient liver or liver extract has been administered, a remission has been produced. It is at present too early to be dogmatic, but the general impression of those who have used this treatment is that in many instances complete cure has been effected and that, in the majority of cases, the symptoms are unlikely to recur provided the patient continues to live on a diet containing a certain amount of liver. Until two years ago, the main lines of treatment advocated were rest in bed, the

administration of arsenic, splenectomy and blood transfusion. The prognosis was always bad and the majority of the patients died in one to three years; some writers went as far as stating that if the patient did recover, it was because the diagnosis was wrong. The position is now reversed and recently it has been said that the reason for the failure of the liver treatment which has been reported in a small percentage of cases is due to a mistake in the diagnosis.

The diet advocated consists of plenty of lightly cooked red meat, from 4 to 8 ounces of liver, preferably mutton or beef liver, to be raw, lightly cooked or even made into soup, but prolonged boiling should be avoided, plenty of fresh green vegetables and as much fruit as possible; fats should be avoided, so that only a limited supply of milk and butter is allowed. Tea and coffee may be taken and a reasonable amount of sugar. The carbohydrate intake is not limited provided it does not interfere with the consumption of the prescribed amount of proteins.

The essential part of this diet appears to be the liver. Recent work has shown that a water-soluble extract of liver is as efficacious as the liver itself, and the extract has the definite advantage that it can be taken in much larger quantities. In many cases no other form of treatment is necessary, but where there is any definite focus of infection, as for example in the intestinal tract, treatment for this should also be given, and in the majority of cases it is advisable to give hydrochloric acid. In cases that first come under treatment in an advanced stage of the disease, it may be necessary to give a blood transfusion in order to improve the patient's condition sufficiently for him to digest the necessary amount of liver.

Pernicious anæmia is universally recognised as a definite clinical syndrome with more or less constant pathological changes, but the ætiology of the disease is not known and it is usually admitted that it is not a constant factor. Malaria, sprue, hookworm disease and *Bothriocephalus latus* infection are said to be amongst the ætiological factors. Achlorhydria is a constant factor and this is usually associated with intestinal sepsis. One school considers that the disease is due to an inherent defect in the blood-forming organs, whereas another considers that it is due to general septic absorption from the bowel, or to poisoning by some specific organism, such as *B. welchii*. It is interesting, and almost amusing, that this latest advance is a treatment which is in no way dependent on new scientific methods, but consists in the regular consumption of an article of diet which has always been in common use amongst meat-eating races.

Now one of the most interesting points about the disease is that although the ætiological factor is not a constant one, the response to liver treatment appears to be constant and the one condition always associated with the disease and looked upon as a possible predisposing cause, namely, achlorhydria, is unaffected by the treatment. It seems likely that the treatment does not strike at

the root cause of the condition but inhibits blood destruction and, to a less extent, stimulates blood formation. So far the treatment has not proved successful in secondary anæmias or anæmias of the chlorotic type in Europe and America, but, nevertheless, these are possibilities for its wider application, especially in India where anæmia, much of which is of the pernicious type, is such a very common condition. The anæmia frequently disappears when the primary infection, malaria, hookworm, kala-azar, etc., is eradicated, but very frequently the patient remains in a weak anæmic condition for months and even years; in other instances the patient is so anæmic that it is impossible to give the full course of the treatment necessary to eradicate the primary infection. There are also many examples of anæmia with enlargement of the spleen of which the ætiology is doubtful. It will be extremely interesting to see the effect of the liver treatment in these conditions.

The orthodox Hindu would naturally be averse to this treatment in any form, and even the unorthodox would probably object to ingesting large quantities of beef liver, but this is not necessary; there is other liver which is almost equally efficacious. Furthermore, the extract of which there are many brands on the market, can be prescribed and taken by the patient in the form of a medicine.

A Mirror of Hospital Practice.

A CASE OF CONGENITAL STENOSIS OF THE PYLORUS TREATED BY RAMMSTEDT'S OPERATION.

By S. A. McSWINEY, M.B., B.Ch., F.R.C.S.I.,

MAJOR, I.M.S.,

Officiating Second Professor of Midwifery, Medical College, Calcutta and Second Surgeon, Eden Hospital, Calcutta.

CONGENITAL stenosis of the pylorus, although comparatively common in certain hospitals in England, is so uncommon in India that the following case seems worth recording: it is remarkable for the early onset and acuteness of the disease.

V. C. H., aged two weeks, European male child, was admitted on 1st July, 1926, to the children's ward of which I was then in charge, in the Presidency General Hospital, Calcutta.

The mother stated that the child had been vomiting for the past four days and that it was very constipated. The weight at birth had been 6½ lbs. It had been bottle-fed from the beginning. On admission it weighed 5½ lbs., otherwise ordinary physical examination was negative.

The combination of vomiting with constipation in a baby a few weeks old—especially a male baby—was so suggestive of congenital stenosis of the pylorus that when I saw the baby on the morning of the 2nd July, I decided to investigate it.

Visible peristalsis was seen without difficulty. (To elicit visible peristalsis, it is necessary to

have the baby fed and then examine it at once in a good light, when the waves will be seen passing from left to right in the epigastrium.) A little later the child vomited in my presence: the character was projectile, the contents being ejected 18 inches to two feet from the lips.

I was unable to satisfy myself as to the presence of the last sign, i.e., the presence of a tumour in the pyloric region.

Treatment by gastric lavage and small hourly feeds was tried for two days, the only result of which was a further loss in weight of 6 ozs.—making a total loss of 14 ozs. since birth. The vomiting was unaffected and the child was beginning to look very ill. It was, therefore, decided to do Rammstedt's operation, which consists in dividing the muscular coat of the pylorus down to the mucous membrane.

The operation was done on 5th July, 1926, and the diagnosis was confirmed. The baby took the anæsthetic (A. C. E.) very badly. The mucous membrane of the duodenum was accidentally opened. It was closed by four catgut sutures. There was profound shock after the operation and, during the following three days, the temperature reached 103° or 104°.

Vomiting ceased the day after the operation and, with the exception of some suppuration in the wound, recovery was steady. The after-treatment is of the greatest importance. It consists of very small frequent feeds which are begun almost at once; the amount is increased daily and given at gradually increasing intervals. He was discharged from hospital on 31st August, by which time his weight had increased by 24 ozs.

The child was brought to me again on 2nd July, 1928, i.e., two years later. He has had no trouble since the operation except ordinary minor ailments.

While attending Great Ormond Street Hospital for sick children in 1927, I was struck by the frequency with which congenital stenosis of the pylorus is met with there. They have practically abandoned every treatment except Rammstedt's operation. I learnt from the various members of the staff that:—

1. The mortality has been greatly reduced since they adopted gas and oxygen as the anæsthetic.

2. Opening the mucous membrane of the duodenum is not an uncommon accident, but is not of very great importance so long as it is recognised and sewn up again. This danger can be greatly lessened by using a blunt dissector to increase and deepen the incision over the pylorus until the mucous membrane is seen to bulge into the wound.

3. Hyperpyrexia used to give trouble until they reduced to a minimum the use of hot-bottles after the operation.

I should like to thank Lt.-Col. A. H. Proctor, I.M.S., and Major H. G. Alexander, I.M.S., for the assistance they gave me in dealing with the case.

A CASE OF INFANTILE SCURVY.

By S. A. McSWINEY, M.B., B.Ch., F.R.C.S.I.,
MAJOR, I.M.S.,

Officiating Second Professor of Midwifery, Medical College, Calcutta and Second Surgeon, Eden Hospital, Calcutta.

THE following case, which was admitted into the children's ward of the Presidency General Hospital when I was Resident Surgeon there, is of interest for the reason that the child was originally breast-fed and also that subsequently twelve months elapsed on diet sadly deficient in vitamin "C" before the symptoms appeared.

E. A., aged 1 year and 3 months, Anglo-Indian, female, was admitted on 16th December, 1925.

Feeding history.—Breast-fed for three months; boiled cow's milk and water for the next nine months; boiled cow's milk and *suji* for the last three months. Fruit juice was said to have been given about once a month! There were hæmorrhages into the left eyelid and gums and a firm tender swelling over the lower third of the left femur. The child screamed if it was handled or expected to be handled, i.e., if one turned back the bed clothes.

Diagnosis.—Infantile scurvy. X-ray of the left femur showed an extensive subperiosteal hæmorrhage in the lower third.

Treatment consisted of fruit juice, "potato-cream" and cod-liver oil. By the 10th of January, the child was the most happy smiling child in the ward. The hæmorrhages had disappeared from the eyelid and gums and the swelling on the femur was very much less. When she was about to be discharged she contracted measles, but her further recovery was uneventful.

STONE IN THE BLADDER.

By S. Y. SHAIKH, L.C.P.S.,

Second Assistant, Civil Hospital, Nasik.

A MAN, aged 30, was admitted into this hospital on 24th March, 1928, for stone in the bladder. On 26th March, 1928, he was anaesthetised for litholapaxy. In trying to crush the stone I felt a few pieces of some soft material in the bladder. I caught one in the lithotrite and pulled it out. It was a piece of stick $6\frac{3}{4}$ inches long. Two other pieces were removed, one of them having some phosphatic deposit on it. The patient passed his urine quite comfortably the next day and was discharged on 28th March, 1928. On enquiry he told me that he pushed the stick in 3 months before when he could not pass his urine. The stick broke and in trying to get the broken piece out he lost two more bits of the stick which was a kind of reed. I have to thank Major Shah, I.M.S., Civil Surgeon, Nasik, for allowing me to do the operation and for permitting me to publish this note.

AN INTERESTING CASE OF STRANGULATED HERNIA.

By PROSAD GUPTA, L.M.P.,

Medical Officer In-Charge, Mallawan Dispensary, District Hardoi, U. P.

PANDIT, S. N., an old man of 80 years, had been suffering from left reducible inguinal hernia for about the last 25 years. One evening, while he was recovering from an acute attack of capillary bronchitis, I was called in to see him, as, all of a sudden, while defæcating, he got an excruciating pain over the left inguinal region with a mango-like tumour in the scrotum. I tried to reduce it by taxis, but failed in my attempts. I then explained to the patient and the relatives the nature of the disease and advised them to take him immediately to Sadar Hospital, Hardoi, or to the Medical College Hospital, Lucknow, for operation telling them that any delay on their part would make the case more hopeless. He took no notice of my advice and began Ayurvedic treatment.

After about 4 days I was again called in to see him, when I found his condition very grave with pain, bilious vomiting, hiccough, very weak, slow and intermittent pulse and marked emaciation. He was quite unfit to be taken out anywhere. His relatives told me to do whatever was possible for him in their place as they had lost every hope for his life and he was unfit for removal. I, immediately, on 5th September, 1927, put him under chloroform and ether anaesthesia and performed Bassini's operation under whatever aseptic precautions I could take in a poorly-equipped outlying dispensary. On cutting the strangulation the bowels were found cynosed and sanguinous fluid escaped. As gangrene had not actually set in, I returned the gut into the abdomen and sutured the wound putting a small rubber tube for drainage, which was removed later on.

The patient made an uneventful recovery except suppuration of 2 or 3 stitches and was discharged cured on 10th October, 1927.

After about a month I was again called to see him, when I found him suffering from excruciating pain just beneath the liver with a very tense abdominal wall. As I was just then going to the Sadar to give evidence in a medico-legal case, I advised the patient to accompany me for the civil surgeon's advice; they said they would bring him the next day, as they could not be ready in a minute.

On my coming back in the evening I heard that everything had subsided after a Vaid's local application. Just after the application he had very severe vomiting followed by complete recovery. I then told them that this must be nothing but a kinking of the gut somewhere inside the abdomen, which was reduced during the fit of vomiting. After about 3 or 4 weeks I was again called in to

see him for the same pain, but this time it was after they had tried the same Vaid's "lep" without any relief. As his abdominal wall over the site of the pain was very tense, I examined him under general anæsthesia. I could palpate an orange-like swelling and, while I was moving it to and fro for the sake of diagnosis, to my great astonishment the whole thing disappeared suddenly with a gurgling sound and the patient on coming round found that he had no pain at all.

This must have been a strangulated hernia somewhere inside the abdomen, probably through the foramen of Winslow. For about 5 months now he has been free from any further attack.

VOLVULUS OF THE SMALL INTESTINE.

By CAPTAIN R. P. GHOSH, M.B.,

Teacher of Surgery, Darbhanga Medical School,
Laheriasarai.

Volvulus of the small intestine is believed to be a rare condition—yet this forms the majority of the cases of intestinal obstruction which come to Laheriasarai hospital—the average of the volvulus cases being about a dozen a year. We have found practically the whole of the small intestine, both jejunum and ileum rotated, some cases having one twist only and others two. In almost every case we get a history of the abdomen having been massaged either by the fist or the heel being placed on the navel and then swung round; this method is supposed to be a cure for stomach ache which is described by the local Vaidas as "displacement of the bowels." During operation we have never found any adhesions fixing the gut and all that we do is to untwist the bowels, and let the colon fall into place. When the sigmoid becomes distended we put in a long rectal tube, guiding it to the pelvic colon with one hand inside the abdomen, and expel a good quantity of the intestinal contents through the tube. Although this process takes time, we prefer it to opening a loop of intestine. Shortly after the operation we give the patient pituitrin 1 c.c. and eserine gr. 1-100, hypodermically, and we repeat this every four hours until a satisfactory condition of the bowels is obtained. The result of this form of treatment has been very satisfactory; the recovery rate is almost 75 per cent.

My grateful thanks are due to my chief, Dr. S. M. Liversey, M.B., F.R.C.S., whose large practical experience of the treatment of such cases has been of great assistance to me.

A SECOND CASE OF MADURA FOOT TREATED BY CHEMOTHERAPY WITH APPARENT CURE.

By F. J. PALMER, F.R.C.S.I.,

LIEUTENANT-COLONEL, R.A.M.C. (Retd.),

Binnakandy, P. O. Silchar, Cachar, Assam.

In the *Indian Medical Gazette* of February 1926, the writer reported what he then considered

to be the first case of Madura foot successfully treated by chemotherapy. In a letter to the same journal in June 1926 Balfour pointed out that Audrain had reported a case as cured in the *Journal of the American Medical Association* for 14th October, 1924. The drugs used in Audrain's case had been neo-arsphenamin, and mercurochrome 220 soluble.

In a short paper on "Mycetoma" in the *Indian Medical Gazette* of November 1927 by Bradford and Vasudevan, the former writer is of opinion that drugs "smile but to deceive," and that early diagnosis and non-mutilative operation is still the best to be hoped for.

With this conclusion the writer cannot agree, as the following case will show.

H—, a villager, was first seen on 23rd August, 1926. He then exhibited a typical mycetomatous infiltration of the right leg and heel, discharging freely from numerous pouting sinuses, and with a similar lesion, ulcerating slightly, on the palmar surface of the forearm above the right wrist. The first photograph shows the leg with fungating sinuses at this time.

Before treatment with numerous discharging sinuses.

I determined to give a thorough trial to oral medication in this case, and selected for trial two drugs, zinc and copper citrate, which, in my hands, have produced good results in the treatment of several cases of leprosy, both producing reactions after oral administration with a minimum of trouble and discomfort.

Treatment was begun with 1 gr. of zinc citrate, twice daily for 14 days. The drug was then stopped for 10 days, and, at the end of that period, copper citrate given for another 14 days, with a ten-day intermission; after which the zinc salt was resumed. This treatment was persevered in for several months with marked improvement; most of the sinuses closing up, and the

lesion above the wrist being reduced to a barely perceptible induration.

After treatment with depressed pits where the sinuses had existed.

At the time when it looked as if treatment might be successful, the man absented himself for two months owing, as he stated, to an attack of dysentery, and when next seen it looked as if a drug-fast parasite might be developing. After a further trial of zinc and copper, it was recognised that the disease was advancing in spite of treatment, fresh ulcerating nodules appeared higher up the leg, and the indurations above the wrist increased and began to discharge.

Intravenous medication was then resorted to:—

31st October, 1927.—Gr. 2 Bismuth tartrate, intravenously.

9th November, 1927.—Much improved. No albumen. Gr. 3 Bismuth tartrate. I.V.

14th November, 1927.—Wrist all dried up and much less swollen, as is foot. No albumen. Last new centres of disease much shrunk, and some near heel closed.

28th November, 1927.—Improvement continued. No albumen. Gr. 3 Bismuth tartrate, intravenously.

6th December, 1927.—All new centres dried up. Gr. 3½ Bismuth tartrate. I.V.

12th December, 1927.—All healed. Leg slimmer. Gr. 1 Copper citrate, and Gr. 3 Sodium citrate. I.V.

No further treatment was given.

The photographs show the condition before and after treatment. For the second photograph the patient walked in 10 miles, and out again after it had been taken.

All sinuses healed. Foot much slimmer.

No induration above wrist or in spots where new foci had formed.

30th April, 1928.—Though patient has had no treatment for over four months, there is no sign of recrudescence.

22nd July, 1928.—Patient reported for inspection. No sign of recurrence so far.

One can only speak of apparent cure, as it is not yet certain that all foci are destroyed. Even if this is not the case, the effect of treatment has been so marked after a few doses intravenously, that it is not at all likely that a drug-fast parasite has developed, and there is every reason to believe that, should relapse occur, a further course of more intensive treatment on these lines, would produce a more permanent effect.

This case, I think, shows:—

(1) That though zinc and copper orally produced marked improvement, the action is not pronounced enough to lead to cure.

(2) The superiority of the intravenous route.

(3) The almost specific action of bismuth tartrate.

Only one dose of copper was given intravenously.

A CASE OF AURICULAR FIBRILLATION AFTER ASPIRIN.

By A. K. DUTT GUPTA, M.B., D.T.M. (Bengal),
Assistant Surgeon, Presidency General Hospital.

SOME people are said to be very intolerant to aspirin and similar preparations. The symptoms usually noticed according to standard books on pharmacology are dyspnoea, a condition of collapse with slow weak pulse and subnormal temperature, cyanosis, rash, and giddiness. The production of auricular fibrillation after its administration, in an apparently healthy heart, appears to be rare. The following case might, therefore, be of interest:—

E. M., aged about 50 years, was admitted with a history of low intermittent fever for 10 days, and high continuous fever with severe pain in the head, back and eyes for 2 days. Before admission he was doing ordinary office work regularly.

He gave a history of suffering from chronic bronchitis off and on for the last two years. His habits were sedentary. He took alcohol, about 6 peps a day, and cigarettes, 30 a day.

He had recently been examined by certain eminent physicians who had never found any cardiac derangement or impairment.

Before admission he had taken some caffeine for pain; this had caused excessive sweating.

On admission the temperature was fairly high, the pulse rate and respiration rate being consistent with it.

Systemic physical examination revealed only a slight emphysematous condition of the chest and harsh breath sounds. The heart was normal in size and regular.

He was put on to aspirin (Pulv. A. P. C.) 5 grains three times a day for the pain; after each dose he perspired excessively and felt bad.

Next day he had taken only 5 grains when he felt very bad. The pulse was weak and very irregular; auricular fibrillation had set in. Aspirin was stopped. Brandy 2 oz. in divided doses was given to combat the collapsed condition.

On the third day after admission the temperature came down to normal but the pulse, though stronger, was still very irregular.

On the fourth day, he was put on to full doses of digitalis and in two days time the pulse was regular again and the patient made an uneventful recovery.

The blood pressure was normal during the attack.

There was nothing in the pathological findings to suggest cardiac degeneration.

My grateful thanks are due to Major Murray, I.M.S., under whose care the patient was, for permission to publish these notes.

A FOREIGN BODY IN THE GLUTEAL REGION.

By JOGENDRA NATH PAUL, M.B.,

House Surgeon, Mayo Hospital, Surgeon-Superintendent's Ward, Calcutta.

THE following case is, I think, a sufficiently uncommon occurrence to warrant its publication.

Hindu female, aged 25, was admitted to hospital on 15th June, 1928, for a gluteal abscess on the left side.

On examination, the left nates was found to be inflamed. It was hard and brawny with very little fluctuation, but intensely tender. The abscess was pointing just above the ischial tuberosity. The patient's temperature was normal and there was no other trouble. The duration of the present complaint was one month.

Next day the abscess was opened under general anaesthesia, an incision being made over the most tender spot, but no pus was found. The incision was deepened but there was still no pus. A finger was then passed within the abscess cavity; this met with no resistance, but at a depth of about 2 inches it touched something hard which was freely moveable. The original incision was now prolonged and with a pair of pressure forceps a slender stem of a plant, 6 inches long, devoid of its bark and with marks of insertion of leaves at frequent intervals was withdrawn.

When she came round, the patient absolutely denied any knowledge as to how the stem got in. External mark of any injury was not to be found anywhere. Suspecting strongly that it had been an agent to relieve a gravid uterus, a vaginal examination was made. The following was the condition:—

Uterus retroverted, somewhat enlarged soft cervix, swollen lips admitted the tip of a finger. Slight seropurulent discharge was running out.

Culs clear, no thickening anywhere, on the posterior part of lateral vaginal wall on the left side a lacerated wound was discovered which was

raw and admitted the tip of a probe. The wound, however, was perfectly clean.

This discovery enabled me to put more direct questions to the patient. She then confessed to having passed this stick in order to get rid of the undesirable content of her uterus which had been worrying her for the last three months. Though the shot went wide—the game was nevertheless brought down and on the second day of her passing the stick evacuation of the uterus took place. The patient said she had a rise of temperature at the time and for seven subsequent days. Judging from the points of entry and of exit of the stick, it is conjectured that the stick must have been passed with some violence through the lateral vaginal wall (narrowly missing the pouch of Douglas) into the pelvis and through the great sciatic notch it had passed into the gluteal muscle and thence was trying to find a way out through the nates.

Hot vaginal douche with tincture of iodine, twice daily, was ordered; the patient made an uneventful recovery and was discharged cured on 1st July, 1928.

The following facts in this case are noteworthy and interesting:

1. The stick, though it missed the cervix, carried out its mission successfully.
2. The abnormal and tortuous course taken by the stick.
3. Perfect aseptic condition of the wound and of the whole tract it had traversed.

My thanks are due to our Resident Surgeon, Dr. S. C. Dutt, for his valuable suggestions as to the probable course taken by the stick and to our Surgeon-Superintendent, Major E. W. O'G. Kirwan, I.M.S., for his kind permission to publish this case.

SYMPTOMS SIMULATING CHOLERA, POSSIBLY CAUSED BY ROUND-WORM INFECTIONS.

By RASIK BEHARI LAL, L.M.P., P.S.M.S.,

Medical Officer, Cholera Duty,

District Gorakhpore, U. P.

I HAD the opportunity of visiting a village which was infected with cholera. There had been 4 deaths, including three children under four years of age. At the time of my visit I saw two females and one male child, four years of age, who were suffering from choleraic symptoms.

As I am at present concerned with only one case, that of the boy mentioned above, I will describe his symptoms in detail. The history of the boy, aged 4, was as follows:—

He had been suffering for 36 hours at the time I saw him with frequent motions and vomiting, marked thirst, and any water or food which was given to him was ejected immediately. He also complained of pain in the abdomen. The temperature was 99°F., pulse 140 per minute, very feeble and sometimes imperceptible, face anxious, eyes much sunken, and tongue quite clean. The boy was very restless, which gave one the idea that

he was having cramps. After a series of questions I found out that the motions were not watery and white, but were greenish and contained some mucus. The patient was put on essential oils mixture, 5ii every hour, this being the only available remedy on the spot, and the relatives were advised to give him nothing but permanganated water.

Next day when I saw the patient again, after 20 hours, during which time he had had 10 doses of the mixture, I found him no better. Vomiting and diarrhoea showed the same frequency, but the pulse was somewhat stronger and more regular. The relatives, who were very anxious about the child, told me that the child had passed a roundworm in one of his vomits.

As I had no santonine and I tried in vain to find pomegranate-bark, I had to be contented with gr. ii of calomel, which I gave in a single dose. After a few hours the child passed 2 motions, expelling 2 worms and his condition rapidly improved; vomiting ceased and by the third day the boy was quite well except for a little weakness. After calomel he was given no other medicine.

QUININE INTOLERANCE.

By BINODE KRISHNA BANERJI, M.B.,
S. C. Coomar Charitable Dispensary,
Chanditala (Hughli).

Case No. 1.—Patient, a younger brother of the writer, aged 30 years, had been suffering from frequent attacks of high fever of the malarial type, i.e., fever with rigors, temperature 104° to 105° , with bilious vomiting and profuse perspiration during remission, and coming regularly on alternate days. Blood examination showed a benign-tertian infection.

Patient has a history of anaphylactic symptoms for the last five years whenever a small dose of quinine is administered. He complains of creeping sensation in the fingers and toes, which gradually extends to the palm and the sole, and finally the whole part becomes slightly oedematous. At the same time he complains of acute pain in the abdomen and restlessness with profuse sweating. The sensation diminishes on the application of hot-water bottles. These symptoms generally last for 3 to 4 hours after the administration of the drug.

Quinine, cinchona, euquinine and aristochin have been tried without his knowledge even in gr. $\frac{1}{4}$ doses but have always been followed by the symptoms stated above. The fever persisted regularly and the spleen enlarged to $2\frac{1}{2}$ inches. He was being given injections of soamin and on one occasion 5 grains of quinine bi-hydrochloride has been tried intramuscularly without his knowledge (he was given to understand that it was nothing but the usual injection of soamin) and he at once developed those symptoms which lasted for nearly 8 hours during which the patient was in great agony.

Ultimately cinchona febrifuge was given in $\frac{1}{8}$ grain doses two and half hours after food—4 times a day and he tolerated some of the doses well.

From $\frac{1}{8}$ grain he began to tolerate $\frac{1}{4}$ grain— $\frac{1}{2}$ grain, $\frac{3}{4}$ grain and 1 gr. and gradually the drug was pushed up to $2\frac{1}{2}$ grains per dose. He took three doses of the above strength regularly for six months and got rid of the fever.

Case No. 2.—A lady, 25 years, had developed an attack of malarial fever almost of the same type as the first case. The anaphylactic symptoms in this case are as follows:—a few minutes after the administration of the smallest dose of quinine, cinchona, euquinine, etc., she complains of a feeling of warmth all over the body—the face becomes flushed and the whole body slightly red in colour; later an urticarial rash appears all over the body. The patient always wraps herself up with a piece of wet cloth with the onset of the symptoms which generally disappear in the course of 2 to 3 hours.

She was also given cinchona in gr. $\frac{1}{8}$ doses and ultimately tolerated $2\frac{1}{2}$ grains per dose—4 times a day.

In both these cases the malaria was of benign-tertian type.

Current Topics.

A Method of Treating Fractures of the Clavicle with Displacement.

By G. W. MILROY, M.B., Ch.B.
(*Brit. Med. Journ.*, April 21, 1928, p. 664.)

PROBABLY the most commonly used method of treating simple fractures of the clavicle with displacement is either that originally described by Sayre, or the bandage devised by Douglas. One great disadvantage of the former method of fixation is the fact that the strapping used to support the elbow so often slips over the point of the olecranon process, allowing the arm to drop, with recurrence of the original displacement.

In an endeavour to avoid this difficulty the plaster is sometimes applied with the adhesive side next to the skin. This certainly prevents any slipping, but it does not allow of accurate adjustment, and also gives rise to much discomfort, often amounting to actual pain, particularly around the point of the elbow. This pain seems to be equally severe whether a slit for the olecranon process is made in the plaster or not. If, on the other hand, Douglas's method of bandaging is employed, the original disadvantage is again evident. The bandage as a whole tends to become loose, and the final turns round the elbow and over the opposite shoulder slip off the elbow and allow the arm to drop. The bandage may remain in good position during the day, but when the patient is in bed, and particularly if he is somewhat restless, as these patients usually are, the bandage will soon work loose. It is a common experience to find a patient with a fractured clavicle, which has been reduced and firmly bandaged on one day, returning next morning with the bandage loose and the deformity renewed.

To overcome these difficulties I have been using a modification of Sayre's method which has given great satisfaction. The method devised is as follows:

Two five-foot lengths of calico bandage are required. The first, as in Sayre's original method, is looped loosely

round the affected arm as high up as possible, the loop being fastened with a safety-pin. The usual pad is placed in the axilla, the shoulder is pulled back as far as possible, and the bandage is carried across the back of the trunk, round across the chest, and pinned to itself just beyond the loop round the arm.

The second bandage, which should be at least six inches wide, is slit from one end for a little less than half its length, and is then applied to the injured arm in the form of a sling, with the two tails to the front, in the following manner. The uncut end of the bandage runs from the unaffected shoulder across the back to the elbow of the affected arm, which it supports, a pad of wool being placed between it and the olecranon. The bandage is adjusted in such a way that the two tails originate an inch or so in front of the point of the elbow. These tails are then carried round opposite sides of the forearm, and are twisted together once or twice as near to the bend of the elbow as is possible. They are then carried forward as spirals in opposite directions round the forearm, thus crossing on the dorsal aspect of the middle of the forearm, and also at the front of the wrist, where they are again twisted together and carried on as one to the shoulder. The elbow is then drawn upwards, forwards, and inwards to the required position, and secured by tying the ends of the "sling" over the unaffected shoulder. The sling effect of the second bandage has been found to be very stable; the first loop of the tails round the forearm just beyond the elbow effectively prevents any slipping off the elbow.

The spiral round the forearm will be found to support the forearm comfortably in the usual position across the chest, and the combination of the two bandages and the axillary pad will supply the forces necessary to carry the lateral fragment of the clavicle upwards, backwards, and laterally, which is so essential for a perfect result in these cases.

The Value of Bismuth Therapy in Syphilis.

By C. LEVADITI

and

L. FOURNIER.

(*Lancet*, April 7, 1928, p. 692.)

THESE authors arrive at the following conclusions:—

(1) Bismuth-stovarsol administered by mouth, whether in solution or in the solid form, is perfectly well tolerated in doses of 2 g. daily for a period of 8–11 days. Even with this very considerable dosage, corresponding to 0.82 g. of Bi. and 0.3 g. As. per day, we have never observed any digestive or other disturbance worthy of note, with the exception of two cases, in which a generalised erythema appeared but quickly subsided.

(2) Cases of primary and secondary syphilis, in which the serological reactions were strongly positive and spirochaetes were demonstrably present, have shown rapid disappearance of the spirochaetes and prompt cicatisation of the lesions. The rash has disappeared in from 10–12 days, and the lesions have been cured in about 13 days.

(3) Under the influence of the treatment, exclusively by the mouth, the serological reactions become more or less rapidly negative whatever the reaction employed (Bauer-Hecht, Wassermann, Calmette-Massol, or Vernes' flocculation reaction). In certain cases they remained negative for a long period without any further treatment.

Admittedly our cases are few, and the time is too short to permit us to judge definitely of the therapeutic value of bismuth-stovarsol administered by mouth. Nevertheless, it is not going too far to suggest, from the actual clinical records, the usefulness of this method of treatment in all syphilitic cases where treatment by injection is contra-indicated, or where it is necessary to employ a method of treatment which is convenient and well tolerated by the patient.

Chemotherapy.*

By PROFESSOR BERNARDT NOCHT.

(*Trans. Roy. Soc. Trop. Med. and Hyg.*,

Vol. XXI, No. 5, Feb. 1928, p. 397.)

THERAPEUTIC science and therapeutical measures in general are based on two principles. We distinguish between symptomatic and ætiologic therapy. Symptomatic therapy is older and more used in general practice; causal therapy is of a more recent date, although already physicians in the past, Paracelsus for instance, designated as the principal aim of therapy the finding of "Arcana"—curatives against the causes of disease, not against its symptoms. But the beginning of real efficacious ætiologic therapy is of most recent date. Causal therapy is a child of bacteriology and general microbiology. We know now a great many sera and vaccines against infectious diseases and we are using them on a large scale as prophylactic and therapeutic agents against many infectious disease. But we are not able to apply this vaccinotherapy and serumtherapy against all infectious diseases, since there are many without a satisfying and applicable production of protecting sera and vaccines.

Particularly do protozoal infections belong to this category, and we would remain in a very awkward position regarding the therapy of and the campaign against these diseases if chemotherapy had not been invented. Its inventor is Paul Ehrlich.

Chemotherapy is not a general therapy with synthetic chemicals in contrast to therapy with pharmaceutical products derived from minerals, plants, or animals, and offered by nature. General therapy with artificially produced chemicals is of very old date; mercury, bismuth, and arsenical and antimonial compounds have been used for centuries in symptomatic therapy. But there is fundamentally no difference between long used chemicals of this kind and modern compounds like antipyrin, aspirin, soporific and hypnotic modern drugs, etc. They have been, and still are, employed against symptoms, not against the causes of the diseases. *Chemotherapy is ætiologic therapy with synthetic chemicals.* In regard to its end effect chemotherapy may also be called "internal disinfection," but this characterisation can only be applied to chemotherapeutic agents which have a direct bactericidal action in the body. But in most cases the action of chemotherapeutic bodies is not directly bactericidal, but is of a rather complicated nature. Further, there exists, of course, a great difference between external and internal disinfection. In external disinfection the chemical compounds at our disposal exercise without exception a general poisoning action against living matter, be it as micro-organisms or as living cells of the body or of any other kind. The aim of internal disinfection is the finding of compounds which may act in the body in a specific elective manner, so that they cause as little injury as possible to the cells and tissues of the body and act as a poison only against the pathogenic microbes in the body. With Ehrlich we have to distinguish between organotropy and parasitotropy in dealing with chemicals introduced into the infected body. The ratio between the organotropic and the parasitotropic action of a chemotherapeutic substance is called its "therapeutic index" or "therapeutic ratio." The greater the difference between organotropic and parasitotropic efficacy, the greater the therapeutic ratio and the better the remedy. The ideal aim is to find compounds without any action on the body combined with a prompt parasitocidal effect.

The Theory of Chemotherapy.

Chemotherapeutic substances are, in general, compounds of a rather complicated structure, with one or several nuclei and side chains amongst which Ehrlich

*Lecture given at the International Continuation Course in Public Health, 28th November, 1927.—*League of Nations.*

distinguished haptophoric and toxophoric groups. The haptophoric groups attach themselves by chemical affinity to certain groups in the parasites, Ehrlich's chemoreceptors; once attached, they bring the toxophoric groups also into action in the parasites.

This theory has proved very fertile, it has had a great heuristic value; but the number of chemotherapeutic agents really acting in this manner seems to be rather limited. It is very probable that some arsenicals (such as salvarsan and its derivatives, antimony compounds, and "Bayer 205") may directly damage certain microorganisms in the body, but on the whole the question is not yet settled. Recently investigators have observed that salvarsan, for instance, after being absorbed by erythrocytes or other cells has a better action on spirochaetes than usual. Therefore it seems probable that, at least within certain limits, there does not exist an antagonism in this case between organotropic and parasitotropic action. Besides, we can observe only in exceptional cases a really direct bactericidal or parasitocidal action of chemotherapeutic agents. In most cases they only damage the parasites, they are *parasitotoxic* not *parasitocidal*, impairing the motility or prohibiting division and multiplication of the parasites. The final death of these is due to the action of the infected body itself. Therefore *therapia magna sterilisans* is still an ideal aim not yet arrived at.

Parasitotoxic action is greatly enhanced by a combined use of different chemotherapeutic substances, which attack the parasites at the same time from different points. So, in many cases of syphilis, a combination of salvarsan with bismuth or hydrargyrum has proved very efficacious. As for malaria, quinine plus stovarsol has a very good effect in subtertian infection. The same applies to plasmochinum compositum, that is, plasmochin plus quinine in subtertian malaria.

The mechanism of the action of quinine in malaria is not yet completely clear. The observation that malarial infection may be obtained by injecting blood containing malaria parasites—but having been in contact with quinine outside the body in a concentration of 1/5000 for some hours—seems to be in contradiction to the theory of a direct action of quinine on malaria parasites. This has to be stated, although there have been put forward explanations of this phenomenon which are still in compliance with the theory of a direct action of quinine on malaria parasites. But in any event it is proven that quinine has a much greater effect in malaria when the patients have, to a certain degree, already developed some self-immunising power. It is true that the degree of self-immunisation which can be obtained in malaria is not strong enough to cure the patient thoroughly; but the effect of quinine is much better when administered after a certain number of attacks of fever, which implies a development of a certain degree of self-immunisation. This fact can be of practical value in the treatment of tertian fever, but in subtertian fever it would be rather dangerous to postpone the quinine treatment until after several attacks of fever, since any attack may cause the death of the patient. On the other side, it is well known that the resistant forces of the body, produced by the first series of febrile attacks, are very easily destroyed by injuries like chills or wetting by rain, by over-exertion, by faults in diet, alcoholic excesses, etc. These influences, almost regularly, cause re-appearance of fevers and relapses in infected persons. But it is not sufficiently known that quinine also can be a cause of the re-appearance of fever and of parasites in the blood. Quinine, when taken daily during weeks and months in rather large doses, very often ends in a chronic quinine intoxication, by which the powers of resistance of the body against recrudescence of the malarial infection are destroyed. Many so-called quinine resistant cases of malaria are due to chronic quinine intoxication. By discontinuing the quinine treatment, fever and parasites, hitherto so very obstinate against quinine, will disappear by themselves; and should a relapse appear, perhaps after several months, you will find that your so-called quinine resistant case is now answering in quite a satisfying manner

to the same moderate doses of quinine as does any case of malaria in general.

Of course a direct parasitotoxic action and a combined action of immunity and chemotherapy do not exclude each other, but they may not always combine in a favourable manner. Thus it seems that salvarsan acts much more quickly and that its effect is much stronger in the first period of syphilitic infection than later.

A third mode of action of chemotherapy is purely stimulant, namely by stimulation of the reticulo-endothelial system, or by another still unknown factor; where there is reason to suppose that such a stimulant action has taken place, we may derive a general practical rule: *Chemotherapeutic substances of this kind must be given very cautiously in small or very moderate doses.* If given in excess they will prove harmful, even though they may not yet be toxic in the healthy body in the same doses. Any substance, if stimulant in small doses, will turn out in bigger doses to be a paralyzer of the still remaining resistant power of the body.

The stimulating effects of compounds are sometimes specific—useful against one kind of infection only; in other cases a wider action of the same stimulant may be observed. We can observe the same phenomenon with directly parasitotoxic agents also. Thus "Bayer 205" acts specifically only against trypanosome infection—sleeping-sickness; antimony compounds have a wider range of action, they influence not only sleeping-sickness and trypanosome infections in general, but also some other infections of an absolutely different aetiology.

The Treatment of Migraine.

By H. C. ROOK.

(*Lancet*, April 1927, p. 705.)

MIGRAINE, or at least a percentage of cases of this complaint, is caused by a hepatic toxin, which in pre-disposed subjects may be produced by nervous over-action or inhibition. Migraine occurs chiefly in persons with a highly sensitive nervous system, and toxins, both organic and inorganic, often show a predisposition to pick out and attack certain portions of the nervous system. Rook's treatment aims at what he regards as the real source of trouble—the liver. One hour before rising in the morning the patient takes 2 to 4 drachms of a 50 per cent. solution of magnesium sulphate, after which he lies on the right side for an hour. A large tumblerful of hot water or hot weak tea is then taken to assist evacuation of the salts. Each case must be treated according to individual peculiarities, but as a rule once a week or once a fortnight is sufficiently often to give the salts, the day or half-day previous being a starvation day. As regards diet, fats, eggs, chocolate, cocoa, coffee and alcohol must be strictly limited. Regularity of habit should be urged, and as far as possible freedom from worry and fatigue.—(*Prescriber*, April 1928, p. 135.)

The Treatment of Otorrhœa in School Clinics.

By A. R. FRIEL, M.D., F.R.C.S.I.

(*The Practitioner*, April 1928, p. 252.)

In considering the subject of the treatment of school children for otorrhœa, it is necessary to discuss two questions: (1) how to treat each individual case of otorrhœa; and (2) how to use the facilities at our disposal so as to get the largest possible number of cases treated. Cases of otorrhœa due to middle ear disease are divided into two classes:—namely, acute suppurative otitis media and chronic suppurative otitis media (a third might perhaps be added—an acute attack supervening in an ear with chronic otorrhœa). In the acute condition, the tissues are attacked by bacteria: usually a pneumococcus or a streptococcus. In the chronic condition the tissues have repelled the invaders, but the discharge has become a fluid swarming with bacteria and irritating the tissues with which it is in contact.

In the treatment of the acute attack the line to follow is to assist the tissues by conserving the energy of the patient by rest in bed if possible; to relieve pain by warmth and moisture applied to the side of the head; to encourage a flow of serum from the ear by the use of glycerine drops; and finally to use every endeavour to prevent the fluid in the ear becoming a culture medium for saprophytes. This can be attained by absorbing the discharge with boracic powder insufflations when the acute inflammation is subsiding and the discharge is becoming less.

Since in chronic otorrhœa the basic factor keeping up the discharge is a septic fluid irritating the walls of the tympanum, the line of treatment indicated is to remove that septic fluid by absorption, or to apply an antiseptic which will make the fluid adhering to the walls a bad culture medium for bacteria and so render it non-irritating. The walls of the tympanum being then freed from irritation will cease to secrete fluid, and so the condition will clear up.

The subjoined table summarizes the lines of treatment to follow based on the indications present in an ear:

Cause of Chronicity.	Treatment.
(i) Accessible sepsis, e.g., tympanic sepsis.	In slight cases, insufflation of boracic powder.
(ii) Accessible sepsis with second factor in ear, e.g., polypus.	In more severe cases, zinc ionization with or without boracic powder insufflation.
(iii) Accessible sepsis with inflammation in a neighbouring organ, e.g., rhinitis.	Remove second factor, then ionize ear.
(iv) Inaccessible sepsis.	Treat neighbouring organ and ionize ear.
(a) Accessible with difficulty, e.g., cell in mastoid opening into tympanum or posterior meatal wall.	Use special instruments to gain access: (a) attic cannula; (b) gelatine covered wire.
(b) Totally inaccessible, e.g., most cases of attic and mastoid disease.	Make area of sepsis accessible by operation and then use ionization.

Zinc ionization, strictly speaking, is not a remedy for chronic otorrhœa, but rather a method of treatment which is applicable to a septic cavity when that cavity is readily accessible. As so many cases of chronic otorrhœa are kept up by sepsis in the tympanum, it follows that zinc ionization is useful in that condition. Moreover, as the results are so consistently good in cases of tympanic sepsis, we have a clue as to how to deal with other cases. Thus, when there is a factor, e.g., a polypus, present besides sepsis, keeping up the suppuration, we should remove this additional factor and then treat the sepsis with ionization; when the sepsis is in a position difficult of access, we should use special instruments to reach it; and when the septic area is totally inaccessible as in most cases of attic and mastoid disease, we should do an operation to make it accessible.

Local Anæsthesia.

(The Prescriber, April 1928, p. 130.)

THE toxic symptoms that not infrequently supervene after the administration of cocaine as a local anæsthetic, according to Leshure, can be prevented by previous oral administration of barbitone or its sodium salt (veronal-sodium). Half an hour before inducing anæsthesia he gives from 6 to 12 grains (0.4 to 0.8 gm.) of barbitone-sodium, and he finds that this completely obviates all symptoms of cocaine poisoning, such as pale, cold, clammy skin, rapid and feeble heart action, and convulsive tremors. Leshure has tried this method in 100 cases, and none of these has manifested any of the

symptoms mentioned. He regards barbitone as an efficient antidote to cocaine, and suggests that in cases where it has not been used and symptoms of cocaine toxicosis have supervened, barbitone-sodium might be injected intravenously as a remedy.

Borocaine.—The work of Copeland and Notton has resulted in the production of a series of borates of synthetic bases, generically termed borocaines. The term "borocaine" is now applied to ethocaine (novocaine or porocaine) borate, while "beta-borocaine" is the borate of beta-eucaine. A chemical investigation of "borocaine" has been made by Collins in the A. M. A. Laboratories, Chicago, with a view to ascertaining the exact formula of the commercial product, its purity, and whether it is a definite compound or a mixture. He points out that in 1910 a borate of *p*-aminobenzoylethylamino-ethanol (novocaine) was described by Einhorn and Uhlfelder, its physical properties corresponding generally with those of the compound now described as "borocaine."

"S. F. 147."—Under this designation a new local anæsthetic has been put on the market by the Sandoz Laboratories. It belongs to the novocaine (procaine or ethocaine) series of local anæsthetics, having the same aromatic nucleus with a longer side chain. It is a white powder, forming crystalline salts with acids. Solutions are clear and stable; they withstand sterilization without decomposition, and can be administered with adrenalin. It is said to be equally valuable for infiltration and for surface anæsthesia, and to have only about one-third the toxicity of cocaine, without the effects of cocaine on the nervous system.

Winterstein has had this compound under investigation at his clinic since 1925. He finds the toxicity to be about 2.5 times greater than that of novocaine and slightly less than that of tutocaine. It produces good anæsthesia, rather more quickly than novocaine, but more slowly than tutocaine. The anæsthesia produced by "S. F. 147" is more prolonged than that effected by either novocaine or tutocaine. Slight hyperæmia is produced by its injection. In man good anæsthesia is produced by 0.2 per cent. solution: such a solution was successful in 230 cases, but to produce more rapid action 0.3 per cent. solution should be used, good results having been obtained with this strength in 470 cases. Winterstein strongly recommends the new anæsthetic for experimental and practical use.

Ephedrine.—In the course of certain experiments made with a view to obtaining a local anæsthetic less toxic than cocaine, Read and Lin (Peking) found that a mixture of ephedrine, adrenalin, and potassium sulphate produced local anæsthesia as intense as a similar mixture containing novocaine in place of ephedrine. The curious feature of this ephedrine anæsthesia is that the alkaloid ephedrine alone does not have any anæsthetic effect—it is only when combined with the two other substances that the result is produced. It is thought therefore that a definite synergism or chemotherapeutic relationship exists between these three compounds. The addition of 0.005 per cent. of ephedrine to a 1 per cent. solution of novocaine resulted in considerable shortening of the time taken in blocking the motor impulse along the sciatic nerve. Read and Lin suggest for use in dental surgery and ophthalmic work a mixture of ephedrine, adrenalin, and potassium sulphate, as the relative toxicity of such a mixture is low.

Narco-Local Anæsthesia.—This form of anæsthesia, in which a local anæsthetic is combined with a narcotic, is believed to be of value in certain conditions. Keller records nine cases of Cæsarean section in which this method was employed. The ages of the patients ranged from 20 to 41 years, and in all cases ether was contraindicated for various reasons. No preliminary enema or purgative is necessary, and a dose of morphine sulphate (1/6 grain) with scopolamine hydrobromide (1/100 grain) is given one hour before operation. At the operation 0.5 per cent. novocaine is administered by infiltration, an attempt being made to infiltrate the entire thickness of the abdominal wall before incising it.

Some Notes on Diagnosis.*

By CLAUDE WILSON, M.D., M.R.C.P.

(*Brit. Med. Journ.*, April 28, 1928, p. 709.)

WHEN invited to read a paper at this meeting I recognized an opportunity for discussing some rather unconventional views on diagnosis—views which in one form and another I have held since my student days, and which have by no means been dispelled by the great additions made to medical knowledge during the intervening years.

Diagnosis is our first object when seeing a fresh case. Our patients demand a diagnosis, and our teachers have ever impressed on us the prime importance of making one, while from time to time an eminent authority deplores the lack of diagnostic accuracy in some widely read journal in a way which would seem to imply that an accurate diagnosis is possible in every case. In hospital diagnosis is at its easiest. The cases are mostly advanced examples of well-marked disease, and the means and methods of exhaustive investigation are at hand. Yet difficult cases are seen; and, in my younger days, a fairly regular attendance in the *post-mortem* room revealed much that had not been anticipated—just as it so often does on the operating table—and I early learned that the most confident diagnostician is seldom the most reliable.

It is well to recognize our limitations as well as our advances. Unless a case is trivial or transient or obvious, we are at once in difficulties. The clinical pathologist, the radiographer, and the expert specialist often help us to a conclusion, but we are perhaps as often left in doubt. The same may be said of the general consultant, whose knowledge, experience, and authority, though of signal value in confirming an opinion already reached, or in bolstering up our ignorance, too often fail to carry us much further. Still, we may generally trust the man who is not afraid to say he does not know; when he thinks he does know he is generally right. But the pronouncements of the pundit who courts the reputation of being able to diagnose every case are necessarily unreliable; the fact being that, up to the present time, a diagnosis that is more than a guess is, at the stage of the disease when it would be most helpful, often quite impossible.

The Relative Value of Clinical Methods.

The aspect and demeanour of the patient are sometimes so characteristic that a diagnosis can be made at a glance. No one can mistake the tabetic, the Parkinsonian, or the fully developed case of Graves' disease. The history of the patient's complaints and sensations can hardly be too carefully elicited, for the key to the trouble is often found here, while the family history and collateral evidence may be of equal value. Still, it is upon evidence obtained through the trained senses that one must depend in all but obvious cases. I propose to offer a few words on the kind of help which each of the senses provides, and in so doing it will serve my purpose best to begin with those which help us least and keep the most important to the end.

Taste hardly counts, though it is historically associated with the diagnosis of diabetes; and, while the olfactory sense may be conclusive, as in alcoholism, ozæna, acetonæmia, and *B. coli* abscess, its scope is strictly limited. Touch and hearing run a close race, though hearing wins easily if we include what is learned from the preliminary inquiry, and from the character of the patient's voice and utterance. In physical examination these two often help each other out, as in the timing of a thrill and a murmur, and in the feeling of resistance which accompanies the percussion note of apical consolidation and pleural effusion. But percussion generally depends on the sense of hearing alone, and the ability to detect slight differences of sound varies very much in different individuals. I never believed that it was possible to map out the stomach by percussion, and the advent of the x-ray meal has put it largely out

of court. Most misleading is the percussion of adjacent gas-filled viscera. A few weeks ago I tapped with two coins over the epigastric and adjacent areas, while a colleague moved his stethoscope about, and pronounced the stomach to be greatly dilated. But a stomach tube failed to bring off any gas, and an hour or two later the coils of an enormously distended small intestine were found to fill this area, indeed the whole of the anterior segment of the abdomen. The only thing certain about percussion of adjacent hollow viscera is that the results are uncertain. To a lesser extent, for the possibilities are less egregious, I have always held as suspect the percussion line of the left border of the heart. Very different outlines are made by equally capable observers of the same case, and I have frequently found that the radiogram is smaller than the area mapped out by percussion.

Auscultation, of course, yields invaluable information as to both lungs and heart, but it is well to bear in mind what erroneous doctrines have been taught through many decades, not because the auscultation was at fault, but because the deductions were founded on theories which have proved to be erroneous. It need not have taken about a hundred years to find out that a systolic mitral murmur was often quite harmless. Possibly the most unequivocally useful information rendered by the stethoscope is connected with the recognition of the foetal heart beat.

Coming to the tactile sense alone, and using the term in its widest significance, so as to include recognition of tenderness, heat, cold, resistance, and fluctuation, we find an immense amount of information available. Texture, irregularity of surface, foreign bodies, crepitus, the examination of the pulse and the heart, aneurysm, fremitus and friction, and the exploration of the throat and pelvic organs, carry us far. And the reflexes are probably destined to carry us much further than is as yet generally recognized.

If I have run rapidly through some points connected with the diagnostic value of what we may almost call the minor senses, it has been mainly for the purpose of bringing into contrast the overwhelming importance of the sense of sight. It has been very large in proportion to the degree in which different divisions of clinical knowledge have been brought within the range of vision that our powers of diagnosis have increased, and, fortunately, the range is being continually extended. The general glance, which, as already mentioned, may be diagnostic, is much more often suggestive. Pallor and cyanosis, obesity and cachexia, facial expression, lameness, and similar features, give us leads which are generally true. The distortions of surface produced by fractures, dislocations, tumours, and hernia are, of course, obvious. Beyond this the skin and the tongue and the throat can be seen unaided: sputa and excreta can be inspected, and urine tested. For the rest we must rely upon instruments, and while the use of almost all instruments requires practice, the interpretation of the results requires more, and invariably lags behind. Probably in all cases interpretation will ever be liable to revision and extension. What should we know of pyrexia without the clinical thermometer? Yet while a glance at a temperature chart, along with its record of pulse and respiration, may be in itself diagnostic, who will say that we are at the end of the knowledge which this simple little instrument may bring? It is only quite recently that the characteristic charts of lymphadenoma and rat-bite fever have been recognized.

What would be our knowledge of the diseases of the eye and of the nervous system without the ophthalmoscope? And what should we know of the larynx if it could not be seen? What would our general knowledge of disease be without the revelations of the microscope, with its histological pathology, its blood counts, and the intricacies of bacteriology? Without transillumination a filled antrum is a sealed book, and the new knowledge of heart disease depends essentially on visible tracings.

The cavities of the body in the immediate vicinity of the orifices have for long been explored by means of specula, but the ingenious applications of electric light,

* An abridged version of a paper delivered before the Tunbridge Wells Division of the British Medical Association.

which provide us with cystoscopes and sigmoidoscopes, and with appliances by means of which the mucosa of the stomach and other remote internal surfaces are being brought into view, are matters of yesterday. The advent of x-rays soon brought the accurate diagnosis of fractures and dislocations, and the localization of foreign bodies; the sockets of the teeth, the pituitary fossa, and the contents of the thorax were brought into the available field later; and while the exploration of the gastro-intestinal tract by means of barium meal and enema seems to have been long enough with us, the discovery of lipiodol and similar substances has recently added the bronchi, pulmonary cavities, the gall-bladder, the pelvis of the kidney, and the ramifications of sinus and fistula to the internal regions explorable by sight. The objection is sometimes raised that skiagrams may give misleading information. But this applies to all diagnostic methods, and skiagrams, like electro-cardiograms, may need expert elucidation. In obscure cases the experts themselves may be puzzled. None of the new methods has reached its zenith, and interpretation, as already stated, necessarily lags behind observation.

It is not without purpose that I have emphasized the paramount value of vision in diagnosis; it is not without purpose that I pass on to a few observations about the skin.

Disease Manifestations in the Skin.

Those parts of the body which are most open to easy and complete examination by sight and by touch ought to be those about which we know most, and in which changes due to treatment, general and local, should be most obvious. If such an area is also that most accessible to microscopic investigation, general and bacteriological, surely every facility exists for obtaining full knowledge of its physiology, its pathology, the diagnosis of its diseases, and their successful treatment. Yet if there is one part of the body which seems more puzzling than the rest, both as to diagnosis and as to treatment, I feel sure that a good many of us would think of the skin.

The experts who gather at the meetings of the dermatological societies often exhibit rarities and curiosities, and one may often notice the words "Case for diagnosis" on the agenda. Truly the skin is a humiliating structure. The limitations of our knowledge as to the essential nature of a lesion, and of its etiology, progress, and treatment, are here so obvious that it is not easy to deceive either ourselves or our patients; and many have said or thought that we know less about the skin than about almost any other system. Yet it may well be that, as should surely be the case, we do know more about the skin than about any other part; and that our ignorance of the invisible organs and systems may still be as profound as was our ignorance of the diseases of the fundus oculi before the days of the ophthalmoscope. There are but few skin diseases concerning which our knowledge may be said to be complete. One such is scabies; the cause is clear, the lesions are characteristic, and the treatment is known and is curative. With the syphilides the case is different; the ultimate cause is known, but why should the lesions be so strangely varied? Why, again, should the ubiquitous staphylococcus have so pronounced an attraction for the skin of the adolescent? And if endocrine instability is evoked, why should it select its unfortunate victims so capriciously? Of many well-known skin diseases we really know nothing as to the essential nature or cause. Of individual lesions we know that vesicles and pustules arise from very different causes—local irritation and infection, certain drugs, small-pox, and so on; but, except in the case of burns, trauma, and local infection, we know nothing of the reason.

Transient anomalies seem, if possible, to be even more bewildering. How strange are the characteristic rashes of the exanthemata, each with its distribution and its period of incidence and decline; and perhaps still more curious are the pallors, flushings, and sweatings from emotional causes, each being part of an immediate response to purely psychic influences involving widespread nervous, endocrine, and circulatory adaptations in

many parts of the body, but of which the skin reactions are alone in evidence. What effect does emotion have over other secretions? We know something of occasional renal response, and a good deal about tears. Emotion may cause profuse weeping or may dry up tears. What effect may it have on the gastric and biliary secretions? Doubtless profound effects, of which emotional vomiting, appetite juice, and the suggestive comments accompanying a carminative prescription are mere hints. What is the meaning of the muddy pallor with brownish wandering patches seen on the face in sea-sickness and in other conditions in which bile regurgitates? We see these things on the skin, but what is the liver—that immense organ which works in silence and in darkness—doing? All we can say is that we don't know. At a recent operation in which the liver was exposed I noticed little blisters which came and went and wandered, raising the capsule as they moved. What was going on within the recesses of the organ? We talk glibly about the liver being "out of order," but we do not know what is happening, and extreme cirrhosis, which had never even been suspected, may be discovered in the *post-mortem* room. One might dilate similarly upon other organs which, like the liver, work in silence and out of sight.

It is on the skin that we do see what is actually going on, and it is here that we may best gauge the extent of our knowledge and of our ignorance; and, surely, the balance is heavily weighted on the side of ignorance. And do not the grey, brown, black, and strawberry furs, and the curious wandering rashes of the tongue, and the little ulcers and hæmorrhages on the gums and on the cornea, point in the same direction? Doubtless analogous pallors, flushings, swellings, furs, ephemeral ulcers, and desquamations occur with equal frequency in unseen areas, and accompany and perhaps account for symptoms for which we have daily to invent mythical reasons.

What Constitutes a Diagnosis?

In discussing any question it is well to know what we are talking about. Which of us, asked to define the word "diagnosis," could supply a definition acceptable to all? In the first volume of the *James Mackenzie Institute Reports* (1922) there is a paper on the results of a collective investigation which had "the primary object of determining in what proportion of the cases met with in general practice it is possible to arrive at a diagnosis," and the first difficulty encountered was that no satisfactory definition of the word could be found. After much debate the following was framed: "The recognition in the patient of a known disease from the symptoms which are characteristic of it." If we agree to include signs under the term symptoms, as Mackenzie always did, the definition will satisfy most of us. But the difficulty which was next experienced in separating what may be fairly called "known diseases" from among "the maze of symptoms and so-called diseases in which medicine is becoming lost" was a real one, and one which we shall all do well to bear in mind. Space forbids more than the briefest epitome of the paper. A classification wide enough to embrace all cases was evolved; the "known" (diagnosable) diseases were divided into five classes according to whether the cause was known, surmisable, or frankly unknown, while end-results, such as the valvular lesions, and secondary diseases, such as cystitis, each received a separate compartment. Of the 794 consecutive cases investigated a "diagnosis" was made in only 28 per cent., while in 22 per cent. a partial or provisional diagnosis was allowed. But just half of the cases examined did not present the symptoms characteristic of a "known disease," and were consequently scheduled as "undiagnosable." Some of these cases were simple ephemeral complaints; some were isolated symptoms, such as unexplained headache, insomnia, tinnitus, and so on. Many were examples of groups of *disjointed* symptoms such as we often meet with and which bring discredit on the profession, because one doctor attaches one label and another another.

"We endeavoured," says the paper, "to divide the undiagnosable class into groups—for example, intestinal

SEPT., 1928.]

toxæmia, neurasthenia, dyspepsia, etc. It might be better not to employ such terms at all, as they are apt to give an unconscious bias in favour of one theory over another. The undiagnosable cases," it concludes, "are apt to cause despair to the general practitioner, but if they were viewed rightly they present him with an invaluable field of study which is really open to him alone."

The reason why the field is "open to the general practitioner and to him alone" is that he is the only man who has the opportunity of following up his cases from month to month and from year to year. By patient observation, record, and study Mackenzie differentiated the cardiac arrhythmias, which had at first caused him "despair," and real knowledge of heart disease dates from these researches. It was only while engaged in general practice that he was able to follow up his cases as he did. But he was alone in his feelings of despair; his contemporaries were satisfied with theories now known to be erroneous.

Turning to the mass of ailments which still are "undiagnosable," how many of us are there that recognize them as such? Are they really apt to afflict us with despair? Are we not prone to think we hold the key to the bulk of these anomalies? Did we not, thirty years ago, ascribe countless ills to "uric acid"? Was there not a time—not long gone by—when the "up-to-date" practitioner had a vaccine for almost everything? That "blood pressure" should ever have been a popular "diagnosis" seems almost as strange as the queer idea that everything could be "Coué'd." These things may have had their day, but many of us become obsessed by the new or revived ideas as they come along, and perhaps it is the word "toxæmia" that is now on top of the wave. Toxæmia may be obvious, or probable, or problematical, but the relegation of its origin to the colon is often no more than a guess, even when faecal analysis seems to point that way.

The colon has had a long innings, but the early canonical axiom, "Cut it out and cast it from thee," has disappeared, while the more recent advice, based on high transpontine authority, "Grease it and leave it alone," is disregarded. Sour milk had a look in some twenty years ago, and fizzled out. Possibly *acidophilus* may share a similar fate. To "change the flora" may prove as difficult as to "disinfect." But we are on firmer ground when the escape of organisms can be proved. Rowlands has shown that the intestinal wall of rats fed on a full vitamin B diet was more than twice as thick and firmly knit as in the case of the controls; and in the few cases where he tried the treatment he found that urine which was teeming with *B. coli* "soon became sterile when the patient was placed upon a concentrated vitamin B diet." May not the well-nourished intestinal wall also prevent the absorption of toxins?

The vitamins have removed several obscure diseases from the region of bewildered speculation into the very front rank of diagnosable diseases—that is, into the small but ever-enlarging class in which the cause is definitely known. But the work by which these results have been secured has not come from the general practitioner. In endocrine disease also the best work has come from the laboratories and the schools; and, though the practitioner has by therapeutic experiment discovered various forms of sub-thyroidism, and done hopeful work with parathyroid and perhaps with other hormones, his blunderbuss work—generally the result of commercial suggestion—has been terrible. I sometimes wonder how many blunderbuss preparations would produce any result at all if the thyroid element was cut out.

If therapeutic experiment along toxicæmic, endocrine, and similar lines can be called "investigation," we general practitioners are doing our duty nobly. But I see little of the patient laborious research to which Mackenzie devoted his life—these two kinds of inquiry lie poles asunder. Mackenzie's standard is too high for most of us; we lack the insight, even if we possessed the energy.

Is there not, however, some midway line along which we may all hope to do a little real, and possibly useful, work? There may be many; but anyone who forms the

habit of taking short notes—if only of cases which are obscure or which possess some points of special interest—finds in the course of a few years that a fund of material has accumulated some of which will certainly throw light on his subsequent reading and experience. Much useful work which, among other results, helps to elucidate diagnostic problems, depends essentially on the existence of some such store. Further, if we keep our eyes open we all occasionally come across cases—or possibly cases in series—of obvious illness which, after careful investigation, are not found to conform to any known disease of even label. Such cases ought to be recorded. The work is seldom wasted, nor is it without reward.

Reviews.

THE TREATMENT OF CATARACT AND SOME OTHER COMMON OCULAR AFFECTIONS.—By Lieut.-Col. Henry Smith, C.I.E., M.D., M.Ch., I.M.S. (Retd.). Calcutta: Butterworth and Co. (India), Ltd., 1928. Pp. 287, with 68 illustrations. Price, Rs. 7-8 net.

THIS is the second edition of this book which has been entirely re-written and brought up-to-date. Its main interest is the latest development of the Indian method of intra-capsular extraction of cataract, which has been elaborated by the author, and with regard to which he states that it constitutes a revolution of the greatest importance, reduces the operation to one of great simplicity, enabling it to be performed by unskilled hands; also that the incidence of vitreous prolapse is lower than in the capsulotomy operation. He further claims that it is destined to supersede all other methods commonly done, and will relegate the capsulotomy operation to the scrap heap for evermore.

Chapter I deals with the clinical examination of the eye, the classification and diagnosis of cataract, and the treatment to which each variety is suited. The author expresses many original ideas of his own, which are not revealed in standard textbooks on the subject.

Chapter II deals with operative technique and forms most interesting reading. The operations are described in great detail, in a simple, clear way and well illustrated. The Indian method of expression from without, with upright delivery of the lens is described as before, but the most interesting part of this chapter is the description of the soft Morganian lens with lower edge foremost as a tumbler, and the tumbling of the hard lens by combined pressure with the lens hook and spatula.

The author describes how he is now able to overcome the difficult problem of delivering hard cataracts as tumblers and states that the method simplifies matters to an extent almost beyond his dreams. Even in relatively unskilled hands an almost perfect control can be kept over the vitreous. The spoon is laid with its convexity over the wound and keeps the upper pole of the lens from moving. The lens hook is laid on the sclerotic below, care being taken that it is behind the lower pole of the lens. The lens then dislocates below and its lower border comes forward to bulge the cornea and is kept in position by pressure with the heel of the hook. The point of the hook is then lifted to disengage it from the conjunctiva in which it is liable to catch as it is brought up after the lens. The point of the hook is then dropped into the sclero-cornea preparatory to insinuating the cornea behind the lens. The spoon, having served its purpose, is then lifted off the wound. The point of the hook is then continued upwards and the lens with its capsule is delivered outside.

Barraquer's apparatus and operation is described by Russell Smith. It strikes one that his article is a very dogmatic section, written by an author of limited experience in criticism of an ophthalmologist with such great experience as Barraquer, and he sums up Barraquer's operation as one which pushes the lens violently to the exterior. Yet by such an eminent authority as the late

Professor Fuchs of Vienna, Barraquer was acknowledged as an expert in this particular operation. Colonel Smith has got hold of an absolutely erroneous idea when he says that Barraquer dislocates the lens backwards before removing it. He does nothing of the kind, nor does any other operator who uses suction methods. It is quite an easy matter to lay the cup on the anterior capsule gently and allow it to make contact without pressing the lens backwards at all. Even if Barraquer had dislocated the lens in a few cases, certainly it is not necessary to do so, and operators with any knowledge of the method would consider this idea wrong.

It is interesting to read the author's ideas on infiltration of the orbicularis muscle with novocaine in which he says anaesthesia and not paralysis, with any degree of regularity, is produced. This is a statement which cannot be accepted. It is carried out as a routine in the Calcutta Eye Infirmary with the result that an escape of vitreous is almost unknown in uncomplicated cataract operations.

Chapter III deals with the routine after-treatment of cataract operations. The author in discussing prolapse of the iris after cataract extraction states that "Excision of the prolapse at once is positively pernicious." This statement is against modern principles, as the safest procedure is to excise the prolapsed iris as soon as it is discovered and so avoid any permanent entanglement in the wound which may be later the cause of secondary glaucoma. In dealing with the treatment of after-cataract, Colonel Smith speaks of the sudden disasters which frequently destroy the eye when the 'trifling' operation of needling is performed on the after-cataract. Needling in after-cataract is exceedingly rarely followed by any reaction when carried out in the correct manner and with a gentle hand. Colonel Smith would replace needling altogether and advises pulling off the after-cataract with a curved iris forceps and does not regard the procedure as one of reckless daring. We cannot agree that the eye would tolerate it better than needling.

Chapter IV gives a short account of lens couching as performed by the Rawals, some observations on the historical aspects of the surgical treatment of cataract, and a consideration of the relative merits of intra-capsular extraction over the capsulotomy operation.

Chapter V deals with the treatment of glaucoma and some other common ocular affections.

In discussing chronic glaucoma, the author does not approve of the permanent utility of the operation of anterior sclerectomy, and states it is no substitute for an iridectomy done properly—a statement with which few ophthalmologists will agree. He dismisses in a few words the classical operation of sclero-corneal trephining perfected by Lieutenant-Colonel Elliott of the Madras Eye Hospital and now carried out so extensively all over the world, as well as being the recognised operation for chronic simple glaucoma in all the teaching Eye Centres in India. He would relegate the sclero-corneal trephine to the shelf of the museum of discarded surgical instruments but he would only have to visit the bigger Eye Centres of Bengal and Madras to see that it is far from being discarded. The sclero-corneal trephine operation of Elliott is still the operation of choice for the treatment of chronic simple glaucoma and will take a lot of replacing. In dealing with the treatment of corneal ulceration, the author takes considerable trouble to warn his readers of the fallacies of using atropine, with which one considers that but few ophthalmologists will agree. Atropine still holds the field as the most useful drug in the treatment of corneal ulceration.

In the treatment of interstitial keratitis, the author states that there is a general consensus of opinion that arseno-benzol preparations have no influence on the local condition. If he will visit the Eye Infirmary of the Medical College, Calcutta, where so many cases are treated, he would alter his opinion. The results that are obtained with sulfarsenol and bismuth injections are really marvellous.

In addition there is an appendix to the book which contains details of the state of vision of 132 cases of intra-capsular extraction of cataract on discharge from hospital; also the after effects of the escape of vitreous

during the operation of extraction of cataract in the capsule by Smith's method, with a tabulated statement and analysis of 98 cases in which escape of vitreous occurred; also the late results of intra-capsular cataract extraction by Dr. Arnold Knapp of New York.

In conclusion, in our opinion Colonel Smith's book is hardly a true representation of present-day methods in Indian ophthalmology, and it is hardly one that we would recommend for the use of students. On the other hand, the author has made enormous contributions to the progress of ophthalmology in India, and the intra-capsular operation is still the one almost universally used in the Punjab. The book is very well published; it is well illustrated and written in a clear and explicit style. It will appeal to many of Colonel Smith's pupils in India, and will be of great interest to medical men with experience of ophthalmological methods all over India.

E. O'G. K.

NEOPLASTIC DISEASES: A TREATISE ON TUMOURS.—By James Ewing, M.D., Sc.D. Third Edition. Philadelphia and London: W. B. Saunders Company, 1928. Pp. 127, with 546 illustrations. Price, 63s. net.

THIS is the third edition of Professor Ewing's great work on tumours.

Important alterations and additions have been made in the sections which deal with tumours of bones, of the brain, and of the breast.

As a work of reference, both from the point of view of its detailed treatment of tumours, and from the complete bibliography, this publication is invaluable to those who are concerned with the histological diagnosis of new growths.

G. S.

A TREATISE ON ORTHOPÆDIC SURGERY.—By Royal Whitman, M.D., M.R.C.S., F.A.C.S. Eighth Edition. London: Henry Kimpton, 1927. Pp. 1061, with 954 illustrations. Price, 45s. net.

DR. ROYAL WHITMAN'S book is not so well known to English surgeons as one would expect it to be from the great reputation of its author as an orthopædic surgeon. In America, however, it is a recognised classic and the fact that it has reached its eighth edition, renders it unnecessary for the reviewer to do more than to introduce it to new readers. It is a large work, over 1,000 pages and nearly the same number of illustrations, intended for the specialist and for the general surgeon, most of whom have to undertake orthopædic work occasionally, but the needs of the general practitioner are kept in mind and methods of systematic physical examination that lead to early diagnosis and the principles of preventive treatment, are allotted much space. Subjects are dealt with in accordance with their importance in the hospital service with which the author is connected, so that we find tuberculous disease of the spine dealt with first, then spinal curvature and other spinal deformities and then the joints seriatim always with tuberculosis heading the list and receiving as much space as all the other affections of the joints together. This detracts from the value of the work to surgeons in this country, where traumatic affections, the sequelæ of acute arthritis suppurative or otherwise, and the results of neglected fractures or dislocations form the bulk of the orthopædic material to be dealt with.

The accounts of the treatment of tuberculosis of the joints is as complete as possible and it is interesting to note that the American school is not so enthusiastic over the merits of the traction trace as formerly in the treatment of tuberculosis of the hip and spine correction with immobilisation in plaster-of-Paris splints is finding increasing favour. The accounts of the construction and mode of action of apparatus are very full, so too are the descriptions of exercises for spinal cases, a necessary feature in a book for those who have to supervise this class of case.

The surgery of paralysis is very fully dealt with and the accounts of the many ingenious operations for

transfer of tendons are given in the author's own words with references to the original; as is to be expected the abduction treatment of fractured neck of the femur, the reconstruction operation for the hip-joint and the value of astragalectomy are treated by the originator of these procedures in a most interesting manner.

The final chapters deal with the reconstructive surgery of injuries and are an expansion of the former chapters on military surgery, a very valuable addition.

The only fault we have to find with an otherwise excellent book is the poor quality of the illustrations. Many of the photographic reproductions of radiograms, such as fig. 364, are unintelligible.

W. L. H.

PHYSICAL DIAGNOSIS.—By G. P. Emerson, A.B., M.D. London: J. B. Lippincott Company, 1928. Pp. 553, with 324 illustrations. Available from Messrs. Butterworth and Co. (India), Ltd., Calcutta. Price, Rs. 26-4 net.

THOSE who have been engaged in the teaching of clinical medicine during the last quarter of a century have recognised, not without alarm, the difference in the outlook of the student of the present day and his prototype of twenty years ago. Compared with recent times laboratory and special methods of examination were then almost rare, and the medical student of the period had to rely largely on his own unaided senses in attempting to make a diagnosis. The advance of medical science, however, has now placed at our disposal an overwhelming collection of tests, clinical, chemical and electrical, and special means of examination, which include almost every tissue, secretion and excretion of the body. This is all very good and necessary to progress, but there is more than a little danger that the all-important training in physical diagnosis, which is the basis of all practical medicine and which is so essential to the physician, may be relegated to a secondary place, instead of occupying the foremost position that of necessity is its due.

The scarcity of recent books on this all-important pivotal subject and the plethora of books on laboratory, chemical and instrumental methods reveals, in no uncertain way, this latter day tendency.

In view of these facts, the present volume entitled *Physical Diagnosis* appears at an opportune time and will be welcomed by practical physicians. The volume runs to over 500 pages, and in it there is no mention of a single test or method of examination that cannot be made by the unaided special senses. A few simple instruments, such as the stethoscope and the ophthalmoscope are mentioned, but no reference is made to elaborate apparatus such as the electro-cardiograph or an x-ray installation, nor to the clinical applications of chemistry, bacteriology or blood work. We believe that the book will be a salutary reminder of the primary importance of the fundamental and pivotal subject of physical diagnosis. To medical students in the tropics this reminder is especially necessary. There is a growing tendency to leave cases undiagnosed until laboratory, chemical, pathological and radiological reports have been received. This is an entirely unjustifiable proceeding and spells inevitable disaster for those who practise it. In the great majority of cases, the diagnosis can be made without special examinations, and these latter, therefore, should be chiefly used for purposes of confirmation.

In the general introduction in Chapter I, there is a brief account of the history of internal medicine which, as the author points out, is in a peculiar sense, the history of physical diagnosis. The rest of the book is divided into chapters on the general body surface, the head, the spine and thorax, the heart, the abdomen and the extremities. In connection with each area or organ discussed, there is a short account of the clinical anatomy of the part. A most welcome and useful feature of the book is the wealth of illustrations, photographs and diagrams—of these there are more than 300, and they add enormously to the value of the book.

The book perhaps is somewhat large for use as a textbook for medical students. As a vade-mecum on physical diagnosis and a book of reference for the

clinician we can commend it very highly. The paper, printing and binding are of the usual faultless style that we have learned to associate with American publication.

J. D. S.

CONVALESCENCE, HISTORICAL AND PRACTICAL.—By John Bryant, M.D. New York: Published by the Sturgis Fund of the Burke Foundation, 1927. Pp. 300, with 104 illustrations. Price, \$5.0 net.

THE author has written this book for two reasons. Firstly, because he considers that for many centuries past, no attention has been paid to this subject, and secondly, because the Directors of the Burke Foundation wanted a comprehensive and authoritative volume for their guidance. It has been admitted on all sides that adequate care of convalescents is very essential. The period of convalescence leads patients from disease to health, and if proper care is taken during this period, the number of half-cured patients is decreased. The majority of cases discharged from hospital have environments which are unfavourable for the convalescent. Chronic illness must be clearly distinguished from convalescence. In spite of the importance of this subject very little attention has been paid to it, but the time is rapidly arriving when convalescent institutions will form part of the general scheme of medical relief. To the physician belongs the period of convalescence no less than that of disease. Inadequate care of convalescence means (a) half-completed medical work, (b) half-cured patients, (c) inefficiency and economic waste.

The book is divided into three parts. The first few chapters are devoted to a chronological review of the subject. This is followed by an account of the activities of the Winifred Masterson Burke Relief Foundation which is a great charity institution for the convalescent poor of New York City and of the Cleveland Hospital and Health Society. In Russia there are houses of rest which are not only outside and inside every city, but exist in considerable numbers in the Black Sea summer resorts area. They are divided into three classes:—(1) where the visitors receive medical treatment; (2) where treatment is little more than regulated diet and routine; (3) simple vacation resorts. These are maintained by different unions for their members and are very useful institutions. The second part deals with the convalescent work in the United States Army, and the writer points out that during the Great War, the care of convalescents reached a higher level of efficiency in the army than anywhere else in the country. Foremost among the procedures which produced these satisfactory results were occupational therapy and physio-therapy, and the writer recommends that these should be adopted for civil institutions also.

There is also an interesting chapter on the medical and surgical aspects of convalescence, and on convalescence as a problem in preventive medicine and public health.

Part III deals with progress reports of the work from 1921–27.

The author has taken great pains to study his subject and we trust that this book will stimulate interest in this important branch of medicine.

R. N. C.

THE SEX PROBLEM IN INDIA.—By Prof. N. S. Phadke, M.A. Bombay: D. B. Taraporevala Sons & Co. Price, Rs. 6.

THIS is the first book on the subject as it applies to India, and the author, himself an Indian and a Hindu, has our greatest admiration for tackling the subject at all. Even more than in the West, sex problems in India are bound up with religious beliefs, and thus are emphatically a subject which if treated by a European would constitute almost an impertinence. None the less, one could wish that the author had sought the collaboration of a medical man before plunging into print.

Chapter II, "The Theory of Heredity," ends with the work of Weissman (whose name, by the way, is consistently misspelt throughout), and makes no mention of the true theory first discovered by Mendel.

Chapter XI, on the female genitals, their parts and function, is clear, though there is no evidence for the statement that interlocking of the glans and cervix is a fairly common occurrence, it has been categorically denied by Sir Archdall Reid, in reviewing for *Nature* Dr. Marie Stopes' works, from which the author has probably taken it, but these are blemishes almost unavoidable when a layman enters on ground hitherto unstudied by him.

The chapters on Hindu marriage customs, however, and the development of the thesis that child marriage is not specifically laid down in the Shastras, are the most valuable parts of the book, though criticism of these arguments presented are impossible to a medical reviewer, depending, as they do, on acquaintance with Sanskrit and Hindu philosophy.

Even supposing that India is weaned from child marriage, is it yet ready for birth control? We tremble to think of the application of cervical pessaries and the like by the uneducated—even if they could afford the contrivances, which, in good order, are short lived. Yet, as the author points out, without birth control, what is the future of this country? This part of the subject forms the subject of a thoughtful editorial in the June number of this Journal. Birth control must keep pace with preventive medicine, if economic disaster is not to follow, and in so far as restriction of population has so far apparently not been mentioned in this country, this book is useful as at least a beginning in the creation of public opinion.

Should a second edition be called for, we recommend the author to enlist a medical collaborator, and to add a chapter containing a concrete scheme of introducing eugenic and contraceptive teachings among the millions of this country that live by the labour of their hands.

FOOD INFECTIONS AND FOOD INTOXICATIONS.—

By Samuel R. Damon, A.M., Ph.D. London: Baillière, Tindall and Cox, 1928. Pp. viii plus 260, with 18 plates and 13 figures. Price, 18s. net.

THE author has written this volume as detailed information regarding food infections and food intoxications is scattered throughout the medical literature. In discussing his subject, the author has gone fully into the etiology, symptomatology, diagnosis prophylaxis and treatment in detail. An attempt has been made to separate the food infections from food intoxications, but there is a certain amount of unavoidable overlapping.

Part I deals with infections from food and contains information regarding paratyphoid infection, Malta fever, tuberculosis from milk, and actinomycosis.

Part II is very interesting and gives a description of botulism, mushroom poisoning, potato and fish poisoning, etc.

Part III deals with 300 parasitic infections acquired through food. Most of the information given in these two sections is to be found in textbooks.

The chapters on mushroom poisoning and grain intoxications are especially interesting and in the latter is also given a detailed account of lathyrism. The book is well worth the perusal of medical practitioners.

R. N. C.

APPLIED BIOCHEMISTRY.—By W. Morso. Second Edition, Revised and Reset with the Co-operation of J. M. Looney. London and Philadelphia: W. B. Saunders Co., Ltd., 1927. Pp. 988, Illustrated. Price, 32s. 6d. net.

THE fact that a second edition has been called for eighteen months after the publication of the first edition of this book, shows clearly that the volume is much appreciated by a large circle of readers. The book itself is fairly extensive, consisting of nearly one thousand pages spread over seventeen chapters. The author quotes in his preface, "The gods sell everything for labour," but it is doubtful if the ordinary medical student will have the disposition, even if he had the time necessary, to labour through so many pages of biochemistry, much of which, it may be added, lies outside his course in this subject. To the graduate and student, however,

who has a special taste for or necessity to study biochemistry, the book can be thoroughly recommended. In addition to the subject-matter of the text, excellent foot-notes for suggested reading, biographical notes and references are given, which should prove extremely useful: possibly in places this is rather overdone, especially where language derivatives are given. The volume is extremely well got up and, if anything, over-illustrated, containing, in addition to the technical illustrations, many portraits of American biochemists. The book on the whole will probably appeal more to the American than the English student of medicine. To the actual worker on biochemistry, however, it should prove of undoubted value.

T. C. B.

DIATHERMY: ITS PRODUCTION AND USES IN MEDICINE AND SURGERY.—By E. P. Cumberbatch, M.A., B.M., D.M.R.E., M.R.C.P. Second Edition. London: William Heinemann (Medical Books), Ltd., 1927. Pp. 332, with 87 figures. Price, 21s. net. Agents in India: Messrs. Thacker, Spink and Co., Calcutta.

THE first edition of this work was published in 1921. It was practically a pioneer work in a subject about which little was known in this country. The present edition is practically a new work, owing to the tremendous strides this branch of medical science has made since then. This is particularly the case with diseases due to infection by the gonococcus, more especially in women. The experience, gained in the treatment of these diseases by diathermy in the Electrical Department of St. Bartholomew's Hospital during the last six years, is incorporated in this edition.

An account of the new "cutting currents," so much in vogue in America, has been added.

Apart from this, there has been a complete revision of the subject-matter of the preceding edition.

As it stands the work is comprehensive, up-to-date, and is easily the most readable of all current works on diathermy. Dr. Cumberbatch is to be congratulated, not only on the research work carried out under his supervision at St. Bartholomew's Hospital, but also on the high standard he sets as a writer, and the inherent modesty of his pronouncements.

We can confidently recommend this work to all practising surgeons and physicians.

J. A. S.

A HANDBOOK OF HISTOLOGY.—By A. McL. Watson, M.A., Ph.D. Edinburgh: E. & S. Livingstone, 1928. Pp. 207, with 1 colour and 53 other illustrations. Obtainable from Butterworth and Co., Calcutta. Price, Rs. 6-6.

THIS is one of a series of new, small and convenient handbooks for medical students, issued by this well-known firm. The author writes that the aim of the volume "is to present to the medical student a short, concise description of the tissues and organs, with illustrations prepared from class specimens." The illustrations are in every instance originals and are in general good. The publishers have done their very best for the book, for it is printed on thick and highly glazed paper, in order to give the best possible reproduction to the numerous half-tone illustrations. There are some weak points in the book; for instance we consider the plate of normal cells of the blood on page 44 very poor.

On the whole, however, the book will be found a very useful one for students, and even to the microscopist who has to look up the normal histology of a part in order to compare it with a similar, but diseased, tissue. The book is very well bound and of most convenient size.

ULTRA-VIOLET RAYS IN THE TREATMENT AND CURE OF DISEASE.—By Percy Hall, M.R.C.S. (Eng.), L.R.C.P. (Lond.). Third Edition. London: William Heinemann (Medical Books), Ltd., 1927. Pp. 236, with 57 figures. Price, 12s. 6d. net.

THIS little book has reached its third edition in three years. This fact alone is sufficient proof of its popularity,

and at the same time emphasizes the author's desire to keep abreast of the times. Owing to the growth of our knowledge of the subject, the work has been largely re-written. As before, it is profusely illustrated—practically every known type of lamp and various pieces of accessory apparatus being figured. Special stress is laid on the quartz and mercury vapour lamp, which is the apparatus of choice for the general practitioner.

A new chapter on infra-red rays has been added. It contains valuable information on the subject, also on the nearly related one of light treatment through screens, cutting out certain parts of the spectrum, such as red-ray treatment and cold light treatment.

This little work—one of the pioneer efforts on this interesting subject—still retains its position as one of the most lucid and up-to-date expositions on a subject which is coming more and more into prominence in the medical world.

J. A. S.

ON THE DYSENTERIES OF INDIA. (WITH A CHAPTER ON SECONDARY STREPTOCOCCAL INFECTIONS AND SPRUE.)—By Hugh W. Aton, Lieut.-Col., I.M.S., Professor of Pathology and Bacteriology, Calcutta School of Tropical Medicine and Hygiene, and R. Knowles, Lieut.-Col., I.M.S., Professor of Protozoology, Calcutta School of Tropical Medicine and Hygiene. Calcutta: Thacker, Spink and Co., 1928. Pp. xiv plus 178. Price, Rs. 7-8.

MUCH has been written on the subject of dysentery but if we except the articles by Manson-Bahr in Byam and Archibald's "System of Medicine in the Tropics" and the treatise by Sir Leonard Rogers on "Bowel Diseases in the Tropics" no publication has appeared recently, which has aimed at giving a comprehensive and systematic review of the whole subject, nor one which applies more directly to the disease as it is found in India. It is, therefore, with the greatest pleasure and anticipation that we welcome the appearance of the present book, written as it is, by the brilliant and facile pens of two authors who are acknowledged experts and are, therefore, exceptionally well qualified to deal with the subject.

In their preface, the authors modestly imply that they are indebted to others for the greater part of the subject-matter. This however is far from being the case. As far as the text is concerned, the reader will find ample evidence of their own researches and the new viewpoints which have been reached by them in regard to the various aspects of this protean disease. It is otherwise with the illustrations. The profession outside India may be surprised to learn that the opportunities for pathological study amongst such a wealth of clinical material as is available in Calcutta are so small that the authors have had to borrow the majority of their illustrations from foreign sources. The difficulty of obtaining post-mortem examinations is, however, one of the greatest stumbling blocks that confronts medical workers in this country and one which hampers true research at every turn. The illustrations are for the most part derived from well-known monographs, those dealing with the macroscopic appearances being reproduced from the Atlas Tropischer Darmkrankheiten by Barmann and Eckwesdroff and "Dysentery in the Federated Malay States" by Fletcher and Jepps, and the figures illustrating the protozoa from Dobell and O'Connor's publications. Two plates giving the appearances of the cysts of the chief intestinal protozoa in man and certain photos showing the X-ray appearances of the gut in chronic cases are new and well up to the standard of the other illustrations. The representations of the various cysts are admirable and should be of great use to beginners at this type of work. Although the sizes of the amoebic cysts are given in the text, a scale of magnification, or better still, a note of the objective, ocular, etc., used in the preparation of the plates and added to the description would enhance their value to the general practitioner who is not accustomed to microscopic measurements.

The book itself is divided into nine chapters, each dealing with special aspects of the subject.

The opening chapter deals with morbidity and mortality, seasonal incidence, causation and relative frequencies of the different types of the disease in this country. Here we are informed that cholera and dysentery are almost equally placed for the third and fourth places in order of importance in the Indian mortality rates and that both are much more important for all India than plague, a fact which is by no means generally appreciated.

The seasonal relationships of the disease are shown by a series of All-India charts which demonstrate the all-powerful influence of the rainy season on the incidence of the disease. It should be remembered, however, that such charts represent general conditions only and cannot be taken as universally applicable; thus in certain areas in Eastern Bengal, the greatest incidence of the disease corresponds with the height of the cold season. Of greater importance to the clinician, however, is the description of the relative frequencies of the different types of dysentery and all the implications it holds with regard to faulty treatment. The authors clearly show that as the result of numerous independent investigations bacillary dysentery is at least five or six times more common than is amoebic dysentery and that the almost universal use of emetine in treatment in this country is entirely erroneous and may do irreparable damage without alleviating the symptoms. We fully endorse the authors' concluding sentence "We wish that we could bring home to the medical profession in India the much greater prevalence of bacillary than amoebic dysentery, for therapy—if it is to be successful—must be based on a correct knowledge of facts."

Chapter II gives a very clear, concise and up-to-date description of the etiology, pathology and symptoms of both acute and sub-acute bacillary and acute and sub-acute amoebic dysentery. We are glad to note that special attention is drawn to the occurrence of mixed infections in which amoebae and the dysenteric bacilli are both found, a fact which has not been generally recognised and the possibility of which has in fact been denied in some quarters.

Chapter III is devoted to the diagnosis of the disease which includes the laboratory examination of the stools and a description of the *Entamoeba histolytica*. Here we see the authors at their best. Full directions are given which contain just those details that make all the difference between success and failure, and can only be supplied by those who are themselves familiar with the practical details of such examinations. Attention is drawn to the cytological differences between the stools in the two types of the disease and full descriptions of the *Entamoeba histolytica* and its methods of cultivation are given. The uses of the sigmoidoscope as an aid to diagnosis are also fully explained.

In the next chapter, the difficult question of the bacteriology of bacillary dysentery is dealt with. A complete survey of the intestinal flora found in such cases is made. Such a survey must needs be condensed and some difficulty in following certain parts of the description may be found by those who have not made a special study of the subject. The directions given for the isolation of the dysentery group, together with their reactions, are easy to follow. The difficulties encountered in the serum tests are fully stated, and as a result, the authors give it as their opinion, that it is safer to rely on the results of the sugar tests than on the agglutination findings. Sufficient stress has not perhaps been laid upon the variability found in the biochemical reactions of the dysentery organisms and their inability in certain cases to ferment such important "sugars" as mannite immediately after isolation. In such cases, serum tests are important, as they enable mannite fermenting strains to be recognised, which might otherwise be considered to belong to the Shiga group. A valuable summary of our knowledge of the toxins and immunity reactions of the two types of dysentery organisms, which are of such practical importance from the point of view of scientific treatment, brings this chapter to a close.

The treatment of acute infections is next dealt with. The correct dietaries, which differ according to the type of organism present, and the principles underlying the use of serum and the bacteriophage in bacillary dysentery and of emetine in the amœbic type are clearly enunciated and will repay careful study. It is interesting to note that, after trial with the majority of the numerous compounds introduced since the war for the treatment of amœbic dysentery, the authors still consider emetine to be unsurpassed for this purpose. We are glad to note that the great importance of absolute rest in bed even in mild cases of the disease as a means of preventing relapses is emphasized.

Chapters VI and VII deal exhaustively with the chronic types of the disease and the carrier state. The immensity of the problem of the "chronic dysenteric" makes this chapter one of the most important in the book. The pathology, symptomatology and the difficulties connected with the diagnosis and successful treatment of these conditions are dealt with in turn. The authors have made a special study of the baneful effects of chronic infections of the intestinal tract on the various systems of the body and they attribute many of the symptoms of chronic ill-health found both in Europeans and Indians, particularly those of the neurasthenic type, to this cause. The importance of secondary infections, especially the hemolytic streptococci and the toxins elaborated by such invaders is emphasized and attention is drawn to the ways in which the different systems of the body, especially the endocrine glands, are affected. The authors have undoubtedly introduced a new conception of the processes at work and their results in these conditions which cannot fail to have a stimulating effect on the treatment of such cases and to improve the almost hopeless prognosis which has been the fate of many of these unfortunate sufferers in the past. The frequency of cirrhosis of the liver in Bengal is mentioned on the authority of Sir Leonard Rogers, as a result of chronic irritation, following the amœbic type of the disease only. No mention of the possibility, and in fact the probability, of the much more active toxins of the dysentery bacilli producing a similar action, is made.

A special chapter is devoted to the authors' views on the results of streptococcal infections secondary to bacillary dysentery. In their opinion, such infections may be responsible for the "mucous disease" of infancy, sprue and hill diarrhoea and an asthenic diarrhoea in Indians of which "Sutika" is a good example.

The streptococcal theory of sprue is no new one, as the authors themselves point out, and the possibility of a close connection between previous dysentery and sprue has also been recognised. There is no doubt, that many cases of the so-called "hill diarrhoea," a disease with very similar symptoms, are in reality cases of Flexner infection. There are, however, certain cases which conform more closely to Crombie's original description, in whom the effect of altitude appears to be of primary importance. Further, Mackie and Fairley, who have recently conducted a most exhaustive investigation into the etiology of sprue, have been unable to find any definite relationship between the two diseases. Further evidence on this subject will thus be required before the authors' views can be accepted in their entirety.

The prophylaxis of the disease is dealt with in the final chapter. In addition to the usual sanitary measures, more recent methods, such as the "macroscopic" examination of the stools, prophylactic vaccination by various types of vaccines, including "bilivaccine" and the possible use of D'Herelle's bacteriophage are all passed in review.

A valuable list of references to the voluminous literature on dysentery will be found at the end of the book. It is curious, however, seeing that dysenteries in India is the main theme, that the authors have omitted reference to the publications of the greater number of Indian pre-war workers. In addition to Sir Leonard Rogers, Forster, Greig, Wells, Morison and finally the reviewer conducted almost continuous inquiries into the disease from 1907 onwards until the outbreak of the Great War.

Forster in 1909 emphasized the great prevalence of bacillary dysentery in the jails in this country and was probably the first, apart from Shiga himself, to use a Shiga vaccine on an extensive scale. The knowledge that bacillary dysentery was the most prevalent type of the disease was thus available in pre-war days, but it required a cataclysm like the Great War to arouse general interest in the disease and drive the knowledge home to the profession at large. The fact that the greater part of the work of research workers in India at that period appeared in reports and memoirs which had little circulation outside this country must, undoubtedly, be held responsible for the fact that this knowledge was delayed so long.

The comments we have made do not for one moment detract from the sterling value of the book. The authors are to be congratulated on the production of a book which can be recommended alike to the clinician and laboratory worker and one in which the two aspects of the subject have been happily blended into one harmonious whole. The print and general get up of the book are excellent. There are singularly few misprints. In fact the only one which came to our notice was the spelling of "fermenters" with an "o" in one of the earlier chapters (page 25) and with an "c" in Chapter IV (page 66, *et seq.*).

J. C.

SIX TECHNICAL LECTURES ON LEPROSY.—

Prepared by the Leprosy Department, School of Tropical Medicine and Hygiene, Calcutta, 1928. Pp. iv plus 140, with 105 illustrations. Published by The British Empire Leprosy Relief Association (Indian Council). Price, Rs. 1-4.

THE more one studies the leper problem, the more one is convinced of the fact that one of the chief essentials in the present campaign against leprosy is the careful instruction of doctors and medical students in the chief aspects of the disease. The appearance of this series of lectures on leprosy is therefore timely. Everything is described in a clear and simple way. To anyone who is undertaking the spread of the present-day knowledge of leprosy, a perusal of this book, coupled with one's own clinical experience of the disease, will enable him to give an excellent course of instruction. Besides the lectures, there are 105 photographs, diagrams and charts. A set of lantern slides corresponding to the pictures can also be obtained.

Lecture 1 gives a clear account of the course of the disease and the classification of the various types and stages. The photographs and diagrams accompanying this section are particularly good and illustrate the various points discussed in a way which leaves one with a good knowledge of the clinical stages of the disease.

Lecture 2 deals with infection. Here are discussed the theories of transmission of leprosy from the diseased to the healthy, the sites of initial lesions, incubation period, predisposing causes, etc.

The pathology of the disease is dealt with in Lecture 3. The lepra bacillus is described, the method of spread of the disease throughout the body and the various types of lesions met with. Several good microphotographs accompany this section.

The last three Lectures are devoted respectively to diagnosis, treatment and prophylaxis.

Under diagnosis the cardinal signs and the subsidiary signs of leprosy are given in detail. The methods of snip taking, staining, and testing for anaesthesia are clearly described. Differential diagnosis is fully dealt with.

The various drugs used in treatment at present are well set forth. These include hydnocarpus oil, hydnocarpus esters, sodium hydnocarpate, potassium iodide, and trichloroacetic acid for counter-irritation, while due attention is paid to the treatment of accompanying diseases, especially syphilis and the necessity for paying attention to diet and exercise.

Under prophylaxis the great danger to others of the infectious cases is pointed out, and the arrangements which are necessary for their isolation. The precautions

to be taken by doctors and attendants are also described. We can unhesitatingly recommend this small volume.

R. S. D.

ESSAY REVIEW.

INDUSTRIAL MEDICINE.

(Being a review of the *Fifteenth Annual Report of the United Fruit Co., Boston, Mass.—Medical Department, for the year 1926.*)

MEDICINE, in the hands of the ordinary practitioner, is primarily the derivation of a livelihood from human morbidity. As "Public Health" in the hands of the State, it is mainly philanthropic, with usually a far too small admixture of paternal legislative compulsion superadded. A more recent development is its direct application to Industry, and now many railways, mines, plantations, and manufacturing concerns maintain a medical department, the function of which may extend all the way from the purely curative to organizations taking entire charge of everything appertaining to the health of the employés, and range in magnitude from the solitary dispenser of the average Ceylon tea garden to a department directly comparable to the medical service of a Government.

In the report under review we are introduced to industrial medicine at its *apogee*. Here we encounter a personnel of—

Medical officers	53 (including one woman),
Consultants ..	6,
Nursing sisters	48,
Other staff ..	583 (including a Chief Sanitary Inspector),

operating in nine divisions, plus a headquarters. Not even the great railway companies of this country can make such a showing; but, in the case of the United Fruit Company, we are not dealing with any organization in which there is the smallest admixture of commercial influence or capital, but with one of the greatest of the American Trusts—those much abused corporations commonly reputed to be soullessly devoted to profits at all costs. That a purely business concern of this nature should devote funds for the maintenance of a medical department of this magnitude can be taken as proof positive that they find the application of medicine to industry financially profitable. Let no one imagine that there can be on this Company, as there might be, even in India, a measure of State compulsion to care for the health of their employés, for the United Fruit Company operates almost entirely in what we have learned from O. Henry's novels to designate as the "Banana Republics"—the tragi-comically volcanic States of Central America, where political instability and administrative ineptitude have reached a pitch only reproduced elsewhere by the present condition of China.

It may, therefore, be taken as absolutely certain that such a Company would not maintain a medical department, unless to do so added materially to its profits, and that the size of the department, great as it appears, is not for any altruistic reason maintained at one sweeper more than can be justified to the management by its Chief. And yet what do we find, from the report, this Company doing medically?

In the first place the report contains photographs of hospitals which any Indian city would be proud to number among its public buildings. In them over 29,000 persons were treated during the year under review, with a further 241,000 out-patients at these hospitals, and an unspecified number of "field dispensaries," particulars of which are unfortunately in no case given. Nearly 2,000 major operations were performed, and we find a classification of diseases treated which for completeness puts the annual reports of the provinces of this country to shame. There are 143 heads of return, but in the case of the 29,000 cases admitted to hospital their diseases are further subdivided into 349 heads, which must be near the full known total of the ills that flesh is heir to. But next we come to statistics really valuable to the general management, the percentages of employés daily in hospital, average number of non-effective, partially effective, etc., statistics in this country only obtainable in regard to the Army. If, in spite of all this care, 14.27 per cent. of employés are non-effective—which we take from our own experience to be an excellent result—what would similar statistics for India reveal? But even this model report fails to institute local comparisons, whilst an expenditure statement, for some reason, is omitted. This, as the crux of the whole problem, is most regrettable; but perhaps it forms an item in the annual "Reports of Accounts" of the Company, published elsewhere.

Truthfully, it would pay the medical profession in this country to compile similar statistics. Clive Street possesses business "savvy" at least not incomparable with that of Wall Street.

Let us turn next from the statistical to the more strictly professional sections of the report. Again, we stand amazed at the volume of investigation reported—not done, be it remembered, by a carefully fostered research staff devoting their whole-time to this, but by practising medical men whose employers apparently expect them to devote part of their time to the enhancement of medical knowledge in aspects immediately useful to the Company. We do not find basic researches, which it is the proper sphere of the great research institutions, such as the schools of tropical medicine, to undertake, but the scientific tackling of every-day problems, which here in India such institutions must tackle for lack of similar interest or opportunity on the part of the vast mass of practising medicos in this country.

Commencing with malaria, which the General Manager of the Medical Department in his covering letter to the President of the Company admits is directly responsible for from 38 to 40 per cent. of all hospital admissions, we find seven papers on subjects ranging from anopheline surveys to the elaboration of a precipitin test for the diagnosis of the disease, which for their "practicalness" would be hard to beat. In the first, the epoch-making researches of James and Shute in England—long since fully noticed in this journal—are very fully summarized, and their results pointed out in their applicability to the problem as it affects the Company. These briefly are:—

(i) That a parasite survey demonstrated that men off duty in labour camps, but not on the sick-list, showed thrice as many positive blood findings as those at work.

(ii) That of these ambulatory malarias, nearly one-quarter showed as heavy a parasitic infection as the general run of cases in hospital.

(iii) That the gametocyte rate (chiefly crescents) was 13.5 per cent.

(iv) And that cases discharged from hospitals after treatment showed a gametocyte rate of 45.9 per cent.

It follows that a malignant tertian case "discharged cured" is a very distinct menace to his surroundings, and warrants in addition to "after-treatment" an intensive, short radius campaign of anopheline larva control around camp sites. The few breeding foci in the immediate neighbourhood are a much greater menace than the large, remote, breeding foci.

As, according to James, malaria is a "house-infection," fly-swatting or house-spraying is indicated. This is very difficult in Asia, owing to the purdah system, and the reviewer only knows of one instance, in Madras, where it has been attempted. In any case, it is very doubtful if Indian anophelines are house-dwellers between bites to the same extent as *A. maculipennis*; they probably affect the surrounding undergrowth for rest and digestion.

Recommendations for after-treatment, and treatment without hospitalization, are made. As the paper concludes "We are attempting a practical control of malaria to reduce hospital admissions and supply more labour. This policy should tend towards the future reduction and stabilization of the labour force." Can any employer desire a more sane or practical outlook from his medical staff?

The anopheline survey and the precipitin test papers cannot be adequately summarized here. The latter—not yet perfected—bids fair to yield better results than even the examination of thick films, but it apparently fails completely to differentiate between the three species of parasite—no small a matter if a drug like plasmochin, which is quite inert against the trophozoites of *Plasmodium falciparum*, should come into general use.

Another paper claims good results with hæmostatic serum in blackwater fever.

In the paper on plasmochin the results of the only post-mortem so far obtained on a case of death after the use of this drug are detailed. The liver was the organ mainly affected, but the actual cause of death remained obscure. It is not proposed to go into detail on the results of treatment with the drug here. The whole subject merits a full analysis of the published results of all workers. The medical officers of the Company are themselves not unanimous in their opinions regarding it.

From malaria, the report passes to the second great group of diseases affecting tropical labour—the dysenteries. The two papers included are: (i) a thoughtful article on the diagnosis of amœbiasis in the hands of the average worker, and not the protozoological specialist; and (ii), a paper by Sir Aldo Castellani, one of the consultants, on the classification of the bacillary dysenteries. Next, lobar pneumonia, which accounts for 23 per cent. of the hospital mortality of the year, meningitis, and influenza are each the subject of a paper. There then follow some forty other papers dealing with unusual cases that have presented themselves in practice; with the serology of syphilis—several papers—snake-bite (four papers), concluding with one paper each on the bionomics of the biting ceratopogoninae—(the author calls these sandflies, which seems strange to oriental workers); equine trypanosomiasis, and embalming. Some excellent book reviews conclude the literary section of the report.

Styled an "Annual Report," the book almost ranks with the *Medical Annual* as an indispensable volume for study by medical practitioners in the tropics.

Finally, owing to its industrial importance, we would draw attention to a report on "The selection of labour recruits" by Dr. W. Cordes, Bacteriologist of the Cuban Division. "The criterion for fitness consisted only in the examiner's judgment as to whether a man was in a satisfactory condition to perform his duty as a cane-cutter for five or six months, and at the same time not become a disseminator of some disease or a charge on the hospital." This is precisely the standard that is required in this country in regard to contractor's labour for public works of all kinds. At present there is absolutely no check of any kind on the collection by recruiting agents of human wreckage of the worst description, so be it that they can collect commission thereon. With regard to tea garden recruiting, Government is more concerned with the prevention of kidnapping than with medical considerations proper. Even Ceylon, with its magnificent quarantine at Mandapam, only holds back a few major infectious diseases, and is not concerned directly with loss to the prospective employing companies, though these have to bear quarantine costs for all importations. But here we find 3.8 per cent. of recruits rejected, of which no

more than 0.6 per cent. might have been caught even by the Ceylon regulations, being children too young for work. As the average coolies for earthwork cost about Rs. 30 in advances to recruit nowadays the saving to prospective employers by the introduction of even a low standard of medical inspection for utility is obvious. The same lesson is also stressed in the observations of Fletcher and Jepps (1924) on dysentery in the Federated Malay States; the worst and most fatal type of dysentery with which they had to deal was among the immigrant malaria-ridden coolie labour imported from Madras. When really expensive labour is concerned, such as tea garden labour, the saving is even more obvious. A magnificent testimony to the popularity of the Medical Department of the United Fruit Company is the statement that many sufferers from chronic diseases endeavour to obtain employment with the Company solely with the idea of obtaining free hospital privileges. Not being a philanthropic concern, the Company rightly discourages this.

In Asia there is nothing on the scale of this organization of the United Fruit Company, except the Medical Association of the Estates of the East Coast of Sumatra. The Indian Empire can show nothing like it. What pays the American and the Dutch—the latter a notoriously conservative race—would surely pay British-Indian industrialism, and we look forward to the day when Clive Street will awake to the losses that it suffers from not having equally well organised medical services under its control.

R. SENIOR-WHITE.

Annual Reports.

REPORT OF THE BRITISH EMPIRE LEPROSY RELIEF ASSOCIATION (INDIAN COUNCIL) FOR 1927.

THIS report marks the completion of three years in the life of the British Empire Leprosy Relief Association, Indian Council. The two reports already published described the efforts made to bring this Council into being, and the measures taken to consolidate its financial position and to outline the basic principles of its activities.

In the scheme of the anti-leprosy campaign which the Association has put into operation, the respective parts to be played by the Central and Provincial Committees in carrying forward the aims and objects of the Association are definitely apportioned. In the year under report the scheme has been in full operation, and the results indicate that the campaign is being directed on the right lines. By reason of the adherence of the Central and Provincial bodies to their allotted spheres there has been no overlapping of activities, nor any waste of energy; and the pace of progress has been accelerated. The policy and principles enunciated by the Indian Council, which are expressed in its "Memorandum on the method of conducting an Anti-leprosy Campaign in India," and to which a detailed reference was made in last year's report, have formed the basis of the work of the Provincial Committees.

It is of course too early to expect any visible results. Many cases of leprosy have responded to treatment; but the leper population is so large that it must necessarily be a matter of years before the Association can claim that its activities are checking and reducing to any considerable extent the incidence of the disease. The campaign must be arduous, long and intensive. The first and foremost difficulty of the task is the prevailing ignorance in regard to the nature of the disease. Even practising physicians have still much, in some cases, all, to learn. Not long ago, one of the Association's workers met a doctor who was ignorant of the fact that both he and his servant were suffering from leprosy. The work which the Association has begun and which fully occupies its present resources has served to reveal the enormity of the problem with which it is confronted. One of the primary tasks is to spread knowledge, and it is for that reason that the Association hopes much from the classes held in Calcutta, at which medical men from all parts of India are receiving instruction in the diagnosis and treatment of leprosy.

Scientific researches, in so far as they have been made, and they are daily throwing fresh light on the different phases of the problem, have proved beyond doubt that effective methods are available of clearing up the symptoms and infectivity of most of the early, and some of the more advanced cases. With this knowledge has come the hope that leprosy can be eradicated from this country, in fact from any country, provided the disease with all the different phases of the problems connected with it can be brought under proper control.

The incidence of the disease and the conditions favouring its prevalence and spread vary so widely with the varied manners, customs and dietetic conditions followed in the different parts of the country, that a comprehensive study of the distribution of leprosy is essential to an understanding of the many difficulties to be overcome in dealing with this widespread, but insufficiently known, disease.

Our knowledge of the incidence of leprosy in India is dependent on the 1921 census figures which were collected by untrained enumerators and are avowedly inaccurate. These figures, while they give very little idea of the total number of lepers in India, are useful as indicating the relative incidence in different provinces and districts. With a view to the collection of more accurate information, as foreshadowed in the last Annual Report, an experimental survey of selected areas was instituted during the year under report, which as the succeeding paragraphs show, has brought to light such facts and figures, as to convince the Council of the necessity of continuing it at least to the end of 1928.

Dr. Santra, who has gained considerable experience in leprosy work while working under Dr. Muir at the Purulia Leper Asylum, Bihar and Orissa, was appointed along with four assistants to carry out this survey. The points to be ascertained were:—

(a) The relative incidence of leprosy in different parts of India.

(b) The classes of people among whom leprosy is most rife.

(c) By comparison of leprosy with non-leprosy areas, and castes and classes of people among whom leprosy is common with those among whom it is not, the ascertainment of the causes that underlie high incidence.

The method employed is to choose a suitable thana or police area in a highly leprosy district and establish headquarters at the centre of this thana. Villages are visited and, with the help of village authorities, cases are sought out. Lantern lectures are delivered at night explaining the nature of the disease and the means which should be taken for prevention. A treatment centre is started and held twice a week, the rest of the time being used to complete the survey by house to house visiting. In some of the centres as many as 200 patients were attending within a fortnight and further survey was rendered easy by the help of grateful patients who welcomed the doctors to their villages and gave them all the help possible. Thus, not only was a census of leprosy taken, but incidentally treatment centres were initiated and a large amount of propaganda work was

carried on. Doctors from the neighbouring villages have also been found to attend and in one place the Civil Surgeon brought a number of his medical officers to attend the clinics and learn the methods of diagnosis and treatment.

It is generally found that the survey of one thana occupies one month and when the survey officers pass on to another place, the district authorities supply a doctor who had been trained in leprosy work to carry on the clinic. A list of lepers in various villages is supplied to this doctor and he is able to supplement the survey by noting down the names of new patients who appear for treatment.

The survey was begun experimentally in the Manbhum District of Bihar and Orissa, the Manbazar and Raghunathpur thanas being surveyed. Then the Onda and Gangajalghati thanas of the Bankura District of Bengal were surveyed; thereafter, three areas in the Sonthal Parganas, and the end of the year found the survey party in the Chin Hills of Burma. In the first three districts, the incidence of leprosy was found to be between 4 and 5 times that given by the census figures; but it cannot be claimed that even this survey has revealed the total incidence as second visits to certain villages generally resulted in the discovery of even more cases. Much help was received everywhere from District Magistrates, Civil Surgeons, District Board Officers, District Health Officers and others. In Deoghur thana, the figures reported by the village police gave 30 cases, whereas the expert survey of a quarter of the thana revealed 274. In one high school, eleven cases of leprosy were found among 300 boys.

The areas surveyed and the proportion of the population examined are still too small to enable any general conclusions to be based upon them; nevertheless they tend to confirm the belief expressed in the last year's report that there are at least half a million people in India suffering from leprosy.

So successful have the Propaganda-Treatment-Survey centres proved that the Bengal Branch of the Association is making efforts to begin a provincial survey on similar lines by appointing a band of survey doctors to work in Bengal, and it is hoped that other provincial branches will adopt the same method of dealing with leprosy. The scheme entails the initiation of such centres in two or three thanas of every district where leprosy is common, to be carried on by specially trained doctors supplied by the district authorities. In this way, every district would have model clinics which, besides furnishing more accurate figures regarding endemicity, would demonstrate the possibilities of leprosy treatment, serve as centres of popular propaganda and help to train local doctors. The method adopted in some places of sending anti-leprosy drugs along with literature to existing Government or District Board Dispensaries and expecting untrained doctors to carry out leprosy treatment is to be deprecated. The treatment when thoroughly understood is not difficult to carry out, but it is generally found that special training of doctors is necessary if they are to obtain good results and attract patients.

It is hoped that during 1928 it will be possible to have a survey carried out in the province of Assam, the Central Provinces and the Bombay Presidency.

Other activities of the Central Committee were those which form its special charge, namely:—

(1) Research into the various phases of the disease and into the methods of diagnosis and treatment;

(2) Training of doctors at the Calcutta School of Tropical Medicine in the diagnosis and special treatment of leprosy; and

(3) Publication of material with a view to propagating a true knowledge of the disease, its treatment and prevention, both for medical men and the laity.

RESEARCH.

Research has been carried on, as before, in the School of Tropical Medicine and Hygiene, Calcutta under Dr. E. Muir, M.D., F.R.C.S.

Considerable progress has been made during the year in the treatment of leprosy, the most important advance

being the adoption of potassium iodide. The effect of this drug in leprosy had been known for a long time but the marked reactions caused by ordinary doses in the best known types of leprosy had led to its being considered dangerous and harmful. The clinical and pathological study of large numbers of cases at the Calcutta School of Tropical Medicine led to a new classification of leprosy, and with the aid of this classification certain types and phases of the disease were found to benefit from this treatment, while certain precautions had to be taken in the treatment of others. Not only has the period of treatment been shortened but the workers in Calcutta have found in iodides a much more accurate means of diagnosis of early and doubtful cases and a more reliable test of the extent of the elimination of the disease in cases in which all active signs have disappeared under treatment. The diagnostic value of iodide has also been enhanced by the conjoined use of the blood sedimentation test.

Dr. Henderson, who was appointed by the Indian Council last year as an assistant of Dr. Muir, has been making a careful microscopic study of the early lesions of leprosy, a work which needed thorough investigation, most pathologists having in the main confined their energies to the examination of the more advanced cases. Interesting results have already been obtained.

Four special courses of instruction in leprosy were held at the School of Tropical Medicine and Hygiene, two of these being in February and two in November. One hundred and four doctors attended these courses of whom one hundred came from the following provinces and states:—

Punjab	2
Madras	8
Bihar and Orissa	14
Central Provinces	30
Bengal	17
Burma	6
Bombay	1
Assam	6
United Provinces	3
Western India States	12
Central India	1

100

One doctor was sent from Egypt, two from West Africa and one from Greece by their respective governments to study leprosy before acting as leprosy experts in those countries.

Each course lasts a fortnight and consists of lectures, practical demonstrations with opportunities for practice in diagnosis, differential diagnosis, pathological study and treatment. An examination is held at the end of each course and a certificate is granted to those who pass.

As some of these doctors are themselves teachers in medical schools, whole-time workers in leprosy and propaganda officers, far more training has resulted from these courses of lectures than the figures suggest. One of the doctors alone, Dr. B. N. Ghosh, since completing this course in February 1927, has conducted intensive six-day courses in leprosy attended by over 200 doctors in various districts of Bengal.

In the last three years, 184 doctors have been trained at the School of Tropical Medicine and Hygiene, Calcutta, and although the achievement coupled with the special training which these doctors have in their turn imparted to others, is satisfactory, it is much short of the ideal, namely, that each district should have a sufficient number of trained doctors to ensure that a leprosy patient may not have to travel any great distance to obtain treatment.

The main key to the situation therefore lies in the ability of the local doctor to administer efficient treatment in cases of leprosy coming to his notice. If early cases come under treatment and, as is expected, a cure is effected, it would not only encourage lepers to seek medical aid more readily but would at once begin to dispel much of the popular prejudice against the leper, who would receive more care and attention from his own people than has hitherto been his lot.

As in the previous year, practically all the doctors deputed to Calcutta have been members of Provincial and Subordinate Medical Services. While doctors from this class are always welcome to the classes the Indian Council would like to see private medical practitioners also availing themselves of this training which is given without any cost.

PROPAGANDA.

A steady demand for propaganda material, which was further supplemented during the year, has been maintained. These demands have been received both from doctors and laymen, in India and abroad.

Dr. Muir's pamphlet "Leprosy: Diagnosis, Treatment and Prevention" has been the most popular necessitating the publication of a further edition of 4,000 copies. The edition has been fully revised to bring the information of subjects dealt with in it up-to-date.

The "Popular Lecture on Leprosy" illustrated with 55 pictures and a set of slides corresponding to these pictures has also been much in demand. The book has been issued gratis but the slides were sold at Rs. 60 per set packed in a suitable box. This book which was published in 1926, has gone through its second edition during the year under report.

APPENDIX II.

Leprosy Survey: March—November, 1927.

Thana surveyed.	District and Province.	Population.	Number of villages surveyed.	Number of villages affected.	Total Lepers (Chowkidars' Census).	Total Lepers (Expert Census).	Ratio Chowkidar Expert.	Total patients attending treatment centre.	Castes chiefly affected.	Period of survey.
Manbazar.	Purulia (B. & O.).	97,504	347	188	237	633	1 2.7	170	Bauri. Kurni.	March April.
Raghunathpur.	Purulia (B. & O.).	70,731	197	124	183	892	1 4.9	250	Bauri. Kurni.	May.
Onda	Bankura (Bengal).	66,862	285	203	246	919	1 3.7	361	Bauri. Gowala. Teli. Brahmin.	July.
Gangajalghati.	Bankura (Bengal).	49,991	178	142	276	1,005	1 3.6	212	Bauri. Teli. Sudi. Gowala.	August.
Jarmundi Centre including Haripur Circle.	Sonthal Parganas (B. & O.).	50,624	526	119	70	328	1 4.7	256	Ghatwals. Kheturias. Khetries. Paharias. Santals.	September.
One quarter of Deoghur.	Sonthal Parganas (B. & O.).	30,000 (approx.)	314	78	30 Deoghur, for whole Thana.	274 For qtr. of Deoghur Thana.	1 9 (Uncorrected.)	70	As in Jarmundi Centre.	October.
Hiranpur Police Station and Hiranpur Bungalow.	Sonthal Parganas (B. & O.).	40,754	163	106	58	478	1 8	290	As in Jarmundi Centre.	November.

"What the Public should know about Leprosy," another illustrated booklet, which was published late last year, has proved so popular that it has become necessary to publish it in ten different vernaculars, namely:—

Bengali, Assamese, Hindi, Urdu, Tamil, Telugu, Marathi, Gujarati, Malayalam and Oriya.

The Burma Provincial Branch is contemplating the publication of a Burmese edition.

A set of 12 charts illustrating the different phases of the disease, its prevention and treatment, was nearing completion when the year ended.

A new book containing six technical lectures, on leprosy illustrated with 105 pictures was also in the process of being printed at the end of the year. This book which is further illustrated with slides corresponding with its pictures, will be of great help to the doctors wishing to make a further study of leprosy and its special treatment.

The film on leprosy is continuing to be used extensively. Two copies of the film were sold during the year and one was sent to the International League of Red Cross Societies, Paris. Writing in regard to the film the Secretary General of the League said:—

"It was found very interesting by the many different persons who had the opportunity of seeing it. This film was for us an exceedingly good demonstration of the propaganda methods utilized in India and gives a better understanding of your problems."

The most noticeable feature of the work in the provinces has been the establishment of leprosy clinics for the most part in connection with existing hospitals. For an extension of this work, trained doctors are required, and the Central Committee will be glad to arrange for the training of a larger number of doctors each year than it has hitherto done if the Provincial Committees are able to secure their deputation to Calcutta. Assam and the Central Provinces have achieved the largest measure of success in opening these clinics, a result which may probably be ascribed to the fact that these Branches have sent for training the largest number of doctors. Bombay, Bihar and Orissa, Madras and the United Provinces Branches have also made good beginnings in this respect.

ANNUAL REPORT ON THE HOSPITALS AND DISPENSARIES UNDER THE GOVERNMENT OF BENGAL FOR THE YEAR 1926. BY MAJOR-GENERAL G. TATE, K.H.S., I.M.S., CALCUTTA, BENGAL SECRETARIAT BOOK DEPOT. PRICE, RS. 7-12.

This report deals as usual with (a) institutions in Calcutta city; and (b) institutions outside Calcutta.

In Calcutta, there were 33 hospitals and dispensaries in operation during the year, with a total of 3,145 beds available. The improvement in these figures over those for the previous year is chiefly due to the opening of a new 32-bed ward at Howrah General Hospital. During the year, 553,521 in-patients and out-patients were treated, the newly opened Sashi Bhusan Neogy Dispensary at Natherbagan having treated 17,155 persons. The average number of patients per nurse in the various large hospitals in Calcutta varied from 2.51 patients per nurse in the Presidency General Hospital to a corresponding figure of 26 at the Campbell Hospital.

The year was notorious for a severe outbreak of cholera which occurred from January to June. A total of 1,915 in-patients was treated, of whom the Campbell Hospital dealt with 1,559—despite the fact that there are only 29 beds in its cholera ward. This accommodation the Surgeon-General holds to be quite inadequate to the needs of the city, but arrangements for rapid temporary expansion are very good. The attendance figures for kala-azar showed some falling off; 9,947 patients as against 11,228 in the previous year, but every hospital in Calcutta still continues to record a large number of patients treated annually. Malaria was responsible for the attendance of 49,893 patients, and is now generally treated by a cinchona febrifuge prescription rather than quinine. Small-pox was unimportant during the year, and influenza sporadic only. Beri-beri,

however, rose to epidemic status, and no less than 6,810 patients were treated in the different hospitals, with 165 deaths. Pulmonary tuberculosis appears to become worse and worse with every successive year in Calcutta; the figures being 4,117 attendances for 1926 as compared with 3,904 in 1925. There is a tuberculosis ward for European patients at the Presidency General Hospital, but for Indian patients the only accommodation available is a ward of 16 beds for males and 8 for females on the roof of the Medical College Hospital. The entirely inadequate provision for treatment of the almost innumerable sufferers from this disease in Calcutta has been an open reproach to the city, for many years and any philanthropist anxious to deserve well of the thousands of sufferers from this disease in Calcutta might well have his attention drawn to this terrible and distressing problem. As matters stand at present a diagnosis of pulmonary tuberculosis in a middle class Bengali clerk or an Indian workman in Calcutta is almost equivalent to a death sentence. Venereal disease, again, is one of the scourges of the city and was responsible for 21,625 attendances.

Surgical operations in Calcutta hospitals totalled 50,191, of which cataract extractions and laparotomy for conditions other than obstetrical head the list. Receipts amounted to Rs. 30,67,376, of which Government found Rs. 18,95,645, or 62 per cent., whilst a sum of Rs. 5,37,905 was collected from private patients, subscriptions, and donations. New buildings and extensions were responsible for much of the expenditure during the year.

Eighty-one patients in all were dealt with at the mental observation ward, Bhowanipore, during the year, of whom 57 were certified as insane and transferred to Ranchi. Six others were treated at the insane ward of the Albert Victor Hospital for leprosy, Gobra.

District Hospitals and Dispensaries.—Outside Calcutta city, the year saw the total number of hospitals and dispensaries increased by 30, the total being 1,062. In addition 43 homœopathic and 11 Ayurvedic dispensaries were at work during the year. The total number of patients treated at the allopathic dispensaries during the year was 7,788,457, whilst 5,444 beds were available in the *mofussil* institutions. Malaria heads the list of diseases in the *mofussil* with 2,115,764 attendances; influenza was slightly prevalent with 68,753 attendances; cholera showed an increase on the previous year's figures, and the small-pox epidemic of 1925 persisted on into 1926. As a result of the activities of the British Empire Leprosy Relief Association, reflected in the greater attention which is now being paid throughout India to the diagnosis and treatment of leprosy, the figures for this disease show a marked advance on those for 1925; 2,661 patients in all treated during the year. Surgical operations in all numbered 139,246, an increase of nearly 4,000 on the 1925 figures. In this connection it is interesting to note that, whereas in Calcutta city the chief selected surgical operations are for cataract, and laparotomy for non-obstetrical causes, in the *mofussil*, most of the selected operations are for cataract, but operations on bones come second (perhaps most of them being for compound fractures), and abdominal sections low down on the list. Abdominal surgery is clearly more a matter for the big hospitals of the big cities in India than for *mofussil* dispensaries.

Correspondence.

BLEEDING OF THE GUMS AFTER QUININE ADMINISTRATION.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—The following case perhaps presents a point of interest:

Mrs. A., aged 28, was delivered of a healthy child. The next day she had fever, a temperature of 101°F., with rigor. On the second day the temperature was

101°F. in the morning, and 103°F. in the evening. There was no abdominal tenderness or rigidity, and the lochial discharge was normal. The uterus was well retracted and not tender on palpation.

On the third day the temperature in the morning was 100°F., and she took a first dose of 5 grains of quinine that morning, followed by a second similar dose three hours later. Soon after the second dose profuse bleeding commenced from the gums, and I was called in to see her. Both surfaces of the gums were involved; there was no rash, and no bleeding from elsewhere (except the normal lochial discharge).

I gave a mouth wash of iced water, alum and hydrogen peroxide in succession with very little effect. Calcium lactate, 15 grains, dissolved in water was given orally every two hours. Tincture ferri perchloride applied locally had a temporary effect only. Stypticin was applied locally and two tablets were given to swallow every three hours. The bleeding finally ceased eighteen hours after its onset.

A year previously, the patient had had a similar attack of bleeding from the gums after taking a dose of quinine. This lasted for twelve hours. At that time she was not pregnant, nor had she been recently delivered.—Yours, etc.,

JAGDISH RAI, M.B., B.S.

MANDI,
ROHTAK,
15th May, 1928.

THE COMPOSITION OF PLASMOQUINE.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—The I. G. Pharma "Bayer-Meister-Lucius," Works Elberfeld, issues the following statement:

As the research work on the new synthetic compounds, to which Plasmogine belongs, was brought to a conclusion, we can publish the exact composition of the said remedy. The effective part of all Plasmogine preparations is a base of the chinolin group, namely, the N-diethyl-amino-isopentyl-8-amino-6-methoxy-chinolin. The therapeutically inefficient acid residue only is different in the different Plasmogine preparations. In the ampoules there is the water-soluble hydrochloric salt of the said base, whereas the tablets contain a salt only difficult to dilute. However, to bring the statement of dosage on a common denominator, the said statement is always calculated with reference to the monochlorhydrate of the said base.

The inventors, Dr. Schulemann, Dr. Schoenhoefer and Dr. Wiegler, will publish exact chemical information in due time in the chemical press.—Yours, etc.,

DR. OSWALD URCHS, M.D. (Prague),
Medical Adviser to:
Messrs. Havero Trading Co., Ltd.,
Pharmaceutical Dept., "Bayer-Meister-Lucius."

Service Notes.

APPOINTMENTS AND TRANSFERS.

The services of Major A. C. L. O'S. Bilderbeck, I.M.S., are placed permanently at the disposal of the Government of Burma, with effect from the 22nd June, 1928.

Major W. J. Webster, M.C., I.M.S., an officer of the Medical Research Department, is attached as a Supernumerary Officer to the Haffkine Institute, Bombay, with effect from the date on which he assumes charge of his duties.

On relief by Major Khan, I.M.S., Major N. S. Jatar, I.M.S., is appointed to the executive and medical charge of the Jubbulpore Central Jail.

Major L. H. Khan, I.M.S., is appointed to the executive and medical charge of the Nagpur Central Jail, from the date he assumes charge.

Major C. J. Stocker, M.C., M.D., I.M.S., Civil Surgeon, Hoshangabad, is appointed to be Civil Surgeon, Pachmarhi, from the 1st April to the 30th June, 1928.

The services of Major J. P. Huban, O.B.E., I.M.S., an Officiating Agency Surgeon, are placed at the disposal of the Government of India in the Department of Education, Health and Lands.

Captain H. W. Mulligan, I.M.S., is appointed temporarily to the Medical Research Department and is posted on foreign service under the Indian Research Fund Association, with effect from the 7th May, 1928.

The undermentioned officers are appointed temporarily to the Medical Research Department and posted as Supernumerary Officers to the Central Research Institute, Kasauli, with effect from the dates on which they assume charge of their duties:—

- (1) Captain R. W. H. Miller, I.M.S.
- (2) Lieutenant M. L. Ahuja, M.D., I.M.S. (T.C.).
- (3) Lieutenant S. M. K. Mallick, I.M.S. (T.C.).

Colonel J. Norman Walker, I.M.S., Inspector-General of Civil Hospitals, Central Provinces, is appointed to act as Director of Public Health, Central Provinces, in addition to his own duties during the absence on leave of Lieutenant-Colonel H. G. Stiles Webb, or until further orders.

The Viceroy and Governor-General has been pleased to make the following appointment on His Excellency's personal staff, with effect from the date specified:—

To be Honorary Surgeon.

Colonel L. J. M. Deas, M.B., F.R.C.S.E., I.M.S., vice Lieutenant-Colonel R. Kelsall, D.S.O., M.D., I.M.S., vacated. Dated 9th July, 1928.

Lieutenant-Colonel J. W. Watson, C.I.E., I.M.S., an Agency Surgeon, on return from leave, is posted as Civil Surgeon, Ajmer, and Chief Medical Officer in Rajputana, with effect from the 12th July, 1928.

The services of Lieutenant-Colonel J. M. A. Macmillan, M.D., I.M.S., Civil Surgeon, Simla (East), are replaced at the disposal of the Government of the Central Provinces, with effect from the 1st May, 1928.

In supersession of the previous orders of the Department of Education, Health and Lands, dated the 9th February, 1928, Lieutenant-Colonel R. W. Anthony, M.B., F.R.C.S.E., I.M.S., Officiating Surgeon-General with the Government of Bombay, is confirmed in that appointment, with effect from the 11th January, 1928.

Major C. M. Ganapathy, M.C., I.M.S., is confirmed as Health Officer, Simla, with effect from the 1st November, 1927.

Subject to His Majesty's approval, the undermentioned officers have been appointed permanently to the Indian Medical Service as Lieutenants by the Right Hon'ble the Secretary of State for India. Their commissions will bear dates as specified against their names:—

Wajid Ali Khan, M.D. (Lieut., I.M.S.T.C.). Dated 2nd August, 1927. (Previous service as a temporary officer in the Indian Medical Service from 10th May 1926 to 1st August 1927 counts for pay, pension and promotion.)

Surendra Nath Lahiri, M.B. (Lieut., I.M.S.T.C.). Dated 2nd August, 1927. (Previous service as a temporary officer in the Indian Medical Service from 27th August 1926 to 1st August 1927 counts for pay, pension and promotion.)

Shankar Sahai Bhatnagar, M.D. Dated 2nd August, 1927.

Bijeta Chaudhuri, M.B. Dated 2nd August, 1927.

Harnand Lal Batra, M.B. Dated 2nd August, 1927.

Priya Nath Lahiri, M.B. (late Captain, I.M.S.T.C.). Dated 2nd August, 1927. (Previous service as a temporary officer in the Indian Medical Service from 27th August 1917 to 31st August 1925 counts for pay, pension and promotion.)

Leonard George Backhurst (Assistant Surgeon, I.M.D.). Dated 10th November, 1927. (Previous mobilized service as a Warrant Officer from 16th November 1916 to 9th November 1927 counts in full for pension.)

Birendra Nath Hajra, M.B. (late Lieut., I.M.S.T.C.). Dated 10th November, 1927. (Previous service as a temporary officer in the Indian Medical Service from 11th February 1924 to 10th February 1925 counts for pay, pension and promotion.)

LEAVE.

Lieutenant-Colonel G. D. Franklin, C.I.E., O.B.E., I.M.S., an Agency Surgeon, is granted leave on average pay for 8 months combined with leave on half average pay for 1 month, with effect from the 12th July, 1928.

Leave for 1 year is granted to Lieutenant-Colonel H. G. Stiles Webb, I.M.S., Director of Public Health, Central Provinces, with effect from the 2nd May, 1928.

Lieutenant-Colonel J. W. McCoy, I.M.S., Civil Surgeon, Sylhet, is allowed leave on average pay for 4 months and 15 days, with effect from 30th June, 1928, or any subsequent date on which he may avail himself of it.

Lieutenant-Colonel B. B. Paymaster, I.M.S., is granted leave, preparatory to retirement, on half average pay for 6 months and 30 days in continuation of the leave already granted to him.

Lieutenant-Colonel K. G. Gharpurey, I.M.S., is granted leave on average pay for 7 months, with effect from the 15th June 1928, or date of relief.

Lieutenant-Colonel J. M. A. Macmillan, M.D., I.M.S., Civil Surgeon, Simla, East, is granted leave on average pay for 8 months combined with leave on half average pay for 10 months, with effect from the 1st May, 1928.

Major E. S. Goss, M.C., I.M.S., Officer-in-charge, Medical Store Depot, Lahore Cantonment, is granted 60 days' privilege leave, with effect from the forenoon of 5th June, 1928.

PROMOTIONS.

The promotion to his present rank of Major K. S. Master, M.C., M.B., I.M.S., notified in Army Department Notification No. 1031, dated the 20th August, 1927, is antedated from the 10th August, 1927 to the 10th February, 1927.

Captains to be Majors.

B. Sahai. Dated 21st May, 1928.
M. L. Bhargava. Dated 5th June, 1928.
D. V. O'Malley. Dated 8th June, 1928.
T. R. Khanna. Dated 20th June, 1928.
Som Dutt, M.C. Dated 24th June, 1928.

Lieutenant to be Captain.

Priya Nath Lahiri, M.B. Dated 2nd August, 1927, but to rank from the 28th July, 1922. Grading after allowing for break in service.

RETIREMENTS.

His Majesty the King has approved the retirements of Captain R. T. W. Stoney, I.M.S., with effect from the 10th May, 1928, receiving a gratuity and of Lieutenant-Colonel H. C. Keates, M.D., I.M.S., with effect from the 3rd June 1928.

NOTES.

ANTIPHLOGISTINE IN PNEUMONIA.

PNEUMONIA is pre-eminently a disease in which prevention is better than cure. Although much can be accomplished by rational treatment, a high mortality persists in spite of all forms of medication.

Very many cases of pneumonia follow in the wake of influenza, bronchitis, or even an apparently innocent upper respiratory tract infection. The pneumococcus, it has been proved, finds it difficult to penetrate the healthy mucous membrane of the bronchial tube and alveoli; but, when this membrane has already been damaged by bronchitis or influenza, the micro-organism gains a foothold and pneumonia may be the result.

The best time to treat pneumonia is before it develops. If every attack of bronchitis or influenza were handled as a potential case of pneumonia, there would be far fewer actual cases.

By relieving internal congestion, by stimulating the superficial blood flow, by increasing the phagocytic

power of the protective white blood cells, and by restoring normal circulation in the inflamed bronchial tubes and alveoli, Antiphlogistine has proved itself an invaluable auxiliary to the physician practising modern preventive medicine.

WATSON'S MICROSCOPE RECORD.

THE quarterly *Microscope Record*, published by Messrs. Watson and Sons, Ltd., 313, High Holborn, London, W. C. 1, continues to be a journal of great interest to laboratory workers and microscopists. In a recent issue received—that for January 1928—Mr. T. Thorne Baker deals with the subject of contrast filters in microphotography; this is an article of special value on account of the table which it includes of the most suitable contrast filters for use with the commoner microscopic stains. Dr. F. J. Brislée, D.Sc., F.R.M.S., deals with micrometry; this short article describes the use and standardisation of the eyepiece micrometer, and also the use of the stage micrometer. Watson's "Binar" is a small but interesting instrument described; it is a combined telescope and magnifier only 15/16ths of an inch long, costing 17s. 6d. For viewing distant objects the draw tube gives a magnification of 2½ diameters; for close work the object glass alone is used, and gives a magnification of 6 diameters. Mr. G. T. Harris of the Quekett Microscopical Club continues his series of articles on the Desmidiaceae. A section of the number is devoted to metallurgical work, and suitable models of microscopes for such work. Other articles deal with the use of the microscope in the paper and other textile industries, whilst the section of answers to correspondents includes many useful "tips." Of special interest is a mounting medium prepared by the British Drug Houses, consisting of a solution of hard Yucatan "elemi" in xylene, which, it is claimed, is free from the organic resin acids so invariably present in Canada balsam; it is claimed for this mountant that stains which are decolourised by balsam—such as the Romanowsky ones—are well preserved. There is also an account of the different types of objectives issued by Watson and Sons; of these we have frequently used Watson's "Versalic" 1/12th inch oil immersion objective, and have always found it a reliable lens, with clear definition.

Publishers' Notice.

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles will receive 25 reprints *gratis*, if asked for at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions, Advertisements, and Reprints should be addressed to THE PUBLISHERS, Messrs. Thacker, Spink & Co., P. O. Box No. 54, Calcutta.

Annual Subscription to The Indian Medical Gazette, Rs. 16 including postage, in India. Rs. 18 including postage, abroad.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

A DISCUSSION ON THE POSSIBILITY OF *ASCARIS LUMBRICOIDES* INFECTION BEING ACQUIRED THROUGH THE SKIN.

By P. A. MAPLESTONE, D.S.O., M.B., Ch.B., D.T.M.

(From the Hookworm Research Laboratory, financed by the Indian Jute Mills Association.)

School of Tropical Medicine and Hygiene, Calcutta.

It is an established fact that infection with *Ascaris lumbricoides* occurs by swallowing eggs containing developed embryos, but owing to certain anomalies that have been noted in the epidemiology of this infection, it seems worth while to consider whether this is the only way in which infection can occur.

The commonest sources of ascaris infection are considered to be green vegetables and drinking water that have been contaminated with faeces containing mature ascaris eggs. There are numerous records of finding ascaris eggs on vegetables, and that of Walker (1927), who traced the high rate of infection in the Singapore garrison to contaminated green vegetables, eaten raw, is a good example. There are also many references in the literature such as that of Isobe (1925), who found ascaris eggs on spinach and cabbage, but these are of little significance, for vegetables of this kind are invariably boiled before being eaten. Certain destruction of the eggs would thus occur for Ogata (1925) has shown that they are very susceptible to heat, being killed in one second in water at only 75°C.

Chandler (1926) quotes the results of faecal examinations in two islands in Bengal, as evidence of water contamination being a prolific source of ascaris infection. In a small island with a single water tank and a population of 92 the water was free from contamination, because the stools were deposited mostly on the outward-sloping banks of the island, and so they were not washed into the tank by rain. Here the infection rate in 66 stools examined was 4.7 per cent. In a larger neighbouring island, however, with several water tanks and a population of 500, many of the tanks showed stools lying on the banks sloping towards them, whence the faecal matter would be washed into the water by rain. In this island 35 stools showed 80 per cent. ascaris infection. This seems conclusive, but only 52 per cent. of the stools from the first island and 85.7 per cent. of the stools from the second island showed hookworm infection, which is clear evidence that soil contamination in the large island is probably much greater; therefore, the contention that the high ascaris rate in the large island and the low ascaris rate in the

small island are solely due to differences in degree of water contamination, is not so definite as at first sight appears. Another fact remarked by Chandler (1928) in the tea gardens of Assam, Northern Bengal, and South-West India, where both hookworm and ascaris infections are very common, was that the ascaris infection rate was approximately the same in gardens where the sole water supply was from heavily polluted surface collections, and in gardens which had tube wells or water borne in pipes from a distance, and therefore free from the suspicion of faecal contamination. The tea garden coolies do not use uncooked vegetables as food to any extent, therefore it must be assumed in the light of present knowledge that contaminated water is the principal source of ascaris infection in these places. In other words, the recognised sources of hookworm infection in the different gardens is the same, whereas the recognised sources of ascaris infection vary, so that one would not expect to find the intensity of infection with these two parasites running a parallel course in all the gardens. Even if it is admitted that coolies with a clean water supply are prone to drink from surface water as well, one would expect to find the partial use of clean water as opposed to the sole use of contaminated water, reflected in a lighter ascaris rate in the former places, but such is not the case. This suggests that there may be other ways of acquiring ascaris infection than by swallowing ripe eggs.

In Penonome, Panama, where human faeces are not used as fertiliser for vegetables, and the drinking water is not polluted, Brown (1927) reports an infection rate of 40 per cent. to 90 per cent. with ascaris, and he found the eggs in the earth floors of huts.

Sasaki (1927) states that the specific gravity of ascaris eggs varies between 22.2 and 11.1 by Baumes scale. Unfertilised eggs are the lightest, and mature eggs are slightly lighter than eggs in which embryos had not yet developed. But whatever their condition, they would sink fairly rapidly in water and would remain at the bottom of a tank, unless carried to the surface entangled in floating matter. Therefore, unless the water was so shallow that the act of dipping from a tank caused the sediment to rise so that some of it entered the vessel or the cupped hands, there would not be much likelihood of ascaris eggs being ingested in this manner.

Swellengrebel (1913) found that ascaris eggs would hatch in water after a period of about three months if they were kept free from bacterial growth. Swellengrebel claims that this is the first record of ascaris eggs hatching outside the animal host. Although this observation is possibly of considerable importance, it seems to have attracted little attention, for it is not until Kondo (1920) reported the hatching of ascaris eggs in soil in about seventy days that any further reference to the hatching of

these eggs in the free state, can be found. Kondo was evidently unaware of Swellengrebel's work for he claims his observation as the first record of ascaris eggs hatching outside the body. This Japanese worker carried the work through a further important stage, for he found that larvæ hatched in this way could live in moist soil for at least a month, and that when they were smeared on the skin of a guinea-pig they were found in the lungs of this animal at a later date. This work was confirmed by Kondo (1922) and Asada (1921). Hirasawa (1927) hatched *Ascaris lumbricoides* eggs in an artificial medium (the nature of which is not given in the summary) and although subsequent development in the free state was not apparent, he succeeded in infecting laboratory animals with these larvæ administered by the mouth. He found that the same course of migration occurred in these animals as when ripe eggs were swallowed. Similar observations were made by Asada (1925). None of this work by Japanese investigators has yet been confirmed in other parts of the world as far as the writer can ascertain. They apparently have some special method of bringing about the hatching of ascaris eggs, which has not been published, except possibly in the original Japanese, and consequently it is not available to the majority of workers. The writer is of the opinion that certain special ways of making successful cultures must be necessary, for from a considerable number of tentative experiments in which ascaris eggs have been placed in tubes of water or on moist soil, only a few eggs out of a large number in one tube of water hatched, the reason for this partial success and numerous failures not being apparent. In confirmation of this, Ransom and Foster (1919) state: "Some writers have found that hatching will occur outside the body if the eggs are placed in certain solutions. We have been unable, however, to cause more than a very small percentage of eggs to hatch outside the body in vitro. The factors which bring about the hatching of eggs have not yet been determined."

Stewart (1916 and 1918), by feeding experiments on mice with ripe ascaris eggs traced the larvæ of *A. lumbricoides*, and *Toxacara mystax* to the cæcum, the route being via the lungs, trachea, cesophagus, etc. They had undergone a certain amount of development, but were soon voided in the fæces as the host was unsuitable. Stewart's work was confirmed by Ransom and Foster (1919), and by using a young kid and a lamb they found worms in the intestines of these animals in a much more advanced stage of development than one can get in rats, guinea-pigs, etc. They regard this as evidence that the larger animals are of an intermediate degree of host suitability between man and the smaller animals. These workers quote Martin (1913), who made eggs of *A. vitulorum* hatch by placing them under the skin of guinea-pig, and they carried his work a step further by repeating the

experiment, and by subsequently finding the larvæ in the lungs.

Fulleborn (1921) has shown that larvæ of *A. lumbricoides* are disseminated by the blood stream, and that they reach the arteries from the veins, via the capillaries. In the case of *Toxacara canis*, he found puppies 3 to 4 days old infected with larvæ 2 to 3 weeks' old. Similar findings have been recorded in the case of hookworms, for Howard (1917) discovered hookworm eggs in the stool of a child 14 days old, and Adler and Clarke (1922) frequently found mature *Ancylostoma caninum* in puppies from 5 to 15 days' old. This indicates that once the larvæ of *T. canis* have gained entrance to the body of a host they are capable of behaving in a similar manner to the larvæ of ancylostomes, and it seems reasonable to assume that the larvæ of *A. lumbricoides* can do the same.

CONCLUSION.

Consideration of the above facts suggests that under conditions not yet generally understood, the eggs of *A. lumbricoides* can hatch in moist soil and that the larvæ can live in this medium for at least a month. After hatching they are probably capable of penetrating the skin and reaching the lungs, whence they would almost certainly migrate to the intestines and reach full development in the human being.

REPORT ON THE INVESTIGATION OF AN OUTBREAK OF EPIDEMIC DROPSY IN SURADA, A VILLAGE IN GANJAM DISTRICT.

By A. V. KAMATH, M.B., B.S.,

District Health Officer, Ganjam District.

Geographical situation.—The village is situated about 47 miles north-west of Berhampur and is reached by road. Together with Boradi and Motto Sahi villages it forms the Union of Surada with a total population of about 4,000. All the three villages lie on the southern bank of the Rushikulya river, between the river on the north and the Surada reservoir on the south. At first a small village, it has gradually developed into an important centre of agency trade, being one of the gateways to the Ganjam agency and the headquarters of the Deputy Tahsildar and of all the sub-offices of various departments. Though it does not come under the agency proper, it is surrounded on three sides by the agency. It has highly malarious villages on all sides and is itself malarious. There is practically no cultivation around the three villages.

The soil is alluvial almost throughout the whole village site except where the new public offices and quarters for officers are built. Here the soil is red earth mixed with gravel.

The sub-soil water level is generally high, being about 6 to 8 feet from the surface. It is water-logged in the rainy season, being surrounded by the flooded rivers and the reservoir. The village generally slopes from south-west towards north-east and the drainage of the village goes into the river Rushikulya.

General sanitation.—In spite of the existence of a union, the sanitation of the village is very bad. Besides the huge reservoir on the south, there is a big disused irrigation tank close to the village which is full of water-hyacinth. They serve as breeding-places for mosquitoes.

Water-supply.—The water-supply of the village is the river which is badly polluted. Only three fresh-water wells exist, two near the officers' quarters used solely by them, and one in the mission quarters.

Conservancy is very bad. There is no night-soil conservancy to speak of and the rubbish conservancy is very much neglected. To add to this insanitary condition, the union administration has been at a stand-still since September 1925.

The climate of Surada.—Like all other interior villages in the district, the climate of Surada is very hot and sultry in summer and cold in winter and the rainfall during the monsoon is heavy.

Previous history of the epidemic.—Every effort has been made to enquire into the early history of the epidemic, but except in one instance no definite information could be obtained as to when the disease first made its appearance. The earliest case in the village seems to have been a Tamil midwife who was attached to the local dispensary. The only definite information that could be relied upon is from the present dispensary midwife. From her was obtained the information that her husband was one of the first victims of the disease. She states that the disease started in the village 19 years ago, a previous Tamil midwife having suffered from "swelling" from which she died about one year after she came to the dispensary. This midwife lived two doors from the present midwife's residence. Next year 6 or 7 persons died of this disease, i.e., swelling of the feet, legs and body accompanied by diarrhoea and dysentery. One of these was her husband. Many others died of the same disease in that year. Three of these are three members of one family, viz., Balla Sahu, Polia Sahu and their mother, all dying within a period of a few days. The midwife and her son who was then about 6 years old also had the disease but recovered. Some 4 families of *dhobies* living in the same street get this disease every year. She herself suffered about 3 or 4 times during these 18 years and her son had the disease twice. Her daughter-in-law suffered from it last year. Others suffer from it every year, but in such cases the swelling is usually slight. The disease has been generally confined to one street only, and there is nothing to show that it has been prevalent anywhere else in the district before or since. The disease generally appears in summer and continues throughout the hot season and subsides at the commencement of the rains. From the fact that this midwife's husband was one of those who died of the disease and from the fact that she is a resident of the locality and reasonably intelligent, her statement may be taken as substantially true.

The first mention of the disease at Surada was by Dr. B. Misro in the Annual Public Health Report of the district for the year 1924. In August 1925, he made a special report to the

Director of Public Health on its prevalence in 1925, and has recorded about 9 cases.

Epidemiology of the disease.—Permanent residents of the village ascribe the disease to various causes, while all agree that the disease was first introduced into the village by the Tamil midwife. The disease was till recently confined to a portion of a street called Paiko Street at the western end of the village and very few cases of this disease were reported elsewhere. In this locality, four *dhobi* families live in adjoining houses and some of these suffer from the disease every summer. Others living in houses in the opposite row have suffered from the disease during the year and are connected with the spread of the epidemic.

About 200 yards from this locality and very close to Jagannathaswami temple, situated about the centre of the village, is a small eating hotel belonging to a woman named Mukti and her son Bhagavan. For the last two years, both these persons have suffered from this epidemic dropsy.

The earliest attacks of the disease occurred among *dhobi* women who had only slight swelling of the feet. About the same time, the hotel-keeper, Mukti, also had a very severe attack, her whole body being swollen while she also had dysentery. All the time she was carrying on her trade with the help of her son who was also attacked later. More than 75 per cent. of the attacks in the present epidemic have been traced to one or other of these two sources.

A. Course of the epidemic in Paiko Street.—Three *dhobi* women living in Paiko Street, aged about 35, 18 and 14, respectively, had slight swelling of the feet accompanied by diarrhoea or dysentery about March last, and were almost better in June when I saw them. Subsequently others in the same locality suffered. They were three Indian Christians employed as teachers in the local mission school. The wife of Chouriappa named Bendi Gitti, aged about 25, and her child 4 years old also had the disease.

A peon in the taluk office living opposite one of the teachers took the infection, and his wife died from the same disease about 15th October.

Infection in the Spanish Mission.—To the west of Paiko Street and separated from it only by a road is the Spanish Mission and boarding school. There have been no attacks inside the mission, the buildings of which stand in a large compound. The mission is run by 5 European priests and one European mother and the school has separate male and female sections. The male section houses about 45 boys in two sub-sections, the agency section for boys of Khond and Savara castes and the plains section for boys of Oriya castes. The former have separate lodging and boarding, while the latter have separate lodging. The mess is common for boys and girls. One kitchen is common to both Europeans and Oriyas, but food is separately prepared. The girls cook for themselves, for the

Oriya boys and for the European priests. A separate kitchen is kept for agency boys. A fresh water well inside the mission compound is used for the common kitchen, but water from the river is never used. On the other hand, the agency boys always use river water for drinking and cooking purposes. The mission has kept absolutely free from the epidemic up to 1926. The mission inmates, however, very rarely come in contact with the people in the village, the only persons who have anything to do with the mission being four teachers and about half a dozen servants who live in Paiko Street. These servants have been in the service of the mission for a number of years, but neither they nor the teachers had ever suffered from the disease. During the last summer season, three teachers, Chouriappa, Anthony and Sebastian were, however, attacked. In the early stages, when diarrhoea or dysentery appears, the effects of the disease are slight and the patient is not incapacitated. The first to be attacked was Chouriappa. He continued to work in the school until he fell sick. Then the other two teachers suffered and afterwards the disease spread to the inmates of the mission. The Revd. J. G. Gnennes, the head of the mission at Surada, was one of the first to be attacked. Finally, all the European priests and about 20 out of some 22 boys getting their food from the common kitchen, suffered from the disease. The "infection" spread to the female section also and among those of the common boarding section all suffered except 5 (3 girls and 2 boys), and four deaths occurred. One peculiarity of the epidemic among the mission inmates is that among the 20 agency boys who have separate boarding and mess and use a separate water-supply, not a single one was attacked although they study, pray and play together.

Taluk Office.—The taluk peon, Jhon Leo Sing, even when he was suffering from the disease, continued to work in the taluk office. Gurnath Dass, an attendant of the same office, got the "infection" and though he had almost recovered in June, he got a relapse and died before my second visit in September. Further, I understand from the medical officer that the taluk head clerk and one or two other clerks in the taluk office suffered from slight swelling of the feet. Besides these who can be connected with the spread of the disease, others in Paiko Street suffered from the disease during the year, e.g., Anthony aged 24 and his wife Sabince, aged 16; Bastinamma wife of Anthony Pillai, aged 50; and R. V. Ring Rao and his wife. The last two came to Surada about 22nd June and put up in the same street. They had severe diarrhoea and dysentery and after about one month both of them got cedema of the body; they are now recovering.

B. Course of the disease among the inmates and boarders of the hotel.—The second source of infection is the hotel-keeper, Mukti and

her son Bhagavan. She was the first sufferer from the disease in this locality during the year. The hotel is a most insanitary and ill-ventilated thatched hut, lying in the most insanitary surroundings. But for want of a better, all persons going to Surada on business or duty have to take their food in this hotel. As stated already, this woman got the disease about April 26th, and suffered very badly. About a month later, her son got the disease in a mild form. The hotel business was carried on in spite of sickness. One of the earliest of the boarders who got the disease was one Somanath Patnaik, a clerk in the office of the local Sub-Registrar. He was transferred to Surada from Russellkonda in December 1925, and got the disease in the first week of May 1926. Owing to his sickness, he went on leave in July and was succeeded by one Govindo Patnaik. The latter also had to take his food in the same hotel. Soon after he came to the village, he also suffered from the disease and has at present slight œdema of the legs.

2. One P. V. Krishna Rao also came to Surada about January 1926. He was boarding in the same hotel and noticed the swelling of the legs on or about 7th June last. He is a clerk under an agent of a tea estate in the agency, whose office is held in the agent's house in Surada.

3. Another boarder of the hotel was the late local postmaster, named M. Viswanath Patnaik. He was messing in this hotel and lodging in the post-office quarters. He suffered from the disease and has gone on leave.

4. Two range clerks and one depôt clerk in the range office at Surada, who were and are messing in the hotel, all had attacks of the disease.

5. Close to this hotel there is a lodging house for the school boys of the local school. They have to make their own arrangements for food. Some cook their own food, while a few others go to the hotel. Of the three boys who messed in this hotel two, namely, Godavari Tyadi and Trimath Das, suffered from the disease while the third has till now escaped. None of the other members of the school house have had an attack.

6. When the new Agency Central Health Range was formed in June last and Surada was fixed as the headquarters of this range, Jagabandhu Patnaik who was Health Inspector, Russellkonda, went to Surada on 22nd July and put up in this school lodging house and had his food in the hotel. He contracted this disease, but his peon and his vaccinators who were also messing in the hotel escaped.

7. Five merchants from Orissa who went to Surada in January last for timber trade, took jointly a rented house in Surada. Three of them have their own mess, while two of them Madhobando Mahanty and Balakrishna Aich were messing in this hotel. Both these men

have suffered from the "infection," while none of the other three got the disease though all five lodge in the same house.

8. A tailor named Arunuru Kondo came to Surada and was messing in the hotel. He too suffered from the disease, but is now having separate messing arrangements.

9. The daughter of the hotel-keeper is married and lives in the village. She very often goes to the hotel and this year she too got the disease, although none of her family seem to have suffered.

10. *Sub-Registrar's Office.*—Subsequent to Somanath Patnaik, clerk, Sub-Registrar's Office, getting the disease, the Sub-Registrar Narasinga Rao was attacked. He was transferred from Berhampur to Surada and took charge on 20th May. He got diarrhoea and dysentery on the 26th and noticed swelling on the 27th. The clerk Govindo Patnaik who acted as substitute for Somanath Patnaik while on leave and who was messing in the hotel also got an attack.

Tea Estate Office.—In the house in which P. V. Krishna Rao was working as a clerk, three attacks occurred. One Panchanan Mahapatro, brother of R. N. Mahapatro, agent of the estate, Heramani Mahapatrini, mother of the above, and Parvati Devi, wife of R. N. Mahapatro suffered from the disease in succession.

Post Office.—After the postmaster got the disease the post peon was attacked, but is now improving. He was residing in Paiko Street. The postmaster went on leave on account of his sickness and was succeeded by one S. Suryanarayana who was transferred here from Parvatipur. He has taken the "infection" and suffers from slight swelling of the feet. He is putting up in the quarters attached to the post office, where his predecessor lived.

M. Subba Rao was the forest ranger, Surada, till July last. He suffered from the disease and consequently went on leave. It has been stated that two clerks working under him and a depôt clerk who were messing in the hotel, suffered from the disease. B. K. Krishna Rao who was posted here as forest ranger in place of M. Subba Rao, put up in the government quarters where his predecessor had lived. This gentleman too has contracted the disease and is now suffering from it.

It has been possible to trace the relation of different attacks from the available information as to the time of onset of the disease in about 88 per cent. of the total number. The other 12 cases are apparently similar as to source of "infection" to those which have been traced.

C. The infection in the following cases has not been traced to either of the two main groups.
Infection in the Sub-Inspector's Quarters and Police Lines.

1. The Sub-Inspector of Police, Mahammad Mazahar, who was transferred to Surada in the last week of February, suffered from

this disease in the last week of March or first week of April. Two sisters who are at present living with him, were attacked, became seriously ill, and were bed-ridden for more than a month. Besides the Sub-Inspector, 3 constables had attacks.

2. Police Lines.

(1) Konaro Moliko, No. 411, constable.

(2) Boli Jim, No. 507, constable in the same station reported to have suffered from the disease.

(3) B. Dalayya, acting head constable.

(4) Wife of B. Dalayya.

The Sub-Inspector lives in separate quarters and the constables are put up in the Police Lines.

3. Ramanath Mitra, Sub-Assistant Surgeon, noticed slight swelling of the feet, but beyond that had no other symptoms.

4. Erusula Lachayya, a goldsmith, came to Surada about the 1st week of July. About the 1st week of September he got swelling of the legs with dysentery and fever. His wife and two other members of the family also suffered from the disease.

5. Boroto Kasi Patro and Krishnamoorthi Patro, two Komaties (trading class), came from the agency about the middle of July. Both got swelling of the feet and some days after their father Boroto Challamayya Patro had swelling of the feet and high fever.

6. The wife of Mahammad Usephi and her son aged 6 years, also fell victims to the disease.

THE DISEASE AND ITS SYMPTOMS.

1. *Swelling*.—The characteristic symptom of the disease in every case is swelling of the feet and lower legs, both legs being equally affected. This is generally accompanied by diarrhoea or dysentery and in some cases by fever. In the early stages, puffiness of the dorsum of the feet and pitting of the skin of the legs on pressure over the shins are to be noted.

Influence of exercise and of gravity on the swelling.—This swelling of the feet and legs is least in the morning, increases rapidly as the day advances, and is most marked during the evening. It is more marked when the patient is constantly sitting on a chair with the legs hanging down than if he is moving about. It is still less prominent if he is actively walking or cycling. During the day, the swelling decreases if the patient lies flat on his bed with the legs raised up. It is evident that exercise and gravity play an important part in determining the amount of the swelling. It is also less when the legs are kept in boots and putties or even socks. In mild cases, the swelling does not rise above the calf muscles or the knees. In moderately severe cases, it reaches up to the thigh and extends up to the hip joints; and in severe cases, the swelling gradually involves the abdomen, hands, arms, chest and face and is present over the whole body including the scrotum and penis. In parts of the body where the skin is tender, it becomes soft, tense and translucent as in Bright's disease. In all such cases, the

patient becomes bed-ridden and there is difficulty in breathing. In the early stages, particularly marked in patients with fair skin, the affected parts become pink and erythematous and the skin is tense. The swelling is soft, pits on pressure, becomes pale and anæmic where the pressure is applied, and then fills up gradually and regains its pink appearance. One intelligent patient has observed that the swollen parts sweat. After the swelling has lasted for some time, say a month or more, the skin becomes slightly rough, thickened and less hairy. The natural colour of the skin changes to a peculiar darkish muddy hue. There is no desquamation, but the skin becomes loose and flabby and loses its healthy tone. Here and there darkish patches of discolouration are also seen.

2. *Gastro-intestinal symptoms*.—Diarrhoea or in severe cases dysentery, is the next important symptom of the disease, though it is not present in all cases. Out of 66 cases, whose history has been more or less accurately recorded, 15 had diarrhoea accompanying the swelling and about 21 had diarrhoea or dysentery, 15 days to 1 month after the swelling appeared. Six patients had dysentery and in one the motions were hæmorrhagic in the last stage. The watery diarrhoea in mild cases is slight, but in others it may cause 30 or 40 motions a day. No pain or tenderness is noted in the abdomen. In one fatal case, hæmorrhage from the intestines occurred. One patient noticed that the swelling increased perceptibly when the diarrhoea was stopped by drugs and so he allowed the diarrhoea to go on untreated to keep the swelling down.

Gastric symptoms.—No nausea or vomiting was ever observed in any of the 69 cases whose history was personally enquired into. Of about 102 cases which have come to my knowledge, only 3 or 4 gave a history of vomiting, having eaten articles of food prepared in adulterated oil and they definitely ascribed the vomiting to that cause. No patient complained of loss of appetite and some even took their usual diet when they had diarrhoea. In the absence of diarrhoea, the bowels were normal and a few have noticed even slight constipation. (It must be remembered here that the water-supply of the village is solely from the river. But in summer, the river is dry and people get water by digging small pits in the bed of the river. Diarrhoea due to the river water may generally be excluded in summer. In the rainy season on the other hand, there is generally an epidemic of dysentery in the village due to the freshets in the river. These have been generally excluded from the list.) The tongue, in cases with diarrhoea and dysentery, was pale, flabby and generally coated. In mild cases without diarrhoea or dysentery, it was normal in appearance.

3. *Fever*.—Of 66 noted cases, there was a history of fever in 18 and in 8 the fever was moderate and could not be said to be malarial.

The rise of temperature came on a few days after the swelling appeared. In 6 of the 18 cases, the fever was slight, but came on long after the swelling appeared. Of the 102 cases that came to my knowledge, a definite history of fever has been obtained only in 18, 4 of which were probably malarial.

4. *Heart and circulation.*—Many of the cases found on 24th June 1926, were examined by Major Carrick, the District Medical Officer, and I have also examined a few. No record of examination has been kept. In his report dated 9th July, 1926, he described the heart symptoms as follows: "One case showed a disturbance of heart, but the pulse in most of the cases was weak with low blood pressure. The first sound was weak in most of the cases, even among the European patients." In 3 of the advanced cases, slight dilatation of the heart was noted. The pulse was slow and soft.

Blood.—The physical condition of the blood was observed only in 3 advanced cases with profound anæmia. It was thin and watery and of a pale colour.

Anæmia.—In severe cases with extensive swelling there is profound anæmia and a peculiar muddy colour of the skin. The sclera of the eyes become yellowish brown.

Hæmorrhage under the skin, mucous membranes, etc.—In some of the fair-skinned patients examined, the skin over the swollen parts is erythematous, this colour disappearing on pressure. No petechiæ were noted and no cases had hæmorrhage from nose, throat or mouth. Only one case (Chouriappa) had hæmorrhagic stools, and he died.

5. *Kidneys and urine.*—In no case in which the urine was examined was there even a trace of albumen. None of the patients noticed any great difference in the amount of urine passed. Only one patient noticed that he had to pass urine 5 or 6 times during the night and from a history of itching sensation and thirst I exclude the case as being probably due to diabetes, although his urine was not examined. Only one (Chouriappa) noticed high coloured urine and burning sensation while passing it. There was no increased thirst in any of the patients.

6. *Nervous symptoms.*—Nervous symptoms are rare. There is no numbness or tingling or dragging sensation in the legs; no patches of anæsthesia anywhere and no tenderness in the calf muscles. The knee jerks are present, but in cases of severe dropsy, they are sluggish. (These have not been examined in all mild attacks.) Nothing peculiar about the gait of the affected persons was noticed even in the severe cases. The patient is conscious of a sensation of distension of the skin where the swelling occurs and feels as if he were walking on soft pads. In the late stages, the tips of the toes become slightly benumbed, but with this exception no symptoms of affection of the peripheral nerves are noted. No sleeplessness or headache accompanied the swelling; and although slight lassi-

tude was noted, the brain is quite alert and the patient, in cases of average severity, goes through his usual work without much fatigue either of brain or body.

7. *Lungs.*—No symptoms referable to the respiratory tract were found. In cases in which the swelling extends up the whole body, cough and difficulty of breathing set in. In all the fatal cases there was difficulty of breathing. In some of these fever also occurred, but probably these were cases of pneumonia and the others were cases of œdema of the lungs.

DISTRIBUTION OF THE PATIENTS ACCORDING TO AGE, SEX, CASTE AND NATIONALITY.

Age.—No cases of the disease have occurred among infants. One child of 4 years had an attack and two children of 5 to 6 years were also attacked. Some of the cases were in boys and girls from 12 to 20 years belonging to the mission and the rest were in people of all ages up to 60 years.

Sex.—Both sexes were attacked. Of the cases recorded, 60 were males and 42 females. In the mission, the boys and girls were equally affected (Khond boys excepted).

Religion.—Three were Muhammadans, 38 were Hindus and the rest were Indian Christians. The preponderance of Christians was due to the fact that the mission was affected. Five Europeans were affected by the disease out of a total of six in the mission.

Effects of the disease.—In about 90 per. cent. of cases, the effects were slight, and patients carried on their work as usual. The Sub-Inspector, the Sub-Registrar, the Health Inspector, the clerks and the European priests all carried on their ordinary duties except when incapacitated by severe diarrhœa or dysentery. In mild cases, the swelling lasted from 15 days to a month. In more severe cases, the patient generally became bed-ridden, with profound anæmia, weakness of the heart and difficulty of breathing.

Duration of the disease.—A few cases having only slight swelling recovered within 15 days, but others who had severe dysentery and moderate swelling had symptoms for more than four months. The average duration of the disease may be said to be about three months. All severe and fatal cases occurred early, i.e., in the months of April or May. Later cases were generally mild and of short duration, showing only slight swelling of the legs and feet.

Mortality.—Out of about 102 cases, six died; and among 50 cases in the mission premises, four deaths were recorded.

PREVALENT THEORIES OF CAUSATION HELD BY THE VILLAGERS.

1. The people of Surada believe that the disease is infectious and owes its origin to the midwife who brought infection into the village. The subsequent history of the disease and the course of the present epidemic fully justify this belief.

2. Another idea gaining ground among the villagers is that the disease is due to some poison

in adulterated gingelly oil. They allege that gingelly seeds are mixed with seeds of an agency plant called in Oriya "Odisimari" and that the oil from the latter seeds is poisonous. In support of this theory, they state that the pure oil of these seeds when applied to the body produces erythema and local swelling, and that, if internally administered, it is certain to produce the disease. Enquiries made from those who extract the oil bear out this statement; unfortunately, it has not been possible to procure the pure oil and test it by external application. A sufficient quantity of the seeds has, however, been obtained for analysis.

3. Still another theory is that the disease is due to the fish caught in the reservoir. This idea need be given no consideration as the villagers almost without exception are fish eaters.

In order to test the second theory, laboratory animals might be given the seeds, or the expressed oil, in their food and their condition watched.

In no other part of the district is the oil of these seeds used as an adulterant of gingelly oil.

Gingelly oil is generally dear in remote places in the district such as Surada.

The seeds of this "Odisimari" plant are available in abundance all round Surada and in that part of the Ganjam agency. The oil is sometimes also used for lighting purposes.

The statements made by some of the *tellies* (whose occupation is extraction of oil) are quite definite that this oil produces oedema when locally applied.

"Food deficiency" theory.—I do not believe that food deficiency is the cause of the disease in the Surada epidemic. Being an important village and a centre of trade, fruits, vegetables and other food-stuffs are more easily procurable there than in other villages lying round. Those who come in close contact with village life know how difficult it is to get vegetables in the villages and fresh vegetables are almost unknown on six days of the week. Only on the weekly *shandy* day in some central village are vegetables, mutton or fish procurable and each family keeps a stock of vegetables sufficient to last for a week. Comparatively speaking, Surada is far better off in this respect than any other village in the neighbourhood. Vegetables and fish can be had every day, and mutton on three to four days of the week. In summer, scarcity of vegetables exists everywhere except in large towns, such as Berhampur, Parlakimedi and Chicacole. The people of Surada are all non-vegetarians and non-vegetarians are at an advantage, for the large Surada reservoir supplies plenty of fresh fish and even the poor can get daily supplies of fresh fish in the absence of vegetables. Very few other villages in the neighbourhood are so advantageously situated as regards fresh fish.

Rice.—The people of Ganjam generally use parboiled home-pounded rice, and the percentage using raw milled rice may be said to be negligible. Round Surada, the paddy crop is not so

abundant as in other parts of the district, and consequently rice has to be imported. As a general rule, storing of paddy is not practised except by the well-to-do, who store it for about 6 months before it is parboiled and pounded. A few of the well-to-do also store rice in a different way. They parboil the paddy, dehusk it, and store the dehusked rice leaving the pericarp intact. Rice is imported from Aska or Kudla Taluk, and the villagers never store the pounded rice more than a few days or at most a month, because want of labour prevents the pounding of the rice in large quantities. Before being cooked, the rice is generally washed twice or thrice, it is then boiled and the rice-water is always thrown away. A dietetic history of the inmates of the mission boarding-house has been obtained as far as the priest-in-charge and the boys could give information.

The paddy, stored in their own granary, is obtained from the fields in sufficient quantity to last for a year and 6 months, so that there is no necessity to use rice until it is six months old. In 1926, however, new rice had to be used as soon as it was obtained. The paddy is given out in small quantities sufficient for about a week. The coolies who pound it return the rice and take fresh supplies every week or so. The rice is not stored as such for any length of time. Only boiled rice is used and it is boiled with water from a dirty tank used by the whole village.

The boys have generally three meals a day and when the harvest of rice is poor, as was the case this year, they get *ragi* gruel in the morning instead of rice gruel. Except for this difference, there has been no change of diet between this year and previous years. On the other hand, the diet has distinctly improved this year owing to new management. The children get meat at least twice a week, and since the outbreak, three times. *Dhal*, gram and vegetables from their garden, in addition to fresh or fried fish are also given. This diet is much better and cleaner than that of the ordinary villager. No milk is given except in cases of illness, nor do the boys get buttermilk. The granary is constructed of timber, is raised above the ground, and has ventilation at the bottom. It is of better construction than the ordinary village granary, for paddy is usually buried under ground until the rains set in. This latter method is not possible in Surada because of the high level of the sub-soil water, but bamboo baskets thickly coated with cow-dung to prevent access of air and water are also sometimes used.

Enquiries as to the diet in the hotel show that it consists of vegetables, fish and rice. No ghee or curd is given except as an extra, and the rice used is bought in the bazaar. It is extremely difficult to get the actual diet for every individual case, so that it can only be noted in general that the people taken two meals a day, consisting mainly of rice, eaten with *dhal*, curry and a vegetable curry and some chutney. When fish is provided,

the vegetable curry is replaced by fish curry with which some vegetable is also mixed. Among the poor, the diet will generally be rice, *dhal* water and a fish curry. The morning meal will generally consist of rice-water kept overnight with some rice added. This is eaten with tamarind, salt and green pepper. Milk and buttermilk are never used by villagers of the lower classes.

From investigation of the epidemic at Surada, the disease cannot be said to be due either to deficiency of proteins or of the organic salts of fresh vegetables. This certainly cannot be the case among people of a better class. None of the European priests can be said to live on a poor diet. The Sub-Inspector of Police, the Sub-Registrar and Range Officer all live on a better diet than the average villager who has escaped infection. In three cases only was there a definite history of a stay of one week in Surada. A deficiency disease, it is felt, cannot develop in such a short time. For example the Sub-Registrar came to Surada on transfer from Berhampore on 20th May, had dysentery on 25th and 26th May, and noticed swelling of the legs on the 27th. The Health Inspector again came to Surada on 22nd July and about the 1st of August he had dysentery and noticed swelling of his feet and legs. Govinda Patnaik, the clerk of the Sub-Registrar's office was in the village only a few days before the swelling appeared.

Another argument against the deficiency theory is that in this epidemic two cases are known to have completely changed their diet within a few days of noticing the swelling but without effect. Both the Sub-Registrar and the Sub-Inspector of Police, as soon as they saw the swelling, changed their diet to wheat, milk, fish and vegetables, but in both cases, the disease ran its natural course of about three months.

Theory of infection.—In describing the course of the disease during the year, the cases which have shown some relation to one another have been linked together as far as possible. With Paiko Street as the centre of dissemination of infection, it has been shown how the "infection" was carried to the mission boarding-house which had been till then free and to the taluk office. Again from the hotel as another centre of infection, it has been possible to trace the "infection" to (1) Sub-Registrar's office, (2) Mahapatro's house, (3) Postmaster's quarters, (4) Forest Ranger's office, (5) School lodging house, (6) timber merchants, (7) Health Inspector, (8) hotel-keeper's daughter, (9) tailor. Another group of cases, apparently unconnected with each other or with any of the cases of the two main groups, have been separately classified.

On the whole, about 102 cases have come to notice and probably only a few have been left out. The Inspector of Surada during his periods at headquarters, has done his best to trace out cases and from enquiries made by myself, I do not think many cases have been omitted. Out of the total number, about 88 cases can be linked together, leaving some 14 cases of which there

are only a few (such as these among the Police staff and Komate's house) having some relationship. From the study of the individual attacks with reference to the time of onset of each case and having the plan of the village in mind, the conclusion seems definite that the disease is infectious, although the investigation of the disease was begun and carried through without any pre-conceived notions of this nature. All the subsequent findings have only confirmed this idea that the disease is an infectious one.

How the disease is spread.—Of the 88 inter-related cases, it is not possible to indicate one common mode of infection. If such does exist, it can only be air or water. The former is too general for discussion and the latter can be left out, considering the infection among the mission inmates, who have a pucca well for water-supply, and among the officers and police constables who also possess a separate drinking-water well. While only about 40 cases have occurred in the whole population of Surada who use the river as a common source of water-supply, about 65 cases have occurred among a little more than 100 persons using the protected water-supply. Further, of the former 40 cases, more than half are among the boarders of the hotel. It is more probable, therefore, that other modes of infection must have been at work.

1. It seems fairly clear that the most important mode of spread of the disease is through food. The cases among the boarders at the hotel and among the inmates of the mission are the best examples of this. [These groups of cases may also be taken to prove that the method of spread cannot be by human parasites, such as lice or ticks. Of about 80 boarders in the mission about 20 agency boarders have separate board and lodging. Of the remaining 60, boys and adults, not less than 55 have suffered from the disease. Similar enquiries have been made in the hotel. Sixteen boarders messed in the hotel more or less permanently, and of these all but three suffered from the disease. As far as possible, a list of persons, who are new arrivals in the village, has also been prepared. Of 33 such persons, excluding the families, 25 have suffered from the disease. Of these 25 persons, 16 have been messing in the hotel and the others were associated with people suffering from the disease or lived in Paiko Street. A few (3 or 4) apparently are of independent origin.]

2. All cases do not come under the same category of infection through food. The infection from Chouriappa to the mission inmates could not be through food nor could the infection of the Sub-Registrar from his clerk Somanath Patnaik. The infection of the members of the Mahapatro's family by P. V. Krishna Rao must also be by some other mode. The only other possibility seems to be by means of infected hands.

The attacks among the Forest Rangers, Postmaster, etc., can only be explained by saying that infected hands conveyed the disease.

In the valuable and suggestive notes sent by Col. MacCarrison, mention is made of the possibility of infection by the bed-bug. A clear inference on this point could be drawn from the two groups of cases investigated.

In the mission group, the patients lodge and board together; in the hotel group, they board together but lodge in different places. The percentage of infection among both groups is equally high. The fact that the infection has not been carried to places where the patients in the second group lodge is conclusive proof that infection was not spread by this means. Further, the European priests asserted that there are no bugs or lice among the inmates and certainly not in the apartments occupied by the Europeans.

The nature of the infective organism is not easy to make out. It is probably present in the intestines or in the soil and becomes virulent in summer, but so far no other place in the district has been affected.

Immunity.—An attack does not give any immunity; on the other hand, the same persons are prone to infection in subsequent years. Some of the villagers have suffered from it annually, and in some cases during the year under report the patient, after showing some improvement in swelling and in the diarrhoea, has had relapses.

Treatment.—The only means of prevention will probably be found in isolation, and a change of residence during the summer months. In the absence of any definite knowledge on the subject, disinfection of excreta and clothing, etc., should be carried out. Good nourishing food with plenty of fresh vegetables and fruits will probably go a long way to maintain health.

Curative.—The treatment must be purely symptomatic. Keeping the bowels open in the absence of diarrhoea will probably lessen the swelling. The local medical officer has found great improvement in patients who were treated with tincture of digitalis and potassium iodide, 10 to 15 minims of the former with 5 grs. of the latter per dose. Major Carrick tried a few cases with adrenalin solution, 2 minims, with little or no success. In severe cases with œdema, rest and diuretics may help to lessen the swelling.

Plans for the future.—The disease is gradually and year by year assuming bigger dimensions. The importance of systematic study of this disease can no longer be ignored. The opportunity of studying an unknown disease confined to a small locality will be lost as years go on.

Col. MacCarrison's criticisms, comments and notes on the disease have been most welcome at the time I was preparing this report and I am much indebted to him for his valuable suggestions.

In conclusion, I must not fail to thank Domburi Torasia, Health Inspector, Surada, who enthusiastically assisted in collecting all available information and intelligently carried out my suggestions.

(There are distinct indications that the infection of these patients came about by means of food, but this does not necessarily mean that the food suffered contamination of human origin. The history of the origin of the rice is not clear, and it seems possible that the clients of the hotel and the other patients obtained diseased rice from a common source. One would not have expected the home-grown rice eaten in the mission to have been diseased, but is the writer quite certain that the mission *never* obtained rice from outside sources?—EDITOR, I.M.G.).

AN OUTBREAK OF EPIDEMIC DROPSY IN ALLAHABAD IN 1927 (FEBRUARY TO APRIL).

By G. GHOSH, M.B., B.S., D.T.M. (Bengal),

Lukergunj, Allahabad.

It was early in February 1927, that a few indigenous cases of epidemic dropsy came under my observation. I immediately tried to strike a note of warning to the public of Allahabad through all the local papers, exhorting people to stop eating rice—particularly the parboiled milled rice.

The number of cases began to increase rapidly till it reached its maximum in April 1927. Then the incidence fell gradually till the end of May, when there were no fresh seizures from the disease.

In my investigations during the epidemic a few facts were brought out which may be of some importance in throwing light on the etiology and prevention of the disease. They may be summarised as follows:—

(1) The disease showed a predilection for the Bengalees, though I came across a few cases of the disease amongst Anglo-Indians. On enquiry I found that these Anglo-Indians were partial to rice. A few Kashmiris were also affected, but they, like the Bengalees, were also rice eaters. Amongst the up-country people, only one single case of this disease came under my observation. He was a servant in the employment of Mr. S. C. D. of George Town (*see* under family No. 15 of the table), who obviously developed the disease after partaking of the infected rice of his master.

(2) Some Bengali families took a timely note of my warning and stopped taking rice from the very beginning of the epidemic (February 1927). A few others, finding it hard to stop rice altogether, took to local coarse (hand-milled, red) rice. Although they were staying in the worst part of the epidemic areas, none of them developed any symptom of the disease.

(3) Allahabad has several *mundis* or wholesale grain markets. All the smaller merchants and the public who buy large quantities of grain at one time, generally make purchases from these *mundis*. One of the *mundis* is known as *Khalifa-mundi* and it was a striking feature of

the last epidemic that the prevalence of the disease was almost limited to localities which were situated round about this *mundi*. That is to say, the affected area corresponded fairly well with the area of supply of rations by this *mundi*.

It is interesting to note in this connection that a rice merchant, Babu N. C. C. of Gushkara (District Burdwan), came to Allahabad for a change in December 1926. He supplied from Gushkara—a well known rice centre of Bengal—7 wagon loads of machine-milled par-boiled rice (variety *dudhkalma*) to three wholesale merchants of *Khalifa-mundi* early in January 1927. Each wagon-load contained about three thousand rupees worth of rice.

(4) There was one remarkable fact about the epidemic. All the babies and small children escaped the disease entirely. In my series of cases, the ages of the persons affected with the disease ranged from 8 years to 65 years.

The principal symptoms of this disease in the last epidemic were as follows:—

(a) Gastro-intestinal symptoms: diarrhoea, loss of appetite, dysentery. These were generally the first symptoms complained of by the patient.

(b) Dropsy: œdema of the legs and feet were present in almost all the cases. In a few cases there were effusions in the pleural and peritoneal cavities.

(c) Cardiac disturbance was a marked feature in this epidemic. Dyspnoea, palpitation, insomnia, tachycardia and signs of dilatation of the heart were present according to the severity of the disease. All the cases that died of this disease had terrible cardiac dyspnoea and died of heart-failure.

(d) Nervous symptoms: most of the patients complained of tenderness of the calf muscles. The knee-jerks were increased in a few cases, but in the majority of cases they remained unaltered.

(e) In most of the cases fever was present. It ranged generally from 99° to 101°F.

(f) Hæmorrhage. In some cases this was present in some of the following forms:—

- (1) Bleeding from gums.
- (2) Bleeding from intestines (dysenteric symptoms).
- (3) Epistaxis.
- (4) Bleeding piles.
- (5) In one case a hæmorrhage from the uterus which terminated in abortion.

(g) Eye troubles—

- (1) Glaucoma—in one case.
- (2) Diminution of vision—one case.

Further details of these cases will be found in the table.

Some of the Cases of Epidemic Dropsy Observed in Allahabad during February to April 1927.

Serial number.	Family of—	Locality.	Total number of persons in the family.	Number of members affected by the disease.	Special symptoms or any intercurrent condition occurring in the course of the disease.	SPECIAL REMARKS.
1	A. K. M.	Grand Trunk Road, Lukerganj.	8 including a baby, 1 year old.	All the members except the baby.	(a) Patient got an attack of chyluria during the course of the disease (about a month after the onset of the attack of epidemic dropsy). His blood on examination showed microfilariae in large numbers. The chyluria is still persisting and the patient is very weak. (b) Mrs. M., had very severe and distressing cardiac dyspnoea. She has now recovered completely.	
2	H. C. S.	Bhawapur, Lukerganj.	23 including a baby, 5 months old.	All members affected (22), except the baby.	(a) Mr. S. (an old man), got piles which bled profusely. (b) Mr. S.'s daughter, aged 22 years, had very severe cardiac dyspnoea (died).	

Some of the Cases of Epidemic Dropsy Observed in Allahabad during February to April 1927.—(Contd.)

Serial number.	Family of—	Locality.	Total number of persons in the family.	Number of members affected by the disease.	Special symptoms or any intercurrent condition occurring in the course of the disease.	SPECIAL REMARKS.
3	G. S. D.	Lukerganj	8	4	Mrs. G. D., showed rather severe cardiac symptoms which were relieved by rest and treatment. About a month and a half after this she got B. T. malaria (fever 104). On exhibiting quinine 21 grs. a day, her old cardiac symptoms and swelling of the feet returned.	Since that time the patient has been getting fever off and on. If she takes quinine her cardiac troubles return and her ankles swell.
4	G. D. D.	Lukerganj	5	3	Mrs. D., marked cardiac symptoms. Profuse bleeding from the nose for several days.	
5	R. M. B.	Bhawapur, Lukerganj.	4	3	R. B. An alcoholic subject, cardiac symptoms marked. Fainted and collapsed once.	
6	S. D. G.	Khurdabad	5	5	His eldest son who had been suffering from kala-azar at Calcutta came here for treatment. His fever broke and his spleen disappeared under urea-stibamine injections, when all of a sudden he developed symptoms of epidemic dropsy. The injections had to be stopped owing to cardiac symptoms.	When the injections were stopped he got a relapse of kala-azar with high fever and epistaxis and enlargement of the spleen.
7	S. C. M.	Grand Trunk Road, Lukerganj.	2	2	Mrs. M., also developed very distressing palpitations and tachycardia (pulse, 130 to 140).	
8	B. K. M.	Lukerganj	5	4	His daughter-in-law had very severe cardiac dyspnoea. For some time under rest and treatment, she progressed towards recovery but all of a sudden she became very ill and died.	
9	M. K. R.	Lukerganj	5	4	Mrs. R., developed high fever, oedema and inter-costal neuralgia.	
10	A. K. B.	Lukerganj	?	2

20	Mrs. Stone (Anglo-Indian).	Civil Lines	1	1	

*In order to avoid repetition of symptoms in every case, only the special and most distressing symptoms have been noted against each case. The 'usual symptoms' in nearly all cases of this epidemic were—diarrhœa, swelling of the feet and legs. Pain in the calf muscles. Knee-jerks—in some cases slightly exaggerated and in others unaltered. Slight fever (100° to 101°F.), dyspnœa and anæmia. In a few cases the urine was examined. No albumin was found.

THE ETIOLOGY OF GREEN DIARRHŒA OF INFANTS: THE DEFICIENCY FACTOR.

By R. K. PAUL, M.Sc., M.B. (Cal.),
Teacher of Physiology, King Edward Hospital
Medical School, Indore.

GREEN DIARRHŒA is one of those fell diseases which are responsible for a great percentage of infant mortality every year. The disease is especially prevalent in summer and, when once it sets in, it becomes very obstinate and difficult to treat, so much so that patients go beyond the power of medicine and consequently infants die by hundreds.

The etiological factor mainly responsible for the disease is surely improper feeding of the infants, and it has been lately proved definitely that in 70 per cent. of the cases it is due to excess of fat and carbohydrate in the diet, and in 25 per cent. of cases may be due to excess of proteins in the food. Not only this—irregularity

in the time and duration of the feeds and sometimes uncleanly habits of the mother, also act as contributory factors. But in my opinion, based on some recent investigations on young rabbits, there is another paramount factor in the etiology of the disease: this is deficiency of the growth-producing and antirachitic vitamins A and D.

One of the female rabbits—with which I was carrying on some research work on vitamins—died six days after giving birth to two young ones. So I was compelled to put these two young rabbits on artificial feeding with a patent food for want of mother's milk. Before the death of the mother they were steadily gaining in weight, but for three or four days after the artificial feeding was resorted to, I noticed no improvement in the growth of the two. However, this was thought to be due to sudden change in their food. But on the 12th day, i.e., the sixth day of artificial feeding, one passed stools exactly like those of infantile green diarrhœa. All feeding except

water was stopped to this rabbit, but two days later to my surprise the other one also went down with a similar kind of diarrhoea. Growth stopped in both and every day there was loss of weight. Both developed rickety features, the hair lost its soft velvety feel, the head became large and box-shaped, and the "pot belly" was remarkable. The first died on the 15th and the second on the 16th day after birth.

Next time when another rabbit gave birth to four young ones, I selected one for the same artificial food as given to the first set: one was put alternately on artificial feeding and mother's breast; and the other two remained breast-fed throughout. The first one of this series also developed diarrhoea, the third and fourth grew quite normally, while the second one, though it did not develop diarrhoea, was still below par.

These experiments with these two series of young rabbits convinced me of the importance of the deficiency factor in the etiology of the disease. This was also corroborated by some of the characteristic symptoms developed in the course of the disease, so typical of rickets which is undoubtedly a deficiency disease.

Ninety per cent. of the human infants also that develop the disease are found to have been taken from the mother's breast, the mother having very little milk in her breast, or in some cases being afraid of losing her own health by suckling the baby. The natural food of a baby is mother's milk which supplies all an infant wants for its proper nutrition and particularly the vitamins A and D, which promote growth and prevent the development of rickets. So, when mothers go against Nature by refusing to suckle the child, they are sure to pay the penalty, as a consequence of which the child develops diarrhoea which very often proves fatal. Even in cases where lactation is not sufficient for the baby, the baby ought not to be taken from the breast, because once the child is taken from the breast, the lactation, whatever there is of it, is sure to fail. Nowadays there are no two opinions about the fact that a hungry suckling child is the best lactagogue ever known.

It may be pointed out that there are many cases in which even breast-fed infants develop the same disease, but even in these cases the deficiency factor comes in. In most cases of green diarrhoea in breast-fed infants, it is found that the mother feeds her baby on no regular system. Whenever the child is crying she thinks it to be hungry and at once puts the nipple of her breast to its mouth, so that it goes on suckling for half an hour to an hour, or every 15 to 20 minutes repeatedly. The whole quantity of milk that the baby takes, does not contain all the essentials proper for its nutrition. Only the very first portion for five to seven minutes contains those; the rest of the milk that comes after this is deficient in vitamins and especially rich in fat and slightly so in carbohydrate (lactose) as well. So under these circumstances there is no wonder that the infant develops the disease, though breast-fed all the while.

Sometimes negligence of the mother in cleansing her nipples and the child's mouth after feeding also supplies a minor contributing factor to the causation of the disease.

Want of proper rest on the part of the mother, improper dieting and constipation of the mother also add to these factors, because all these lead to disturbance in lactation, causing disturbance in the child's nutrition. The mother should also avoid as far as possible taking excess of milk, sago, or those articles that have the reputation of so-called lactagogues amongst the common folk, and during the period of lactation should never take anything that may give her constipation or flatulence.

Sometimes babies have got to be fed artificially, the mother having died or having no milk at all in her breast. In such a case, slight indiscretion in dieting will surely cause diarrhoea. The best natural food for a child after mother's milk is cow's milk—humanized by dilution and addition of sugar and cream. Never should food be given in excess at a time. The excess of fat and carbohydrate or protein, will also lead to the development of diarrhoea. The best way to avoid this is to weigh the child after each feed. If it has taken too much, the number of feeds must be reduced. If it has taken too little, it may lead to malnutrition of the child. So some whey water or skimmed milk ought to be given in addition. The feeding of the child should be according to a definite rule in proportion to the age; the simplest one is to give the child up to six months each time one ounce more than the number of months the child is old.

The main point of this note is to lay stress on the deficiency factor in the etiology of the disease, and the writer can confidently assert that the disease can also be grouped in the same class as the other deficiency diseases of infancy, such as rickets, spasmophilia, scurvy, marasmus and infantile cirrhosis of the liver.

LATE MANIFESTATIONS OF SYPHILIS WITHOUT A HISTORY OF PRIMARY SORE.

By A. C. BHARADWAJ, L.M.P.,
Thomason Hospital, Agra, U. P.

It is a mistake to regard the primary sore as a certain precursor of the later stages of syphilis. Many failures of treatment—some of them amounting to blunders—can be avoided if it is remembered that, apart from the tendency on the part of the patient to deny the history of a venereal sore, many primary chancres are extragenital, and trivial lesions on the genitalia, which are in reality due to syphilis, are frequently overlooked. Not infrequently such trivial sores on the genitalia are treated as simple abrasions, without any suspicion on the part of either physician or patient that they are really of syphilitic origin. Intra-urethral chancres are usually mistaken for gonorrhoea, and treated as such; the

primary lesion then heals up, and when secondary or tertiary lesions develop, and the patient is questioned by his physician, he innocently denies all history of a primary sore.

It is likewise futile to place explicit reliance on the presence of a scar on the genitalia, for often the scar left is imperceptible, and the lesion may even not be noticed by the patient himself. In women, the primary chancre is usually situated in the vagina; there is no discomfort at all, and the patient may be entirely unaware that she has become infected. Further, the patient often tries to mislead the doctor with reference to the previous existence of a chancre, and Indian women in particular are extremely reluctant to confess to previous possibilities of infection. Perhaps the majority of patients will admit to the possibility of infection, but there is a certain minority who will not. Consequently, it is the duty of the medical practitioner, whenever certain signs of secondary or tertiary syphilis are present, to give antisyphilitic treatment, whether the patient confesses to the possibility of infection or not.

Osler remarks that "irregular sexual intercourse has existed from the beginning of recorded history, and unless man's nature wholly changes—and of this we have no hope—will continue. And therefore syphilis is common in the community, and is no respecter of age, sex, or station in life There is seldom any doubt concerning the recognition of syphilitic lesions, but the number of persons without any evident sign of the disease in whom a positive Wassermann reaction is found, proves that a negative diagnosis cannot be based on the absence of history and clinical manifestations."

A case of this type is quoted in the *Tropical Diseases' Bulletin* for January 1926, on p. 41. Some gummatous lesions appeared on the face of a boy aged 18, without any previous history of syphilitic infection. The reviewer suggests that this might either be a case of congenital syphilis, or of an overlooked extragenital sore. In my opinion either of the two suggestions is possible, but the possibility that the case might have been one of an acquired and overlooked primary chancre, must be taken into account. Hereditary syphilis usually shows its marked stigmata.

The following cases may be cited, as examples of how concealed or overlooked syphilitic infection may lead to the presentation of symptoms which are very puzzling, unless the possibility of syphilitic infection is borne in mind.

Case 1.—This occurred in the practice of the late Dr. C. M. Dey, a well-known eye specialist of Agra. A female child, aged 10, was brought to him by her father with a history of dimness of vision and haziness of the cornea of two years' duration. The father stated that he had consulted specialists in Bombay, Calcutta, and Madras, and despite much treatment and many remedies prescribed, the child had obtained no relief. Dr. Dey asked his students for a diagnosis, but none of them had any suggestion to offer. Dr. Dey then pointed out the characteristic forehead of the patient and the linear marks about the angles of her mouth, and the

diagnosis became clear—syphilitic keratitis of congenital origin. Two months' antisyphilitic treatment cured the condition.

Case 2.—T. R., a female patient, aged 40, had been suffering from chapped hands and feet for several years. The trouble used to clear up during the winter months and reappear in the hot weather. When I first saw her, the palms and soles were cracked with many deep and ugly fissures. The patient was so tortured with the pain from these that she frequently had to dip her hands and feet into cold water during the night. She gave no interesting previous history, except that her hair had shown a tendency to fall out. Several doctors had treated her, including one who had prescribed sarsaparilla, even in this present century of knowledge. The Wassermann reaction was tested in Calcutta and was found to be strongly positive, and the condition cleared up on a course of neosalvarsan injections.

Case 3.—Mrs. P. A., a married woman, 35 years of age, and the mother of four healthy children, had been subject to epileptic fits for two years. When I first saw her, she had had the fits every two or three hours during the previous five days. She was lying unconscious, and restoratives had to be employed to bring her round. On detailed enquiry she stated that she had had severe pain in the shins, and that this condition had preceded the fits. On examination I found marked thickening of the periosteum of both tibiae. The husband denied all history of syphilis, but his friends volunteered the information that he was keeping a prostitute. A course of seven injections of neosalvarsan effected a radical cure. The fits disappeared, the menses—which had been irregular and scanty—became normal, and the thickening of the shin bones disappeared. Two-and-a-half years later the patient was in sound health. The neosalvarsan injections were supplemented by a mixture containing potassium iodide and mercury by the mouth.

Case 4.—S. B., a married woman, 30 years of age, and a mother of two healthy children, consulted me for severe menorrhagia and pain in the back of two months' duration. In the left iliac region there was palpable a hard, horny growth, about the size of a mango. It was very irregular in shape and very tender on palpation. The pain was so severe that the patient had great difficulty in getting out of bed. I examined her in consultation with a lady doctor, who considered that the case was one of abscess in the pelvis, and advised immediate operation. My own tentative diagnosis was fibroid of the uterus, since the patient had no fever, had had severe bleeding from the vagina, and was extremely anæmic. I called in the then Civil Surgeon of Benares, who agreed with the diagnosis of fibroid of the uterus. He advised hysterectomy, but to this the patient would not consent. I gave a mixture of potassium iodide and mercury orally, and iodine douches to the vaginal canal. To my surprise the patient immediately started to improve rapidly. I now had the Wassermann reaction carried out and it was found to be strongly positive.

I then advised injections of neosalvarsan, but the patient refused all injection treatment, and continued with the mixture orally. To-day she is in good health and the tumour has disappeared. I have lately had her examined in consultation by the Civil Surgeon of Benares, and he is of opinion that the tumour might have been a gumma somewhere in the pelvis, together with syphilitic endometritis.

Case 5.—This was a middle aged man, about 38 years of age, suffering from chapped hands and feet for several years. He was a clerk and much worried both about the appearance of his hands and the effect on his writing. There was a history of slight paresis of the right side of the body some months previously, but he denied all history of syphilis. He admitted, however, that he had suffered some years previously from gonorrhoea, which had subsided within a few weeks without treatment. He was quite frank when cross-examined, and did not suspect that he could have had syphilis. Yet one fact set me on the right track: his two sons, aged 10 and 6 years respectively, had extragenital sores on the lips. His condition rapidly cleared up on

antisyphilitic treatment. In this case the primary sore was probably situated in the urethra.

Case 6.—This was a similar case, who came under treatment for leucodermic patches bilaterally situated on the legs and scrotum. Again, he admitted a history of gonorrhoea, but denied all history of syphilis. The lesions disappeared entirely under antisyphilitic treatment.

Case 7.—An unmarried girl, 10 years of age. No history of primary sore and no signs of congenital syphilis were present, yet she had a typical syphilitic macular rash all over her body. The Wassermann reaction gave a strongly positive result. I did not disclose the diagnosis to her parents, but gave a full course of neosalvarsan injections, and mercury orally. The condition cleared up completely.

Case 8.—This was a young married woman suffering from optic neuritis. There was no definite history of syphilis in either the husband or the wife, yet the case completely cleared up on antisyphilitic treatment.

My object in writing this note is to show the importance of not depending on the history, or of examination of the genitalia for a scar, when lesions typical of secondary or tertiary syphilis are present. The symptomatology of syphilis is so protean in character, that it is always advisable to have a Wassermann test carried out in all cases of doubt. Negative history with reference to a primary sore should never be allowed to rule out a possible diagnosis of syphilis.

A PRELIMINARY NOTE ON THE DECOLOURISATION OF A SOLUTION OF METHYLENE BLUE WHEN LEFT IN CONTACT WITH KALA-AZAR SERUM.

By T. C. BOYD,
LIEUTENANT-COLONEL, I.M.S.,
and
A. C. ROY, M.Sc.

RECENTLY while experimenting with solutions of various dye stuffs on kala-azar serum, we observed that when solutions of methylene blue were left in contact with kala-azar serum, the dye gradually decolourised. We have tried out various strengths of methylene blue solutions varying from 1 in 2,000 to 1 in 80,000 and obtained the most satisfactory results when working with a solution of 1 in 40,000.

The procedure adopted was to take 0.5 cc. of a known kala-azar serum and then add an equal quantity of a 1 in 40,000 solution of methylene blue. Controls were put up using normal serum. The tubes containing the mixtures were then corked and paraffined and left at bench temperature (about 85°F.). Usually about the third or fourth day decolourisation commenced in the tubes containing the kala-azar serum and gradually became more pronounced, no change being observed in the tubes containing the normal serum. The addition of a layer of toluene altogether inhibited the reaction. We also observed the fact that variations of temperature affected the result. These points, coupled with the presence of a Gram-negative motile bacillus, led us to the conclusion that the decolourisation effect was due to the presence of a

micro-organism growing in the medium and we think it worth recording the difference noted between the normal serum and kala-azar serum, especially as we know that the latter serum is rich in globulin. We hope at a later date to be able to investigate this peculiarity more fully.

ECONOMIC SIGNIFICANCE OF MALARIA TO AN INDUSTRIAL CONCERN: A RAILWAY.

By G. R. RAO, D.T.M. (Cal.).

(Late Malaria Medical Officer, E. B. Railway),
Medical Officer-in-Charge, Leper Asylum, Cuttack.

Introduction.—To the clinician and to the purely laboratory worker, the question of "Economics," is apparently of no significance. But, to the prospective malaria expert, it is the most important question to be answered. For, he has first to convince the shrewd industrialists, the proprietors of large industrial concerns, who refuse to think of anything but rupees, annas and pies that it pays to eradicate malaria and has thus to justify his position. To do this successfully he has to estimate first, the precise economic loss caused by malaria, to the industrial concern which appoints him. Herein lies the importance of the "Economic survey of the disease."

That such a survey is an essential preliminary to any preventive scheme has been stressed by Sir Ronald Ross, who, in his book "The Prevention of Malaria"—1911, p. 252, writes:

"What precisely is the economical loss to the community caused by malaria? From the preventive point of view, that is perhaps the most important question before us, because, obviously it governs the question of the expenditure, which may be demanded for the 'Anti-malarial campaign.'"

No apology is, therefore, needed for submitting this short note.

Area of Survey.—The Lalmanirhat district of the E. B. Railway has an unenviable reputation of being the most "feverish district." When the writer was first appointed in October, 1926, as the Malaria Medical Officer to conduct preliminary survey, the opportunity was taken to collect as far as possible accurate figures—representing the incidence of malaria—amongst the staff throughout the district. Before touching upon the methods employed to secure these figures, it may not be out of place to describe briefly the nature of the area surveyed.

The "District" comprises parts of the civil districts of Bogra and Rangpur from Bengal and parts of the civil districts of Goalpara and Kamrup from Assam, besides the state of Cooch Behar, the Duars, and the terais of the Jaintia and Bhutan Hills. Two important rivers course the district, the Brahmaputra and the Teesta, besides numerous small rivers and jungle streams. The physical features of the district present several variations from absolutely flat plains to the slopes of the terais and the marshes of the jungle, with varying incidence of malaria.

Oct., 1928.]

For descriptive purposes the whole district is divided according to the physical features into several sections and a brief description of the chief physical features of each section together with its malarial incidence, is given below:—

Section (1).—From Gabtali to Fulchhari is fairly flat, slightly under 1,000 ft. above sea-level and presents a varying incidence of malaria—Bonarpara Junction showing the highest, 18 per cent. "fever index."

Section (2).—From Bonarpara (exclusive) to Kaunia—is also practically flat, with thick jungles here and there. Only one station, Bamandanga, shows rather a high incidence, about 50 per cent. fever index.

Section (3).—From Kaunia to Parbatipur Junction (exclusive) is slightly on a higher level than the preceding sections and shows a slightly lower incidence.

Section (4).—From Teesta to Kurigram and Teesta to Lalmanirhat is also practically flat and is comparatively free from malaria.

Station Lalmanirhat being a headquarters station of the metre gauge and having a big railway colony with a population of about 1,355 employees and their dependents, who come from various parts of Bengal with different degrees of malarial incidence shows malaria practically throughout the year with seasonal exacerbations.

Section (5).—Gitaldaha to Cooch Behar lies within the state of Cooch Behar and shows different degrees of malarial incidence in different stations with seasonal exacerbations.

Section (6).—Cooch Behar (exclusive) to Raja Bhatkhawa comes within Alipur Duars. From Raja Bhatkhawa to Jainti comes within the terais of the Jaintia Hills and Raja Bhatkhawa to Dalsingpara comes within the terais of the Bhutan Hills. This section is the worst from the malariologist's point of view. The station Raja Bhatkhawa deserves special notice as malignant tertian malaria is present there throughout the year and a fulminant epidemic is the rule. The staff consider it a punishment to be posted to Raja Bhatkhawa. Also this is the section in which one could not but come across several cases of blackwater fever. The incidence of malaria in this section is practically 90 per cent. Any one coming to serve in this area is sure to wire for sick leave within a month of his arrival.

Section (7).—Gitaldaha (exclusive) to Golakganj is also flat with patches of jungle here and there with a patchy malarial distribution.

Section (8).—Golakganj to Dhubri is flat and sloping towards the Brahmaputra and belongs to the Gauripur State. Malarial incidence here is comparatively low.

Section (9).—Golakganj (exclusive) to Sorbhog is a gradual ascent and the line traverses thick forests, mostly "Sāl" forests and woody jungles common to the tropics. This section shows a fairly high malarial incidence throughout the year with seasonal exacerbations.

Section (10).—Sorbhog to Rangiya and Tangla. Here the line passes through an area full of the bushy weeds of Assam fed by numerous jungle streams, and malaria exists practically throughout the year.

Section (11).—Rangiya (exclusive) to Amingaon slopes towards the Brahmaputra and is rather hilly. This area shows comparatively very little malaria.

Amingaon (Station) by virtue of its being the terminal station contains a fairly large staff (about 480). Except the large borrowpits in the vicinity of the station, there is practically no depression of land and no possible breeding grounds. The land slopes towards the river and so there is a natural drainage of the subsoil water into the river. This station can be said to be almost free from indigenous malaria. But the large staff coming from different districts of varying malarial incidence with varying degrees of infectivity and immunity is responsible for a slight amount of malaria.

Now it is clear that one has to deal with tracts of different physical features with varying malarial incidence.

COLLECTION OF FIGURES.

For administrative convenience the district is divided into several units—Lalmanirhat, Kaunia, Cooch Behar, Fulchhari, Raja Bhatkhawa, Sorbhog, Rangiya and Amingaon. Each unit is under the medical charge of a travelling sub-assistant surgeon, who is responsible for the collection of malarial statistics and for the treatment of cases in his unit.

Lalmanirhat and Amingaon each have a hospital in addition, with a medical officer (assistant surgeon) in charge, to deal with the station staff. These medical officers are responsible for the collection of statistics for these stations only and for treatment.

The number of cases of malaria treated by the travelling sub-assistant surgeons and medical officers in their respective units, together with the number of days of certified sickness and other particulars, were submitted to the Special Malaria Medical Officer of the district, every month, on special forms. These figures form the basis of this present paper.

For comparing the malarial incidence from year to year, in addition to the figures for 1926, those for two previous years 1924 and 1925 were also collected.

The figures representing the incidence of malaria throughout the district, month by month, for the 3 years 1924, 1925, 1926 are given below in Table I. To give an idea of the proportion of malaria to all other sickness, the total number of cases of sickness from all other causes for the whole district, month by month, is also given side by side. Graph I shows the same, viz., proportion of malaria to sickness from all other causes for the district, month by month, for the

three years 1924, 1925 and 1926, more vividly than Table I.

GRAPH I.

Graph showing the relation between the number of cases of malaria and the number of cases of sickness from all other causes.

TABLE I.

Months.	1924		1925		1926	
	All cases.	Malaria.	All cases.	Malaria.	All cases.	Malaria.
January ..	355	195	542	223	381	180
February ..	284	154	385	125	261	97
March ..	236	151	354	187	289	94
April ..	338	144	326	178	364	126
May ..	344	210	437	195	351	162
June ..	410	201	400	118	372	176
July ..	403	230	380	229	422	203
August ..	437	305	497	340	418	160
September ..	364	243	359	356	451	187
October ..	591	327	435	347	512	231
November ..	563	386	417	307	480	224
December ..	415	287	532	268	380	122

From a study of Graph I it is evident that the proportion of malaria to all other sickness is the same in the years 1924 and 1926. The curves for malaria and for all other sickness, in both the years, run almost parallel. But the year 1925 is rather peculiar. Both the curves in the year 1925 begin rather high and it seems that the year 1925 began with bad luck to the railway. The curve of malaria follows more or less closely the curve of all other sickness up to July. From

July the curve of malaria begins to rise comparatively higher and follows the rise of the all-other-sickness curve up to August and in September, while the latter comes down considerably the malarial curve does not come down. On the other hand it rises still higher than in August. From August to November, the curve is more or less maintained and the proportion of malaria to all other sickness during this period is obviously higher in comparison with the same period in the other two years, which means that there was comparatively more malaria in the year 1925 during the period August—November than in the years 1924 and 1926.

This holds good not only for the district of Lalmanirhat, but also for the whole line excluding, perhaps, Calcutta, as will be seen from the report of the then Chief Medical Officer Dr. Sladen, who, in his "Report on Methods of Malaria Control, on the E. B. Railway" page 2 observes: "The year 1925 was a bad one * * * There were 120,000 cases of sickness compared with * * * 112,258 in 1924. The year 1926 has been marked by considerable efforts to lessen the scourge of malaria in this railway, which has been the largest single factor in causing sickness and unfitness for service."

Both from the railway administrators' as well as the economist's point of view, the number of days lost on account of sickness is of greater importance than the actual number of cases of ill-health. Therefore, the number of days of certified sickness from malaria alone, is given below in Table II. For the sake of comparison the number of days of certified sickness from all other causes is also given side by side. A comparative study of both these figures in Table II will reveal the proportion of certified sick days due to malaria to the certified sick days due to all other diseases, but the same information can be more easily obtained by a reference to Graph II.

TABLE II.

Months.	1924		1925		1926	
	All cases.	Malaria.	All cases.	Malaria.	All cases.	Malaria.
January ..	2111	1041	2571	1169	3359	953

October ..	3315	1092	3478	2319	3526	1624
November ..	3809	1623	3447	2390	3763	1676
December ..	2110	940	2821	1411	2867	919

A cursory glance through Graph II will show that the curves of certified sick days, i.e., days

lost to the railway, due to malaria and to all other causes, follow closely in the years 1924 and 1926 as was the case in Graph I, which means that the proportion of malarial cases to all other sickness and the proportion of number of days lost due to malaria to that from all other sickness was identical in both the years 1924 and 1926. But 1925 presents a different picture. Not only was there a relatively higher incidence of malaria, but there was a disproportionate increase in the number of days lost to the railway administration and the economic significance of this cannot be over-estimated.

GRAPH II.

Graph showing the proportion of certified sick days due to malaria to certified sick days from all other diseases for the three years 1924, 1925 and 1926 (monthly).

N.B.—The proportion of sick days from malaria to sick days from all other diseases was relatively higher in the year 1925 during the period August–November than in the other two years.

The correlation between the number of cases of malaria that occurred and the number of days lost to the administration by malaria alone in the 3 years 1924, 1925 and 1926 can be learnt from a study of Table III, which shows both the figures, month by month.

TABLE III.

Months.	1924		1925		1926	
	Cases of malaria.	Number of days lost.	Cases of malaria.	Number of days lost.	Cases of malaria.	Number of days lost.
January ..	195	1091	223	1169	180	953
February ..	154	876	125	634	97	459
March ..	151	745	187	746	94	423
April ..	144	726	178	824	126	517
May ..	210	1344	195	1086	162	813
June ..	201	1077	118	1120	179	899
July ..	230	1311	229	1456	203	1523
August ..	305	1679	340	2071	160	1289
September ..	243	1335	356	1976	187	1317
October ..	327	1092	347	2319	231	1624
November ..	386	1623	307	2390	224	1676
December ..	287	940	268	144	122	919

The same is represented graphically in Graph III which shows the relationship more clearly. A reference to the graph will show that a fairly constant relationship has been maintained between the number of cases of malaria and the number of days lost to the administration in the years 1924 and 1926. But in the year 1925, as is to be expected, this relationship is disturbed. A considerably greater number of days have been lost—due to malaria—in this year in comparison with the other two years, particularly during the period August–November, as is evidenced by the extreme height of the curve of “days lost” during these months.

When this is evaluated in terms of rupees, annas and pies what a tremendous loss it represents will be manifest.

To appreciate the amount of loss caused to the railway by the absence of the staff on sick leave, it is necessary to translate the figures representing the number of days lost into rupees, annas and pies. To do this successfully is rather difficult. Because, it is a well-known fact that of all the factors, the human factor is the most difficult one to monetise. Several points have to be considered in monetising human labour:—

- (i) Whether skilled labour or unskilled labour.
- (ii) If skilled, what degree of skill is required to do the work.
- (iii) Whether an experienced worker or a raw recruit.
- (iv) Individual efficiency.

(v) Last but not least the mental state of the individual while performing his duty, has also to be considered. Suppose, for example, the dependents of a railway employee are sick. Naturally, the quality of work turned out by the employee while in a state of mental perturbation (brought on by domestic calamities) could not be on a par with what he may turn out in his normal mental state. We are apt to belittle the significance of this, and while it may not have any tangible effect on unskilled labour, the case is different with skilled labour.

GRAPH III.

Graph showing the relation between the number of cases of malaria and the number of days lost thereby to the railway.

N.B.—There is a fairly constant relationship between the number of cases of malaria and the number of certified sick days in the years 1924 and 1926. But in the year 1925, this relationship is disturbed. Comparatively a greater number of days were lost from malaria in this year than in the other two years, particularly during August—November.

The writer knows the case of a station-master whose wife was suffering from a bilious remittent type of malaria. Though calm and sober-minded always, he lost his mental equilibrium to such an extent (due to the illness of his wife), that he gave orders to his pointsman to receive the mail train on the platform line, while a goods train was shunting on the same line. Fortunately, the pointsman was an intelligent man and he averted a serious collision by disobeying the station-master. In a big railway administration with thousands of skilled employees, the mental factor has a definite significance.

Therefore, it is necessary to consider all the factors enumerated above in assessing the loss due to malaria.

It is admitted that the ideal method of calculation of the loss is to find out the number of days lost on account of malaria, for each employee and evaluate the loss in terms of rupees, annas and pies, bearing in mind the several factors

enumerated above. But considering the magnitude of the figures representing the number of employees, the different grades of pay, the variations in each grade, individual variations in pay and the number of days lost, etc., the ideal method becomes impracticable.

Further, it is doubtful if such a mathematically accurate estimate is necessary for practical purposes. Moreover, it is extremely difficult to assess the value of individual efficiency and the mental factor—both of some importance—in a big concern like this railway. So, making due allowance for all these factors, an easy method of calculation has been adopted:—

All the employees have been grouped into 3 broad classes:—

- Class (I) Employees whose pay ranges from Rs. 250 and upwards per mensem.
- Class (II) Employees whose pay ranges from Rs. 30 to Rs. 250 per mensem.
- Class (III) Employees whose pay is below Rs. 30 per mensem.

The number of days lost to the railway on account of malaria among Class I employees is comparatively small, for most of them protect themselves by the use of mosquito nets and take all other precautionary measures. Further, they are not exposed to the same risks as the employees of Class II and Class III, viz., night duty entailing loss of sleep, exposure to all sorts of weather in the performance of their duties, "running duties," involving travelling to endemic areas at night and halts at such stations en route, etc. The main loss is from the sickness of Class II and Class III employees.

The ratio of the number of days lost from malaria by the three different classes of employees for the 3 years is given below:—

1924	Class I:	Class II:	Class III:	Ratio
1925	do.	do.	do.	1:38:91
1926	do.	do.	do.	1:45:94
				1:37:92

Dividing the total number of days lost to the railway from malaria by the same ratio and multiplying the resulting figures by the average pay per day for the respective class of employee, we arrive at the following figures:—

1924.

Total number of days lost by malaria 13,789. This divided by the ratio 1:38:91 and multiplied by the average pay per day, i.e., Rs. 20 for Class I, Rs. 4 $\frac{2}{3}$ for Class II and Rs. $\frac{2}{3}$ for Class III employees, the loss caused by malaria is Rs. 27,367 or Rs. 27,000 (approximately).

1925.

Method of calculation same as before. The loss caused by malaria is Rs. 35,957 or Rs. 36,000 (approximately).

1926.

Method of calculation same as before. The loss caused by malaria is Rs. 24,248 or Rs. 24,000 (approximately).

These figures represent fairly accurately or at least proportionately the amount of loss to the railway caused by malaria in the district of Lalmanirhat. That the estimate presented here errs, if at all, rather on the side of under-statement than on the opposite, will be evident from a comparison of the figures representing the savings, said to have been effected in consequence of the saving in number of certified sick days—*vide* E. B. Railway Annual Report 1926-27, Vol. I, Section I, p. 32, wherein the approximate equivalent cost of 34,769 staff days, is estimated at Rs. 37,000 which is acknowledged to be an under-estimate. Also *vide* "Report on Methods of Malaria Control on the E. B. Railway by Dr. R. J. L. Sladen," dated 15th March, 1927, page 3, wherein 8,377 days, representing the saving in days of certified sickness, has been estimated at Rs. 8,377 which is admitted by Dr. Sladen to be an under-estimate.

If the figures given by the writer (for the district of Lalmanirhat) represent the loss from one district, what about the total loss to the Railway from all the districts combined? Of course, the other districts may not be as bad as the one the writer was in charge of. Nevertheless, the total loss from the whole system must be considerably greater than the figures given for one district. Naturally such a great loss had its effect on the balance-sheet, as is admitted by the Agent (*vide* E. B. Railway Annual Report 1926-27, Vol. I, Section I, p. 31).

It may be of interest to know what percentage of the total loss from all sickness, malaria alone contributes. The total number of days lost to the railway on account of all sickness, is given below for the 3 years:—

1924.	1925.	1926.
31,829	34,158	35,112

Correlating these figures with those representing the number of days lost from malaria alone, we arrive at the following percentage:—

1924.	1925.	1926.
43 per cent.	50 per cent.	35 per cent.

These figures support the view expressed in an earlier part of this paper, viz., that 1925 was a very bad year, both from the Railway administrators' and from the staffs' points of view. There is also a perceptible reduction in the loss from malaria in the year 1926 as is evidenced by the fall in the percentage of malarial loss from 43 in 1924 to 35 in 1926. It is needless to say that this fall explains the efficacy of the anti-malarial measures started in 1925 by the Chief Medical Officer with the enthusiastic support of the Agent.

SUMMARY.

(1) A brief description of the physical features of the Lalmanirhat district of the E. B. Railway together with its malarial distribution has been given.

(2) The district comprises areas of varying physical features with different degrees of malarial incidence.

(3) The number of cases of malaria and the number of cases of all other sickness in the district for the 3 years 1924, 1925 and 1926 are given for comparison.

(4) The number of days lost to the Railway on account of malaria amongst the staff is given, and this is compared with the number of days lost from all other sickness.

(5) The monetary value of the number of days lost from malaria has been estimated for the 3 years 1924, 1925 and 1926 and this has been shown to be not a negligible amount.

(6) What percentage of the loss from all sickness does malaria alone contribute? This has been calculated and incidentally the anti-malarial measures started in 1925 have been shown to have been effective in reducing the loss due to malaria from 43 per cent. in 1924 and 50 per cent. in 1925 to 35 per cent. in 1926.

Finally, the writer takes this opportunity to express his indebtedness to Dr. R. J. L. Sladen, F.R.C.S., D.P.H., the then Chief Medical Officer, E. B. Railway, for kindly providing him with all the necessary facilities and for valuable advice and guidance.

The writer's thanks are also due to Dr. C. D. Newman, the D. M. O. of Saidpur for his help and advice.

OBSERVATIONS ON 8 CASES OF BLACKWATER FEVER, TREATED WITH SERUMS AND ALKALIES.

By S. J. BELLGARD, D.M.C. (Cal.), L.T.M.,
D.T.M. (Bengal),
Medical Officer, E. B. Railway, Purnea.

Geographical Distribution.

BLACKWATER fever is met with in intensely malarious districts, with high endemic indices. Dinajpur district in North Bengal is specially mentioned by Sir Leonard Rogers in his book on "Fevers in the Tropics" as one of the districts with a notoriously high mortality; this obviously accounts for the occurrence of blackwater fever.

During the 18 months I was in the district as Medical Officer of the Dinajpur Ruhea Construction, E. B. Railway, of the malaria cases which came under my observation, 90 per cent. were *Plasmodium falciparum* infections.

Seasonal incidence.

	Number of cases during the			
	1st	2nd	3rd	4th qrs.
Blackwater fever ..	0	0	6	2
Malaria ..	459	293	897	732

The above table clearly shows that blackwater fever cases were most numerous when malaria was at its height. Thus it is apparent that malaria plays an important part in the causation of blackwater fever in conjunction with some factor still obscure.

Species of Anopheles mosquitoes found in this district.

<i>A. culicifacies.</i>	<i>A. vagus.</i>
<i>A. barbirostris.</i>	<i>A. fuliginosus.</i>
<i>A. sinensis.</i>	<i>A. philippinensis.</i>
<i>A. umbrosus.</i>	<i>A. funestus.</i>

Among the above mentioned species prevalent at the time, *A. sinensis*, *culicifacies*, and *barbirostris* were numerous and heavily infected. The presence of the above three species, which are well-known carriers, accounts for the high incidence of malaria in epidemic form in the 3rd quarter. Following the hæmolysin theory of damaged liver and lowered salt content of the blood, I adopted serum treatment together with alkalies.

The following are the details of treatment:—

(1) The diagnosis being confirmed as blackwater fever, the patient was given 10 c.cms. of anti-streptococcus serum intravenously, followed after 8 hours by 5 c.cms. of hæmostatic serum by the same route.

(2) Malaria parasites were found in the blood in large numbers in cases 1, 2 and 8, so desensitizing doses of quinine hydrochloride and sodium bicarbonate were given for 2 days.

(3) Alkali mixture consisting of:—

Sodii bicarb.	grs. 30
Sodii sulph.	grs. 10
Sodii benzoas.	grs. 15
Sodii citras.	grs. 5
Liq. Adrenalin hydrochlor. (P. D. & Co.) (1 in 1,000)	..	m.	10
Aqua	ad. oz. 1
Sig. one mark every 2 hours.			

(4) Glucose and saline per rectum, in the following proportions:—

Liquid Glucose, drachms 2.
Normal saline, ounces 10 b. d.

(5) Continuous application of hot water bottles over loins.

(6) The patient throughout his illness was strictly confined to a liquid diet consisting of whey, barley water, and ice to suck when there was a great tendency to vomiting. No alcohol was administered throughout the treatment.

I might mention that the alkali mixture was discontinued if the patient complained of terrible burning sensation all over the body, and Hearesay's mixture (modified) given.

Sodii bicarb.	grs. 30
Liq. Hydrag. perchlor.	..	dr.	$\frac{1}{2}$
Aqua	ad. oz. 1
Sig. one mark every 2 hours.			

(7) Hot fomentations, 4 hourly, with 1 c.c. of pituitrin if the abdomen was tympanitic.

DETAILS OF CASES TREATED.

Case No. 1.—Mahommedan male, aged 46 years. Resident of the district. Case seen on the first day of disease. Previous history of malaria. Ten c.c. anti-streptococcus serum intravenously was given immediately, lower bowel evacuated by a large saline enema, alkali mixture 2-hourly alternately with desensitizing doses of quinine and sodii bicarb. Glucose and saline b.d., hot fomentations to loins continuously with a hot water bottle. Urine showed signs of clearing up 8 hours after the injection; 5 c.c. of hæmostatic serum was given and the following morning the patient passed clear amber coloured urine. Recovery in this case was rapid, he was subsequently kept under treatment for 14 days, without return of any symptoms.

Case No. 2.—Hindu male, aged 36 years, Inspector of Police, Bochagunj. Residing in the district for 2½ years. Previous history of malaria. Seen on first day of disease. The same treatment was followed, recovery was a bit delayed as his was a very serious case and he had persistent hiccough for the first 2 days. Cases 3, 4, 5, 6, 7, were milder cases, and they all responded well to treatment.

Case No. 8.—Hindu male, aged 42 years, a relapse case, merchant, a permanent resident of the district, previous history of malaria. Seen on first day of disease. This case was undoubtedly of a serious nature being a relapse; he unfortunately did not carry out my instructions and ultimately died on the 4th day. I might mention a few points in his case which may be of interest. After the 2nd serum injection he felt comparatively better and his urine cleared up considerably, a faint pink colour remaining. On the 4th morning he insisted on my giving him some solid diet which I refused. At about 2 p.m. of the same date I was sent for by his relatives who stated that his abdomen was swollen and that the patient was in great pain. On making enquiries I found that the patient had insisted on having a hearty meal of *dal* and rice which was foolishly given him by his wife. His abdomen was acutely tympanitic and there was complete retention of urine. The bladder was emptied by a catheter, hot fomentations over loins with 1 c.cm. of pituitrin were given, 4-hourly, without any success; the patient succumbed after 4 hours.

The malarial origin of blackwater fever from the history of these cases seems obvious for the undermentioned reasons.

1. The susceptibility of a community to blackwater fever exposed to intense malaria.

2. It was noticeable that blackwater fever cases occurred when malaria was at its height, and subsequently declined with a fall in the incidence of malaria.

3. Quinine prophylaxis was seldom or never carried out, accounting for the high endemic index.

4. Length of residence in the district is another fact accounting for the close relationship of malaria with blackwater fever.

In conclusion since these cases responded to anti-hæmolytic treatment, I would like to suggest the possibility of a hæmolysin being present in the blood brought about by some pathological condition which is still obscure.

"MESSAGE IN THE TREATMENT OF VENOMOUS SNAKE-BITES."

By LUCIUS NICHOLLS, M.D., B.C., B.A. (Cantab.),
Director of the Bacteriological Institute (Ceylon).

WHERE poisonous snakes exist there will be found people who profess to be able to cure snake-bites. These people may be generally designated "bush doctors." The methods of

treatment pursued by some of these have some similarity to the methods of bone-setters.

Many years ago I first witnessed the rough treatment of a "bush doctor" for snake-bite. It was in the West Indian Island of St. Lucia where there exists the Fer-de-lance (*Lachesis lanceolatus*), a viper which grows to over four feet in length.

One day I received information that a youth had been bitten by one of these vipers and the scene of the accident was about five miles from my bungalow. I went as quickly as possible to his assistance and I arrived about 2½ hours after he had been bitten. The patient was a robustly-built Mulatto of about 17 years of age, he had been bitten on the outer side of the fleshy part of the calf of his right leg. He was undergoing treatment at the hands of an old negro "bush doctor," who had enlisted the services of two bystanders; the three of them were vigorously scrubbing the skin of the youth with tightly screwed up bunches of herbs. The rubbing was such that the bunches quickly frayed and wasted, when the "bush doctor" went to the nearest jungle growth and gathered any weeds he found and made fresh bundles for the scrubbing.

He made little selection of any particular weeds, except that he seemed to prefer those with rough stems.

The patient was not kept in one position for more than about a minute, he was turned over and over, and not a square inch of his skin was allowed to escape, even his scalp and the soles of his feet were rubbed. And further, the rubbing was accompanied by pressure on the deeper structures, which might pass as massage of the muscles.

This treatment had been given for about two hours; and because it appeared to be brutal and to be exhausting the patient, I persuaded them to cease, whilst I gave the youth stimulants and injected a strong solution of potassium permanganate into the site of the bite.

I left about half an hour later, and I do not know whether or not the "bush doctor" continued the treatment. Thirty-six hours later the patient had almost recovered from the snake-bite and the treatment of it, except that his leg was very swollen and there was an area of gangrene about three inches in diameter around the site of the bite. It was many weeks before the leg finally healed.

There are "bush doctors" in Africa who make use of similar methods of rubbing and massage in their treatment of snake-bite. They often assert that the rubbing must be done with herbs known only to themselves.

Cases have been recorded in Ceylon where patients have been treated by being vigorously rubbed with lime-juice; and again plantain-juice is used in other cases.

It is impossible to decide the value of treatment in any case of snake-bite, because it can never be known whether or not the snake has injected a lethal dose of venom. Yet there is a

reasonable explanation why rubbing and massage should be of value in snake-bite.

After venom has been injected beneath the skin, the portion which does not combine with the tissues near the site of the bite quickly reaches the blood-stream and is distributed throughout the body. When the patient is at rest there is proportionately more blood passing through the organs and tissues supplied with involuntary muscles than through the skeletal muscles and the other tissues of the body. Therefore the heart, diaphragm, the intestines and other important structures will receive a relatively larger quantity of venom than the muscles and tissues which are at rest.

When the skin is vigorously rubbed, the capillary vessels are dilated and an increased volume of blood passes through the skin; and the same occurs in the skeletal muscles when they are massaged.

Therefore it is probable that vigorous massage and rubbing will cause much of the venom to combine with the muscles, skin and subcutaneous tissue and prevent a proportionately large quantity from acting upon the "vital" organs within the thorax and abdomen.

It follows from this that rest and quiet are contra-indicated for the first few hours after snake-bite and that rubbing and massage with some embrocation or mild vegetable irritant are indicated.

(This explanation of how massage may possibly act in a case of snake-bite is ingenious. Another amateur method of treatment is to make the patient walk about; much the same action would occur here, though less satisfactorily. We have shown this paper to Lieut.-Col. H. W. Acton, I.M.S., who comments as follows:—

"With viperine poisoning a certain amount of fixation occurs when a ligature is put on and the circulation stops, as by this means one can save animals from the effects of several lethal doses. I have not experimented with massage and would have thought that it would tend to drive the venom into the circulatory system rather than to fix it. Massage would be useless in colubrine poisoning, as the venom does not become fixed on the local connective tissues, but only in the brain."—Editor, I.M.G.)

DIPHTHERIA AN EVER-PRESENT DANGER IN INDIA: A REPORT ON A SERIES OF CASES IN BILASPUR DISTRICT, CENTRAL PROVINCES, INDIA.

By V. C. RAMBO, M.D.

ON arrival in India two conflicting reports came to the writer's attention. One was that diphtheria is exceedingly uncommon in India and need not be feared or expected. The other, that four young boys of the Mission of which he was a member had in previous years lost their lives, two having suffered from definitely diagnosed diphtheria where no antitoxin was available until too late, and two (not diagnosed diphtheria) of some disease with sudden onset which caused

choking and cyanosis after a period of sore throat and fever and great intoxication. In one of the cases the parents, who suspected diphtheria, were notified by the civil surgeon that the case could not be diphtheria because "there is no diphtheria in India."

Other reports reached us that in Kashmir State, in the United Provinces, in South India, and in Bengal, children of Europeans had died from diphtheria.

It is to refute the common idea that diphtheria is not present and not to be feared in India that this small series of cases is presented. It is to be hoped also that no hospital or dispensary where any European children are likely to come for treatment will ever be without diphtheria antitoxin and that, when in doubt concerning a case, antitoxin will be administered first and a definite diagnosis made afterwards. Atypical types are the rule; therefore more than ordinary care must be taken in looking at all suspicious throats and following the slogan, "Safety First."

Case 1.—Victor T., of Bishrampur, Bilaspur District. European, age 3 years. On November 12th, Victor went to a picnic to a neighbouring village perfectly well and healthy. On the 15th he developed a cold. This became more severe and on the 17th the tonsils were swollen but no spots or membrane were present. Diagnosis acute tonsillitis. On November 18th, there was no cause to change the diagnosis as the tonsils and throat were simply congested and only one yellow spot was noted on the tonsil. On the 19th, however, the patient started choking. Laryngeal diphtheria was diagnosed and antitoxin was administered. The choking was relieved and also the dyspnoea, but the patient died on November 20th at 10 a.m. of heart failure.

Case 2.—Rachael, Victor's sister, 6 years old, also went to the picnic perfectly well on November 12th, 1928. She vomited on returning and was given castor oil after which there were no symptoms until the 15th when she too developed a cold. On the night of the 16th there were small "specks" on her tonsils. On the 17th she was diagnosed acute tonsillitis along with her brother. On November 18th she went to bed and was cheerful, tonsils swollen as before, diagnosis as before. November 19th symptoms continued. November 20th diphtheria antitoxin was administered. Recovery was uncomplicated. Diagnosis, diphtheria.

On November 20th prophylactic antitoxin was given to all Europeans in the station.

Case 3.—One month later, December 15th, 1928, John, European, age 12, Bishrampur, developed diphtheria with typical membrane. Antitoxin was given, followed by complete, uneventful recovery.

Case 4.—Mr. K., John's father, immediately afterwards, December 16th, showed definite signs and symptoms of diphtheria. On giving antitoxic serum there occurred a very severe anaphylactic reaction followed by dyspnoea from oedema

of the glottis and general anasarca. Recovery was complete after a stormy convalescence.

Case 5.—Mrs. K., at this time had malaria and simultaneously with her son's and husband's cases developed diphtheria also. Antitoxin was given and a quick recovery followed.

Case 6.—The history is given here of an Indian boy of 17 years living in Bishrampur who developed an apparently simple sore throat followed by partial recovery but who, a week later, had severe hæmorrhage from the throat or post-nasal space which area as well as his whole mouth was now covered with a grey diphtheritic membrane. One week later after apparently greatly improving, he died suddenly of heart failure.

Case 7.—On January 12th, 1928, a relative of the tahsildar, Mr. R., a small girl child 5 years of age, suffering apparently from a simple cold was brought to the dispensary of the Mungeli Area Christian Hospital by a servant. On looking at her throat a very extensive greyish membrane was seen over both tonsils and the pillars of the fauces. A smear showed the Klebs-Loeffler bacillus. Antitoxin was given immediately and a note written to advise the child's isolation and further observation and need for further injections. Upon inquiry later, it was found that the child had been sent home to the United Provinces immediately after her visit to the dispensary. Recovery was apparently complete.

(It is an interesting conjecture as to the number of persons infected during this child's return over the four hundred miles journey home to her people.)

Case 8.—February 20th, 1928, an Indian girl child of Mr. P. S., Pastor of Mungeli Christian Church, was reported as having had sore throat and fever particularly resistant to treatment. Observation presented a girl child of 2 years, fairly toxic in appearance, fever 100° and a sore throat with very irregularly shaped ashen-grey patches of membrane which did not brush away easily and whose smear with methylene blue showed many banded and clubbed bacilli with typical arrangement in groups. Diphtheria was diagnosed and antitoxin 5,000 units was given. The fever was normal the next morning and recovery was uncomplicated. Vincent, the older brother 5 years of age, was given a prophylactic dose and never presented any symptoms or positive smears of the disease. This child's father had a few days previously returned from Jubbulpore and also presented the bacilli in a smear; the organisms persisted for ten days and cleared up without any symptoms or antitoxin, as antitoxin was refused by both of the child's parents. The mother's throat smears were at no time positive. The suggestion is made that this man was a carrier bringing the disease from some infected person whom he met on his journey.

Case 9.—On March 2nd, 1928, the writer's daughter, age 3½ years, developed a sore throat in Mungeli. The next morning she was listless and toxic and complained of her throat

being painful. The temperature was 100° and apparently rising. The examination of the throat showed a dirty ashen-grey membrane on each tonsil. The membrane on each tonsil was firmly attached, not giving away on being briskly rubbed with a cotton swab. Smears showed typical Klebs-Loeffler bacilli, but only after a rather long search. No culture material being available a culture was not taken. At 12 o'clock noon of the same day, the temperature was 101° and the toxicity had greatly increased. Antitoxin 10,000 units was given under the scapula. The fever rose no further and gradually came down towards evening. During the night and early morning, though the temperature was 97° , the pulse continued 130 and in the child's sleep the respiration was laboured and of a character suggestive of that seen in shock with cardiac failure. The next morning there was marked improvement. The membrane was gone that evening and recovery was uncomplicated.

The patient was kept in bed for nine days—with difficulty. All European children and adults were given prophylactic doses of antitoxin. No other cases appeared and ten days later all throats were negative for diphtheria bacilli.

Case 10.—On March 5th, 1928, in the Jackman Memorial Hospital, Bilaspur, Paul M., a slight, fair European boy of 8 years with very diseased tonsils and adenoids was operated upon by Dr. Nicholson and the offending members removed. Recovery was not as rapid as desired, but on March 12th he was sent home to Sakti with his throat presenting nothing abnormal considering his post-operation condition. His father and mother and three-weeks-old baby brother accompanied him. At home he was apparently recovering when on March 14th he started to have difficulty in breathing. He was rushed to Champa where antitoxin was given and then on to Bilaspur, where he was brought in a moribund condition from the 5-30 train in a tonga 3 miles to the hospital, where in spite of further antitoxin he died of heart failure, his throat covered with the ashen-grey membrane.

Case 11.—Following Paul's death his baby brother, 3 weeks old, had prophylactic antitoxin. However, notwithstanding this precaution on March 21st, this little infant developed sore throat and hoarseness and was at once taken to Champa. Dr. H. Bowman found many kinds of organisms; staphylococci, streptococci, bacilli, diphtheroids and also quite typical diphtheria bacilli. At Champa, additional antitoxin was given. He made an uneventful recovery.

No further cases have appeared until May 22nd, 1928.

Notes on possible Epidemicity.

With our insufficient knowledge, the possible source of infection of these cases cannot be definitely traced. That the Bishrampur cases came from one source and the later contacts from those infected is possible. The child, the first case in Mungeli, Case 7, probably was an

imported case, perhaps infected on the train. Even though there were many uninoculated contacts with this child, it is to be noted that none became infected.

P. S. probably brought the organisms from some source on his trip to Jubbulpore, and gave the disease to his child. That he was not a permanent carrier is shown by the fact that shortly after his daughter's recovery his throat was negative for diphtheria bacilli and that no other case followed.

Before the infection of Case 8 was known, P. S. had visited in the home of the writer though he was at no time near his daughter. If such was the case, it is interesting that the disease took such a long time to develop. Prophylaxis should have been given but insufficiency of antitoxin prohibited this step. By the time a new stock had come, it was needed for treatment. All the Europeans were inoculated at this time as noted before and no further cases developed.

The question of Indians not being susceptible to diphtheria, or very slightly so, is apparent—death occurring in the Indian youth only after very extensive membrane formation. The first Mungeli case recovered from a rather severe attack with only 2,000 units antitoxin. The Schick test used on a large number would throw light on this question.

SUMMARY.

Eleven cases of diphtheria are presented, all of which were authenticated by a trained observer and many by smears. Of the eleven cases, eight were children and one a youth. Of these, three were Indians, two of whom were girls and one a young man. Of the six European children, three were girls and three boys. Of the adults, one man and one woman were affected. In all cases antitoxin was used. There were 3 deaths. One case showed a dangerous, almost fatal anaphylactic reaction as he had had antitoxic serum one month previously.

CONCLUSION.

Diphtheria appears from time to time and should be thought of and looked for in all cases of colds and sore throats. Atypical cases should have special attention and antitoxin should be given immediately where there is any doubt whatever.

Diphtheria antitoxin should be kept in sufficient quantities in all dispensaries or stations where there are children, Indian or European.

All school children should have toxin antitoxin administered where the Schick test is not used as in the Kodaikanal School for Missionaries' Children, and to all those susceptible following the Schick test if this more scientific method of finding those susceptible is used.

The need for further investigation concerning the susceptibility of Indians to diphtheria is mentioned.

My sincere thanks are due to Dr. M. C. Lang of Baitalpur, Dr. H. Nicholson of Bilaspur

and Dr. H. Bowman of Champa who have kindly allowed me to published their cases.

Comments by Dr. M. C. Lang on his cases at Bishrampur.

"In regard to the diphtheria cases, I would say that the first thing I learned was not to expect a text-book picture. In only 3 cases did I see anything at all like the grey membrane of the text-books. In one fatal case, Victor, the throat was simply congested and one small yellow spot was noted on the tonsil. Rachael's case looked for all the world like a simple case of follicular tonsillitis.

The second point is that I feel justified in giving all our missionaries' children who complain of sore throat antitoxin at once, as I do not know of a single case of sore throat among them which was not diphtheria.

The Indian boy undoubtedly had diphtheria as he had a definite membrane over the whole of his tonsils and palate which spread over the mouth cavity."

TECHNIQUE FOR LEISHMAN'S STAIN SUITABLE FOR "FIELD" APPLICATION.

By J. C. CHUKERBUTI,

CAPTAIN, I.M.S.,

Commanding Indian Military Hospital, Risalpur.

(1) SELECT an inch of the most homogeneous portion of the slide.

(2) Draw a perpendicular boundary line on either side with a grease pencil, or better with a piece of ordinary candle, which is less expensive.

(3) Pour as much freshly prepared Leishman's stain as will cover the enclosed space, and let it dry thoroughly on the slide, preferably in the air, or over a gentle distant flame.

(4) Hold the slide with a pair of dressing forceps, dip it into methylated spirit kept in a wide mouth bottle always well corked and opened only at the time of carrying out this step, and shake it well in the spirit until the film becomes a greyish pink colour. Too much decolourization will not entail restaining, because even if the white blood cells have lost their nuclear staining, the parasites retain their characteristics. Too little may entail a residual deposit.

(5) Wash in a jet of tap water.

(6) Blot immediately, dry and mount.

(7) If sediment is still present, repeat (4), (5) and (6).

I have not been using any distilled water in staining blood films with Leishman's stain since 27th October, 1927, when I first tried this method and the result is very satisfactory.

Perfectly clean homogeneously stained fields show malaria parasites in bold relief even in their earliest stage. The nuclei of white blood cells are stained deep violet, and the neutrophilic and acidophilic granules are beautifully shown up.

I have further observed that methylated spirit used for decolourization does not lose its fuel capacity and can be used for lighting primus stoves and burning in spirit lamps.

More than two hundred 1 inch \times $\frac{1}{2}$ inch films can be effectually decolourized by dipping and shaking them in 4 ounces of methylated spirit kept in a wide mouth bottle, well corked and opened only when required, until the spirit loses its decolourizing power but retains its fuel property absolutely intact.

The colour of the stained film will depend on the degree of purity of methylated spirit which should be neutral in reaction.

Appearance of Parasites and Cellular Elements Stained by this Method.

Red Blood Cells—Shades of greyish pink.

Nuclei—Deep violet or shades of violet.

Acidophile granules—Red.

Basophile granules—Deep violet.

Neutrophile granules—Lilac.

Blood platelets—Violet.

Malarial parasites—Shades of blue.

Chromatin—Ruby red.

This method is not suggested as an improvement on the historical Leishman's technique, but as a rough "field method" to be used where pure distilled water free of CO₂ is difficult to obtain.

(This method is not entirely original, nor does Captain Chukerbuti claim that it is an improvement on the standard method. We are publishing this to draw attention to a method which is particularly suitable for field conditions and which, in our own experience, gives good results.—EDITOR, I.M.G.).

AN EPIZOOTIC IN SQUIRRELS AT KUMBAKONAM.

By K. S. RANGANATHAN, L.M.P.,

Sub-assistant Surgeon.

(From the King Institute of Preventive Medicine, Guindy, Madras.)

BETWEEN 28th September 1927 and 6th October 1927, spleen smears from four squirrels found dead in two adjacent bungalows in Kumbakonam Extension were received at this institute. All of them showed bacilli morphologically indistinguishable from plague bacilli. Spleen smears from many rats found dead were later received, but these were all negative. It was decided to inquire into the cause of death among squirrels and I was sent in charge of an investigation unit for the purpose. The following are the findings of the investigation on the spot:—

A squirrel was seen on 16th September 1927 to crawl on the ground and die in a few minutes in the Sub-Collector's compound at Kumbakonam. The dead squirrel was thrown away. Whether any more died in or around the bungalow between the 17th and 22nd September was not known as the officer was away in camp. Between the 23rd and 25th, five more

squirrels died in a similar manner in the open yard at the back of the bungalow. The one that died on the 25th was examined and found to show bacilli resembling *B. pestis*. The other four were not sent for examination. On the 4th October, two more were found dead in a room upstairs and both of them were found infected with similar organisms.

Another squirrel was found dead in a bungalow about two furlongs from the Sub-Collector's on the 2nd October. Smears from this squirrel showed similar bipolar stained organisms. So it is very likely that all the unexamined squirrels found dead also had a similar infection.

Deaths among rats were reported from five places in the town between 11th October 1927 and 18th October 1927, but smears from all these rats were found to be negative to plague. No cases of human plague occurred.

Squirrel falls were confined to the Extension, while the rat falls were restricted to the town proper. Instructions were, therefore, issued that squirrels were to be caught only in the Extension, particularly in the compounds of infected bungalows, but that rats were to be trapped evenly in all parts of the town so that the rats caught each day would represent a fair sample of the rats of the town. Every endeavour was made to procure as many squirrels and rats alive as possible. A record was maintained showing the places where the rats were trapped and the squirrels caught.

Dissection of all the animals was done by me. Diagnosis by naked eye examination alone was never relied upon and smears from organs were examined microscopically in every case. Live squirrels and rats were chloroformed and killed. Fleas, if present on them, were collected. They were then dissected and abnormal appearances were recorded.

114 squirrels were examined in all. No abnormal appearances were observed in any of them and smears from the spleen and liver showed no plague bacilli.

113 rats were dissected which were of the following species:—

1. <i>R. rattus</i>	92
2. <i>R. norvegicus</i>	20
3. Bandicoot	1
Total	113

As most of the traps were set in houses, *R. rattus*, the common house rat, was trapped in larger numbers. No abnormal appearances were noted in any of the rats and smears from the spleen and liver from these showed no plague bacilli.

Fleas.—One hundred and thirty-one fleas were collected from off 40 rats which is an average of 3.2 per rat. Fleas were not found on the other rats, presumably because some time had

elapsed before the rats were brought to the laboratory. Further the traps had not been at once enclosed in flea proof bags.

The following species of fleas have been identified:—

Species.	Number.	Percentage.
<i>Xenopsylla astia</i>	.. 123	93.9
<i>Xenopsylla cheopis</i>	.. 7	5.3
<i>Ceratophyllus</i>	.. 1	0.8
Total	.. 131	

Only five fleas were found on squirrels and these on only four out of 114 squirrels caught. They were all of the species *Ceratophyllus argutus*. They were identified by Mr. Shariff of the Zoological Survey of India and the other fleas by Mr. P. V. Seetharama Iyer, M.A., of the King Institute of Preventive Medicine, Guindy, Madras.

Sources of infection.—The exact source of infection—if it was plague—and the manner of importation could not be traced out on account of the large number of persons who had access to the bungalow and the long interval that elapsed between the beginning of the epizootic in squirrels and the commencement of the investigation.

CONCLUSIONS.

1. The occurrence of an epizootic of what looks like plague in squirrels without coincident disease in rats or men is recorded.

2. A rat flea survey of Kumbakonam—though a limited one—shows the huge preponderance of *Xenopsylla astia* (93.9 per cent.) over the plague-carrying species *Xenopsylla cheopis* (5.3 per cent.). *Ceratophyllus* accounted for the small remainder of 0.8 per cent. of the rat-flea population.

3. All the squirrel fleas were found to belong to the species *Ceratophyllus argutus*.

4. In the absence of cultural or animal inoculation tests one cannot be certain whether the disease in squirrels was caused by *B. pestis* or *B. pseudo-tuberculosis rodentium*, but morphologically the appearances were typical of *B. pestis*.

My thanks are due to Major H. H. King, I.M.S., Director of this Institute, for permitting the publication of this article.

A Mirror of Hospital Practice.

A CASE OF GLIOMA (EMBRYONAL NEUROCYTOMA) OF THE BRAIN SIMULATING PITUITARY TUMOUR.

By K. G. PANDALAI, M.B., F.R.C.S.,

MAJOR, I.M.S.,

Surgeon, General Hospital, Madras.

and

T. BHASKARA MENON, M.B., M.R.C.P.,

Department of Pathology, Medical College, Madras.

T. V., a young Indian Christian aged 30 years, was admitted to the surgical

wards of the General Hospital, Madras, on 22nd January, 1928, with a history of severe headache of 6 months' duration. Later, he noticed slight dimness of vision which gradually increased. Next he had double exophthalmos. There was also a history of occasional vomiting.

On admission, patient had vomiting of a cerebral type with bilateral exophthalmos more marked in the right eye. There was marked papilloedema on both sides with left-sided facial paralysis. Romberg's sign was present. X-rays showed pituitary fossa enlarged and the shadow of a tumour with a calcified centre. Wassermann reaction was negative.

The diagnosis was a tumour in the region in front of the chiasma pressing on the optic nerves on both sides, causing widening or erosion of the sella turcica and impeding the venous circulation on both sides resulting in exophthalmos. Though signs of endocrine disturbance were not noticeable, a tumour which could cause such bilateral signs was regarded as possibly of pituitary origin.

The tumour appears to have arisen from the floor of the 3rd ventricle in connection with the optic thalami and to have grown forward underneath the frontal lobes as a soft grey mass of the size of an orange. It has made its way down displacing the frontal lobes and hanging as a pedunculated mass which has perforated the ethmoid plates on both sides and through the ethmoid bone made its way into the orbit causing diffuse infiltration of the tissues of both eyes, pressure on the optic nerves and bilateral exophthalmos. To the naked eye, the tissue is soft and friable and shows small hæmorrhages. The growth cannot be well demarcated from the rest of the brain tissue on the left side where it has infiltrated the pia mater and the dura at the base of the brain as well as the left frontal lobe to a slight extent. But the whole of the mass is well defined on the right side where its point of origin can be made out.

Microscopically, the tumour consists of cells which are rounded or cuboidal with scanty fibrils here and there. A palisade arrangement may

Fig. 1.—Neurocytoma. Showing the round and cuboidal cells that make up the growth, the palisade arrangement of the fibres and also the arrangement of cells round the vessel. (x 312).

Fig. 2.—Photograph of the tumour showing its origin near the floor of the third ventricle marked by an X. Note how the tumour grows forward displacing the frontal lobe upwards.

Operation Notes.—On 1st February, 1928, a large right-sided frontoparietal osteoplastic flap was raised. The brain was pulsating. The dura was opened but the brain bulged out to the height of an inch. An attempt was made to elevate the frontal lobe but the pressure was too great and the cortex was torn. The attempt was given up to be repeated at a second stage a few days later. The bone flaps were removed as the skin could not be sutured otherwise. Rectal ether anaesthesia was employed with local novocain infiltration. Patient died on 7th February, 1928, without recovering consciousness.

Pathological Note.—By T. Bhaskara Menon, M.B., M.R.C.P.

be made out in the fibrils. There is no definite arrangement of the cells into pseudo-rosettes, but a grouping round the blood vessels is evident in parts of the growth. But for the fibril formation of the cells, which may be made out in places, to the uninitiated eye the tumour appears like a round-celled sarcoma.

Following Bailey and Cushing's division of the gliomata into thirteen different groups, one would place this tumour among the embryonal neurocytomata, which are tumours derived from the embryonal cells that line the medullary plate. With regard to the origin of these fibrils one view is that the neurocytes themselves form fibres in the process of development into what have

been called spongioblasts. Another view is that the fibrils are derived from neuroglia cells which are included in the growth. Whatever view is correct, it must be understood that the neurocyte is the cell that forms the medullary epithelium of the medullary groove which forms the brain vesicles. Some of these cells become elongated and form fibres and are called spongioblasts which are the precursors of the adult neuroglia cells, the astrocytes. Others become differentiated into neuroblasts which are the precursors of the nerve cells. It is of interest to note that neurocytomas of similar structure may originate in the retina in children and spread up into the brain and even to the corresponding eye on the other side.

VERTICAL SQUINT OF HIGH DEGREE IN WHICH BINOCULAR SINGLE VISION WAS MAINTAINED IN COM- PARATIVE COMFORT.

By R. E. WRIGHT,
LIEUTENANT-COLONEL, I.M.S.,
and

V. G. MUTHAYYA, P.M.S.,
Government Ophthalmic Hospital, Madras.

MR. X., European, aged 35, has very little to complain of except that the head tilt and blinking movements of the lids which he has adopted to enable himself to get single vision for distance make him feel somewhat self-conscious. He thinks that the trouble is due to his right eye having been injured at birth by the accoucheur's instruments. He is inclined to see double except when reading or looking down at near objects, but is enabled to maintain distant single vision by the manœuvres noted above. These movements have to be frequently repeated in the ordinary course of his daily life.

On investigation of the case, it appeared that Mr. X was a perfectly fit healthy-looking individual of cheerful disposition and, in spite of his self-consciousness, quite inclined to mix freely with his fellow men. He was, moreover, successful in his work and highly thought of. He maintained a very erect attitude with straight back, chest thrown out, head thrown back and tilted to the left shoulder. In this position while engaging him in conversation, one noted that the lids drooped a little and that every few moments he made a series of three or four small quick movements of his head, tilting it up a little more, at the same time the lids made a series of short deliberate blinks after which steady fixation was resumed. He states that his earlier photographs do not show any head tilt, but that in those taken after 12 years of age, the condition is definite. He had measles and neurasthenia (?) not long before the head tilt was established, but did not

have any other serious disease of childhood. His vision is 6/5 in each eye. With the head placed straight so that the eyes should assume the primary position, there is vertical squint of 25° (prism measurement). He can fix with either eye, but the tendency to fix with the left is greater. He has, therefore, a hypertropia which becomes a hyperphoria on tilting; the tendency to deviation is, however, great and fixation is maintained with difficulty. He gets double vision frequently as the fixation breaks down, but it does not worry him except that it gives the indication for blinking and tilting and picking up single vision again. He has binocular vision for near objects and no difficulty in maintaining steady fixation.

Tested with the Duane's screen it is found that the elevators of his left eye are at fault, but although the vertical diplopia is more marked in the upper and outer field when the false image is seen by the left eye, a certain degree of committance has become established. The question of operation arose and recession of the left inferior rectus was discussed, but it was considered sound judgment to leave well alone in view of the fact that the patient had no symptoms except the intermittent diplopia which did not worry him as he was able to correct it immediately. The self-consciousness had evidently been largely overcome by the patient's pluck and philosophical outlook.

A CASE OF HÆMORRHAGIC PLEURISY.

By GANESH DASS, S.A.S.,
Bahawalnagar, S. P. P., Punjab.

A PATIENT named Lal Shah of the labouring class was carried to hospital for the treatment of the following complaints; he suffered from cough, shortness of breath, constant pain in the abdomen, slight fever and palpitation of the heart during the early days of November, 1927.

History.—He was bitten by a snake of the viper variety a fortnight before and was said to have been cured by quack's treatment in a week's time, but he subsequently developed the above complaints.

It is unnecessary to give complete and descriptive details of the signs and symptoms of the disease he was suffering from but on thorough examination, a provisional diagnosis of total empyema of the right side of the chest was made. While confirming the diagnosis by the exploring needle, I found it to my great surprise to be a case of hæemothorax. The question arose as to whether the removal of such a large quantity of blood would be safe.

Treatment on simple lines for the absorption of fluid was considered necessary for a few days but failed and as the life of the patient was threatened by direct pressure on the heart and subjacent viscera, about 5 lbs. of bloodstained jelly-like opalescent serum was evacuated by Potain's aspirator; at the same time I prepared

to meet with subsequent complications. Immediately after the operation an intramuscular injection of calcium chloride gr. 5 in 10 c.c. of sterile distilled water was given in the buttocks to prevent further hæmorrhage into the cavity and an intravenous injection of tr. iodi. min. 22 in 10 c.c. normal saline to counteract viper poison in the system was also administered.

The patient passed the night quite comfortably and next morning he was quite cheerful as he had had no sleep for the last ten days, but all of a sudden, as was expected, he began to develop cardiac failure. Injections of pituitrin 1 c.c. and adrenaline min. 10 were continued alternately every four hours and a stimulant mixture containing tr. digitalis min. 10, was given every four hours for two days consecutively; the patient rallied and made an uneventful recovery after four days further stay in hospital.

Points of Interest.—(1) In general practice hæmothorax is relatively uncommon, though I have seen a few cases of snake-bite poisoning with complications of hæmorrhages from nose, gums, hæmatemesis, hæmaturia, melæna and petechial hæmorrhages, all cured by treatment on general principles.

(2) It is just possible that the patient would not have developed hæmothorax had he suffered from hæmatemesis, a common occurrence in snake-bite poisoning cases.

I am greatly indebted to Dr. J. J. Dunn, M.O., Bahawalnagar, North Western Railway, for his kind consultation and advice.

THE SUCCESSFUL TREATMENT OF "VITILIGO DIFFUSA" BY INJECTIONS OF SODIUM CACODYLATE.

By MOHOMMED ABDUL QUIYUM, L.M.P.,

Medical Officer, District Board, Darbhanga.

A BRAHMIN boy, Paratab Narain, aged 14 years, came to me while I was in charge of the Buchouli dispensary with the complaint that for the last 4 years he had been suffering from progressive generalised distribution of white patches almost all over the surface of the body, but most marked over the trunk and upper extremities. On examination I found that the patches were whitish in appearance, of the size of four anna silver coins, but not symmetrical in any respect. He also complained of constipation since the appearance of the trouble. I enquired from his father as to whether he had ever suffered from any venereal troubles, but he responded with a very definite negative. During the last 4 years of his ailment he had undergone a regular treatment at the hands of the local vaidya and quacks, but none could procure him any benefit. He was the only son of his parents, so they were most anxious about his ill-health and the stubborn advance of the disease. I decided to treat him by

arsenical preparations parenterally, and chose sodium cacodylate for this purpose. I injected him hypodermically with sodium cacodylate solution ($\frac{3}{4}$ grain in 1 c.c.m.) on alternate days until 10 injections had been given. On finding a marked improvement in him, I used the solution of higher potency (3 grains in 1 c.c.m.) with the same alternation and by the same route. After a course of 24 injections, the symptoms disappeared; the patches vanished completely. Of course I had prescribed him a good combination of medicines for oral administration in association with the injections.

KYPHOSIS AFTER TETANUS.

By M. B. VARDE, L.C.P.S.,
Shirpur (W. Khandesh).

IN May last I met a case of tetanus which was successfully treated, but curiously enough the patient developed kyphosis as a result of tetanus. As this is a rare sequela of tetanus, I wish to bring this case to the notice of the profession with the intention that I may be enlightened on the causes thereof.

I saw at 6 p.m. on 4th May, 1928, S. H., shoemaker's boy, aged 11 years suffering from lock-jaw and stiffness of the neck. Duration of the illness, a week. With great difficulty he could swallow liquids. A small wound was present in the great toe of the left foot. He was given immediately a dose of anti-tetanus serum P. D. and Co. and the following mixture:—

℞	
Chloral Hydras	.. gr. xxx.
Pot. Bromide	.. gr. xxx.
Tr. Digitalis	.. m. xx.
Tr. Hyoscyamus	.. 5 ii.
Spt. Chloroform	.. 5 i.
Aqua.	.. 5 ii.
Ft. mist. $\frac{1}{3}$ rd part	t. d. s.

The next morning the symptoms had slightly abated. The cost of the serum being prohibitive, the parents of the boy could not afford to spend money for the serum treatment. I therefore gave the patient 20 c.c. of a 25 per cent. sterile mag. sulph. solution 10 c.c. in each flank under the skin once a day for three consecutive days and the above mixture for a week more. The treatment was stopped on the 14th of May as the patient was completely cured. The patient had grown so weak that he was unable to move about.

He had no trouble now, but after a month the patient came to me and showed the deformity he had developed after his last illness of tetanus. On examining I found it was kyphosis. The chief point of interest in this case is that the patient developed kyphosis during convalescence after tetanus.

(It would appear that the original diagnosis of tetanus rests on a somewhat slender basis.—Ed., I.M.G.)

Indian Medical Gazette.

OCTOBER.

THE LEPROSY PROBLEM—A STEP TOWARDS SOLUTION.

"THE Leprosy Problem" is an expression which has become relatively common in the press—medical and lay alike—within recent years. Until comparatively recent times, leprosy was not considered a disease worthy of co-ordinated scientific investigation. Valuable pioneer work by Hansen, Looft and Danielssen in Scandanavia, by Unna in Germany, by Clegg, Duval and their associates in America and by Rogers and Row in India laid the foundation but the super-structure, in the shape of a world-wide campaign against the disease, was completely wanting. Now all this has been changed: the intensive work of American investigators (backed up by the weight of American public opinion), bids fair to stamp the disease out of the New World while the ever-increasing activities of the British Empire Leprosy Relief Association augur well for the progress of the campaign in those areas of the Old World within the radius of the commonwealth of nations constituting the British Empire.

With the advancement in knowledge, old ideas are rapidly going by the board and in particular the old policy of segregation is being subjected to drastic modifications. So far as India is concerned, a policy of absolute segregation is financially impracticable, even were it justified on medical grounds. The 1921 census gives the total number of lepers in this country as slightly over 1,00,000. Conservative estimates based on recent investigations indicate that there must be at least four to five times that number.

A careful study of the problem in all its aspects has fully demonstrated that the most effective line of attack so far as India is concerned is that of combined propaganda, treatment, and survey. Centres designed primarily for the treatment of early cases are opened by small bands of specially trained workers, operating in different highly endemic areas. At the same time propaganda is carried on among the inhabitants of the district particularly with regard to the necessity for treatment in the earliest stages of the disease, and thirdly, careful enquiry is made into the factor or factors responsible for the disease in any given district. Small preliminary surveys of this nature have already brought to light many facts of considerable importance, not the least of which is the unreliability of the official census figures as an indication of the actual incidence of leprosy in this country.

It is obvious that a scheme of this nature, applied as an All-India measure, cannot be finan-

ced solely from the relatively limited funds allocated to the Indian Council of the British Empire Leprosy Relief Association and that outside assistance is necessary. It is in this connexion that Provincial Governments have, in our opinion, a clear duty to perform.

Certain provinces, recognising the undoubted merits of this new line of attack, have already taken steps to initiate schemes of combined propaganda treatment and survey in their respective areas. These provinces are the exception, however, rather than the rule. In the province of Bengal, for example, in which the incidence of leprosy is a problem of considerable gravity the plans have been on the table for some time but the necessary financial support is lacking. We are advised that a period of 5 years would suffice for a survey of, and the establishment of treatment centres in, the 15 or 20 districts of Bengal in which the incidence of the disease is greatest; moreover it is estimated that the cost would certainly not exceed the relatively trivial sum of Rs. 12,000 per annum.

The ever-increasing facilities for inter-communication and the consequent commingling of the population are undoubtedly leading to a spread of leprosy, and nothing is to be gained by a few spasmodic and isolated attempts at an anti-leprosy campaign. Is it too much to hope that this small but necessary provision will be found in the next year's provincial budgets, so that those provinces and states that have not yet come into line will be able to do so in the immediate future?

SPECIAL ARTICLE.

A NOTE ON WEIL'S DISEASE, OR LEPTOSPIROSIS ICTEROHÆMORRHAGICA.*

By D. A. TURKHUDD, M.B., C.M. (Edin.).

"Ifley," Kodaikanal, S. I.

ON the 21st April, this year (1928), Dr. Beals of Wai, who had just come up to Kodaikanal, wrote to me that she had heard that some children at this hill-station had suffered from fever followed by jaundice, that she had come to know altogether of nine such cases, and that at the time of writing, she had staying in her own house, a little girl who had only just got over an attack of fever and jaundice. I quote from her letter:—"Now the question arises as to the cause of such an epidemic. The four cases I have seen have all been mild. However,

* Read at the Missionary Medical Conference held at Kodaikanal in May 1928.

questions have been raised of its possibly being Weil's Disease.....To me, these cases seem much too mild to be the disease, but I suppose there might be mild epidemics of it as we see in other diseases." I saw the case referred to by Dr. Beals, the following day; her history was as follows:—

D. B., after being miserable for a week began to develop jaundice. The exact dates, however, of the onset of the fever and the appearance of jaundice, could not be ascertained. When I saw her, which was about a fortnight after the commencement of her illness, the girl had no rise of temperature and no jaundice, but there was a good deal of weakness present. The motions were clay-coloured, and there was no abdominal tenderness. The urine was highly bile-stained, specific gravity 1010, but showed no albumen. The centrifuged sediment from specimens of urine obtained on two occasions, showed a few bile-stained renal epithelial cells. No leptospiræ could be detected with Giemsa's stain. Within a few days the girl was quite well again.

On the 23rd of the same month, I was asked to see another girl:—

C. V. P. Her temperature, when I visited her, was 102°F., and pulse 88, slow in relation to the fever. The conjunctivæ were clear, the liver very slightly enlarged but not tender, no pain anywhere, and no weakness. The next day her temperature was normal. She did not develop any jaundice and was soon all right. The urine showed nothing abnormal except high specific gravity, 1030.

From the examination of these two cases only, it was not possible to come to any definite diagnosis without further observations on similar suspicious cases. On the other hand, it is interesting to note that a similar epidemic of fever followed by mild jaundice was, I understand, noticed here during the season of 1927. And although the present epidemic, from the history of the cases seen by other physicians, the course of the illness, and the clinical signs, is highly suggestive of Weil's disease, the actual demonstration of the causal organism by laboratory methods, still remains to be carried out.

As I had had something to do in connexion with a small epidemic of Weil's disease which was diagnosed in Bombay in the year 1921, I thought that these cases might be of some interest especially as epidemics of fever followed by jaundice have been reported from time to time in this country.

WEIL'S DISEASE

In 1921, a few sporadic cases of fever in which jaundice supervened after the fever had lasted from three to eight days, were reported in Bombay. Dr. M. J. Parmanand, M.B., B.S. (Bom.), who at the time was my assistant in the bacteriological department of the Grant Medical College, and was also working in the Adams-Wylie Hospital in that city, had the opportunity of observing these cases and of watching their progress in the wards of the hospital. His attention was particularly attracted as during the period of only a month and a half he came across no less than seven such cases, three being met with in his private practice. Altogether eleven cases were studied; their chief clinical symptoms are shown in the following table:—

Case.	Jaundice.	Conjunctival congestion.	Vomiting.	Limb-pains.	Hæmoptysis.	Epistaxis.	Albumin-uria.

9. B.Y.	..	+	—	+	—	—	+
10. F.A.	..	+	+	+	—	+	+
11. S.K.K.	..	+	+	+	—	—	+

Of these cases, No. 4, L.M., was the most interesting from the diagnostic point of view. This patient was admitted into hospital on the 23rd of August, 1921, with a history of high fever and delirium for three days. On admission the temperature was 100°F., and the liver was enlarged and tender. On the 25th, *i.e.*, the fifth day of illness, slight jaundice appeared. The next day the jaundice was deep, the conjunctivæ became congested, and the temperature rose to 101°F. On the 27th, the conjunctivæ were bloodshot, and there was a purpuric eruption on the upper extremities and on the abdomen, while the temperature had dropped to normal. This combination and sequence of symptoms left scarcely any doubt as to the clinical diagnosis of Weil's disease. The examination of blood smears showed no spirochaetes or any other parasites. The urine was then centrifuged, and smears made from the deposit were stained by Fontana's method. Out of five smears examined, three showed organisms which resembled leptospiræ. As saprophytic spirochaetes not infrequently occur in contaminated urine, catheter specimens were taken from three subsequent cases and similar leptospiræ obtained.

Several epidemics, clinically resembling Weil's disease, have been reported from time to time in this country and also from the Andamans, and have been variously described as "toxic jaundice," "infective jaundice," "camp jaundice," etc.; and Knowles, in his *Introduction to Medical Protozoology*, writes "it is almost certain that Weil's disease occurs in India."

The history of epidemic jaundice dates from the year 1800, when it affected Napoleon's army at the siege of Cairo; and epidemics have since been reported in Europe by several observers. It was in the year 1886, however, that Weil of Heidelberg, described for the first time, the clinical signs and symptoms of the disease which has been since known as Weil's disease. But as the features described by him are those of epidemic catarrhal jaundice, Osler suggests that "it would be an advantage if the designation Weil's disease were dropped."

Until 1914, the exact cause of the disease was unknown; but in that year, Inada and Ido discovered the causal organism and described it in the *Journal of Experimental Medicine* for March, 1916. This pathogenic agent is a spirochaete, and as it resembles the leptospira of yellow fever, *L. icteroides*, it is now called *Leptospira icterohæmorrhagiæ*. According to Noguchi, a leptospira shows minute elementary spirals running throughout the body; there is entire absence of flagella as well as of undulating membrane, and progression is by rotary movement with one end hooked. These organisms differ from other blood spirochaetes in that they resist the action of 10 per cent. saponin, but are dissolved by bile-salts.

The leptospiræ of Weil's disease are present in the blood only during the first five days of

fever, and are best detected under dark-ground illumination. After ten days they appear in the urine, being excreted by the kidneys, and may continue to be discharged in this way, sometimes for weeks. They are agglutinated by the patient's blood after the second week. This serological test serves to distinguish the leptospiræ of Weil's disease from other strains and species. *Leptospira hebdomadis*, which causes the so-called seven-day fever of Japan, and *L. icteroides* of yellow fever are not agglutinated by the blood of patients suffering from Weil's disease.

The usual laboratory method of diagnosing Weil's disease, is by injecting about 3 c.cms. of the patient's blood, taken early during the febrile stage, intraperitoneally into a young guinea-pig. If the fever has subsided, the centrifuged sediment from a specimen of sterile urine obtained by passing a catheter, should be used for intraperitoneal injection. After the death of the inoculated animal, which occurs in about a week, the kidneys should be removed and macerated in a little sterile normal saline, and the emulsion examined under dark-ground illumination, or smears made therefrom and stained by Fontana's method. Coles recommends Giemsa's stain. This leptospira has been cultivated on suitable liquid and semi-solid media, under anaerobic conditions.

The actual method of transmission of the infection in Weil's disease is not yet definitely known. In 1915, Miyajima reported the presence of organisms resembling *L. icterohæmorrhagiæ* in the kidneys of field-mice in Japan. Ido and his colleagues subsequently discovered typical leptospiræ in the kidneys of rats; they, therefore, came to the conclusion that rats played an important part in the transmission of the disease. Inada believed that infection took place through food contaminated with the urinary secretion of rats. Ido and Oki, however, have succeeded in transmitting the disease to animals by the application of the infective material to the unbroken skin; they moreover found that Weil's disease was common among workers in damp, rat-infested coal mines and in swampy fields, the leptospiræ evacuated by rats' kidneys finding a suitable medium for thriving in the damp soil. During the Great War, soldiers became infected in rat-infested damp trenches, and examination of the rats caught in these places, showed the presence of leptospiræ in their kidneys and urine.

In an investigation of an outbreak of the disease in West Lothian, Buchanan (*British Medical Journal*, 1924, II, p. 990), was able to trace the infection to certain coal mines. He showed the presence of *L. icterohæmorrhagiæ* in the slime of the roof, in situations which appeared to be inaccessible to rats. Inoculation of the slime into guinea-pigs produced characteristic symptoms of jaundice, and leptospiræ were recovered from their organs.

Manson-Bahr, Wenyon and Brown have reported in the *Lancet*, 1922, II, p. 1056, a very interesting case of a seaman who fell into the Thames, off Gravesend, and five days later, developed an attack of fever and jaundice. Wenyon and Brown were able to recover leptospiræ from the guinea-pigs inoculated with the blood of this patient.

Typical leptospiræ have been found also in samples of water in various places, and in Europe, epidemics have been traced to several insanitary bathing establishments. Noguchi has found typical leptospiræ in stagnant pools, swamps and ditches. Coles has recorded the presence of free-living leptospiræ in the tap water at Bournemouth, and also in decaying vegetable matter.

In the last proved case of spirochætal jaundice reported from Virginia (*Journal A. M. A.*, 7th April, 1928, p. 1113), although the actual mode of infection could not be ascertained, it is interesting to note that the patient, a boy of 20, was a member of a swimming team. Mulholland and Bray, who have reported this as the eighth case in America, say that Weil's disease is much more common in the United States than has hitherto been suspected.

As regards symptomatology, in the cases under observation in the Bombay epidemic of 1921, the following symptoms were observed:—"In the majority of cases the onset was sudden with a sensation of chilliness, headache, pain in the body, and gastro-intestinal disturbances. The fever was irregularly high, rising to 101° or 102°F., and the pulse slow in proportion to the pyrexia. During this febrile stage, which lasted from four to eight days, acute congestion of the conjunctivæ was a marked feature. Leucocytosis was moderate, about 10,000 leucocytes per c.mm. Jaundice occurred towards the end of the febrile period, and seemed rapidly to become intense, lasting for about eight days. In this stage, although the fever disappeared, the gastro-intestinal disturbances became aggravated, and there was nausea, incessant vomiting and extreme prostration. The pulse became feeble, and there was restlessness and a marked tendency to hæmorrhages. The liver showed enlargement. The symptoms then gradually abated and convalescence began. About the beginning of the third week, however, some cases showed a secondary rise of temperature, which lasted for two or three days, but not accompanied by any of the symptoms which showed themselves during the initial fever.*" The urine in the febrile stage is generally scanty, high coloured and loaded with albumen. In the more severe cases bile pigment is present in abundance. Microscopic examination of the deposit shows casts and blood cells. According to Manson-Bahr, the urine from the 5th to the 8th day, gives an intense green reaction after the addition of 1 or 2 drops of acetic acid.

* (Parmanand, thesis for the M.D. degree).

The mortality of the disease varies from 5 to 6 per cent., as met with in Europe, to about 30 per cent. in Japan. Among the eleven cases seen in Bombay, there was one death.

As regards the morbid anatomy, in the great majority of cases there is congestion and slight enlargement of almost all the organs, and in icteric cases, the pigmentation affects all tissues and organs. The liver is enlarged, and on section shows a moderate degree of focal necrosis. The kidneys are congested and enlarged, and microscopically show, in most cases, degenerative changes in the epithelial cells. Stevenson, who examined Barker's cases from the Andamans, found marked general parenchymatous nephritis, and the sections, when stained by Levaditi's method, showed leptospiræ in the cells and in the lumina of the straight tubules. (Brown, *Lancet*, 25th February, 1928). In a case which died in the Sir Jamsetjee Jeejeebhoy Hospital in Bombay, with suspicious clinical symptoms of Weil's disease, Parmanand found leptospira-like organisms in the blood-stained fluid aspirated from the liver.

The exact diagnosis of leptospiral jaundice can only be made by laboratory methods. Examination of stained blood-films rarely reveals the leptospiræ, as their number is small. Animal inoculation is, therefore, usually resorted to, and as a routine measure, Stokes, Ryle and Tytler recommend intraperitoneal injection of young guinea-pigs with 3 c.cms. of patient's blood within the first seven days of illness. For obtaining positive results in every instance, however, it is advisable to secure about 10 c.cms. of blood, and to inject one-third of the quantity into three separate guinea-pigs.

In the Bombay epidemic the guinea-pig inoculations were inconclusive; and in this connection it is interesting to note that in all of Barker's cases in the Andamans also, animal experiments yielded negative results. The disease that Barker was dealing with has now been proved to be leptospirosis, by the finding of leptospiræ in the kidneys of some of his autopsied cases.

But even without these laboratory methods, the diagnosis of Weil's disease can be arrived at with a certain degree of accuracy by clinical examination.

Barker, in his thesis on "Leptospirosis" for the degree of M. D. of Cambridge, gives the following main diagnostic symptoms of the disease. (*Indian Medical Gazette*, October, 1926):—

Sudden high fever.

Relative tachycardia for temperature.

Severe headache, backache, intense myalgia of the entire body, and great prostration.

Early conjunctival injection.

Jaundice.

Epistaxis and other hæmorrhages, eruption, constipation, nausea and vomiting.

Albuminuria and choluria.

In this connexion, there is also a paper on "Weil's disease in the Andamans" by Deuskar, in the *Indian Medical Gazette* for January, 1928.

In the Bombay epidemic, limb pains, jaundice and albuminuria were present in all the cases under observation. In the Andamans, violent muscular pains, prostration, and conjunctival injection were met with in practically all Deuskar's cases; while jaundice was seen in 14 cases out of 23, and albuminuria in 9 cases only. Stokes, Ryle and Tytler found jaundice in more than 60 per cent. of cases in their investigations in the epidemic in Flanders.

rash, and a saddle-back fever, but no jaundice. In the seven-day fever of Japan, the causative organism is a leptospira, and there is a rash, but no pains, no jaundice, and no mortality. The organism of the relapsing or famine fever of India, is not a leptospira, but a spirochæte, now known as *Borrelia carteri*, which can be very readily made out under the microscope. Finally, Weil's disease has to be differentiated from epidemic catarrhal jaundice, in which no organism has been discovered, and which is a local disease limited to the bile-ducts and not a general infection. Moreover, in the latter disease, there is enlargement of the spleen as well as of the liver.

TABLE OF SYMPTOMS.

In India, leptospiral jaundice has to be differentiated from certain epidemics. It resembles in every respect, a mild epidemic of yellow fever, but this disease is not supposed to exist in this country. In dengue, there are joint pains, a

Treatment.—Inada and Ido have prepared a polyvalent serum by immunising horses. It has marked protective and curative properties, and is used in the treatment of the disease in Japan. Apart from this, the treatment is symptomatic.

Deuskar tried salicylate injections with large doses of alkalis by the mouth, but his fever charts do not show that this treatment in any way affected the course of the disease. For hæmorrhages, he got no results from calcium chloride and adrenalin. Urotropine has been found useful according to the *Memoranda on Medical Diseases* issued by the War Office in 1919. Grey powder in small doses may be tried, but as albuminuria is present, the effect of these drugs should be carefully watched. Sodium phosphate and ammonium chloride have also been recommended. From the laboratory point of view, it appears to me that as these leptospiræ are dissolved by bile-salts, Weil's disease might be treated with 3 to 5 grains of sodium taurocholate, given internally, two or three times a day.

Before concluding, I should like to draw attention to the accompanying table of symptoms in the seven-day fever of Japan, dengue, Weil's disease and yellow fever. It shows how the same symptoms are common in all these diseases. They all appear in epidemic forms; but the symptoms, which are mild in the seven-day fever of Japan, increase in intensity in dengue and Weil's disease, until they become very severe in yellow fever, in which a high degree of mortality is reached. Manson-Bahr, in his *Tropical Diseases* states that "dengue is probably one of the most difficult diseases to differentiate from yellow fever." The temperature charts are more or less similar. In three of these diseases, viz., the seven-day fever of Japan, Weil's disease and yellow fever, the causative organisms are leptospiræ, morphologically alike, and differing only in certain immunological reactions. May it not be, however, that all these leptospiræ have been derived from the same original stock, only, that the virulence has been greatly diminished in the case of *Leptospira hebdomadis* by a number of passages through certain animals like the field-mouse, while in the case of yellow fever, the virulence is highly exalted by a long series of transmissions through man?—Who knows? In this connection I would like to quote the following from Glen Liston's address at the Medical Research Section of the Indian Science Congress held at Madras in 1922:—"Epidemics of jaundice with a considerable mortality have occurred in India and the Andamans, but no person has yet proved that the leptospiræ found in these epidemics were *icterohæmorrhagicæ* and not *icteroides*. With these facts before us, I would ask you to consider whether we have, or have not, yellow fever already present in India."

It is interesting to note that Sellards, in his investigations in connexion with the epidemic of yellow fever at Paratyba in Brazil in 1926, has come to the conclusion from his serological experiments, that *L. icterohæmorrhagicæ* is identical with *L. icteroides*.

And now, as the result of the latest experimental work in West Africa, considerable labora-

tory evidence has been collected in support of the former view that yellow fever is caused by a filterable virus, and not by a leptospira. Adrian Stokes (who fell a victim to it while conducting this research work), with his colleagues Baur and Hudson, made the important discovery that the common *rhesus* monkeys are extremely susceptible to the infection, and that no leptospiræ could be found in their blood, or after post-mortem examinations. (*Journal A. M. A.*, Vol. 90, No. 4, p. 253).

Sellards' observations have also been confirmed, and independent investigators have shown the serological identity of *L. icterohæmorrhagicæ* with *L. icteroides*; and it appears to be now almost certain that the organism described by Noguchi as the cause of yellow fever, must have been obtained from cases of Weil's disease, or probably from patients with a double infection. Sellards and Hindle have now further discovered that the filterable virus of yellow fever, like that of vaccinia and rabies, is unaffected by cold, and if frozen, will maintain its virulence for at least twelve days, and possibly much longer. (*B. M. J.*, 28th April, 1928, p. 713).

Unfortunately, Noguchi, who had done an immensely valuable work in connexion with spirochætosus and leptospirosis, has also now fallen a martyr to yellow fever while conducting this important research work in West Africa, and it will be some time before investigators will be in a position to say definitely, whether Weil's disease and yellow fever are different manifestations of the same disease, or totally different entities.

Note.—Since my reading the above paper before the Missionary Medical Conference, two other cases have been brought to my notice by Dr. Wilder and Dr. Manley, and their history, symptoms, and clinical signs leaves no doubt in my mind about the presence of Weil's disease in Kodaikanal.

Current Topics.

Bombay Letter.

THE J. J. Group of Hospitals is situated on an area of land measuring 42 acres. It is a small town by itself and is continually expanding. The total population numbers 2,000 and this includes patients, nurses, doctors, students and the menial staff. The J. J. Group of Hospitals comprise the following:—

Sir J. J. Hospital.

Sir Cowasji Jehangir Ophthalmic Hospital.

Bai Motlibai Lying-in Hospital.

Sir D. M. Petit Hospital for women and children.

The J. J. Hospital was built in the year 1843 and Sir Jamsetji Jeejeebhoy the first baronet, gave the munificent sum of Rs. 1,64,000 towards the cost of building. As hospitals go in India, it is one of the oldest and certainly the largest in the western Presidency. The Sir C. J. Ophthalmic Hospital was

built in the year 1866 for diseases of the eye as an adjunct to the J. J. Hospital. Owing to the great demand for more beds, the hospital was extended in the year 1909, and a new block was erected by the donor's son, the present Sir Cowasji Jehangir, Bart. The total number of beds at present is 73. The present baronet has generously offered a donation of Rs. 1,50,000 and the building being too old for modern requirements is to be pulled down and a modern, up-to-date eye hospital will be built in the course of the next two years, the expenses being jointly defrayed by Sir Cowasji Jehangir, Bart, and the Government. The Bai Motlibai Lying-in Hospital and the Sir D. M. Petit Hospital for women and children were opened to the public in March, 1892. The total number of beds in both these hospitals is 80: 40 in each.

Ever since the present Governor of Bombay set his foot on the soil of this country he has espoused the cause of suffering humanity. In a speech which he delivered in reply to an address of welcome given to him by the Municipal Corporation of Bombay, he pointed out that the ratio of beds to the population of this city was woefully inadequate. He started a Hospital fund known after him, and—thanks to the untiring efforts of himself and a band of devoted workers—a handsome sum of Rs. 13 lakhs has been collected towards it. Sir Byramjee Jeejeebhoy came forward with an offer of Rs. 2 lakhs to build a hospital for children; the building is nearly complete and will be formally opened before His Excellency leaves India. There has always been a keen rivalry as to which is the premier city of India—Calcutta or Bombay. It is a matter of pride to Bombaites that this is the first city in India to own a separate hospital for children and Bombay has set a fine example which Calcutta is sure to follow.

A sum of Rs. 4 lakhs was handed over to His Excellency the Governor by the trustees of the late Rao Bahadur Ellappa Balam, and a handsome pavilion of three storeys bearing the name of the Rao Bahadur has been erected and will be declared open early next year. Accommodation for 104 additional patients has been provided in this hospital, which in compliance with the wishes of the trustees will be reserved for Hindus only. It is also proposed to build another pavilion of about 100 beds in which accommodation will be provided for venereal diseases, skin diseases, and a special ward set apart for diseases of the ear, nose and throat. A special up-to-date theatre is to be built for the specialist in Otolaryngology and Rhinology. It may safely be said, that Bombay again is in the van of the other cities of India in providing beds for the special branches of Medicine and Surgery.

Thanks to the generosity of the Trustees of the Sir Currimbhoy Ebrahim Memorial Fund, a sum of Rs. 1 lakh was handed over to the Sir Leslie Wilson Hospital Fund to build a dental college and hospital on the spacious terrace of the out-patient department. Twenty-seven dental chairs will be provided in this hospital and it is proposed to put students through a course of four years in dental mechanics and dentistry, and the University of Bombay has been asked to grant a degree in dentistry. Even at the risk of wearying the readers of this article, the writer cannot forbear to observe that Bombay, whose civic coat of arms bears the words "urbs prima in Indis," will be the first city in India to train her own dentists.

As the number of beds has increased, additional accommodation is to be provided for the extra nurses that will be required. A block for 99 nurses is being built as an annexe to the Wadia Home for nurses which is a model of its kind and one of the best homes for nurses in India.

A central clinical laboratory under the charge of an expert clinical pathologist will be located in the Out-patient Department. It is proposed to spend a sum of Rs. 10,000 in equipping this laboratory. The clinical pathologist will work under the Professor of Pathology and will thus be a *liaison* officer between the clinician and the Professor of Morbid Anatomy.

Grant Medical College, Bombay, 1923–1928.

By S. L. BHATIA, M.C., M.A., M.D. (Cantab.),
M.R.C.P. (Lond.),
CAPTAIN, I.M.S.,

Dean, Grant Medical College, Bombay.

DURING the quinquennium 1923-28, some changes of a far-reaching character have taken place in the college, which promise to increase the efficiency and usefulness of the institution. The more important changes consist in increased facilities for practical instruction in Midwifery, Medicine and Surgery, expansion of Sir J. J. Group of Hospitals, revision of the medical curriculum, reorganisation and expansion of the Pathology Department, establishment of Sir Currimbhoy Ibrahim Memorial Dental College and Hospital, and the introduction of the system of staffing the hospital by officers working in an honorary capacity. Most of these developments have taken place during the régime of His Excellency Sir Leslie Orme Wilson, K.C., C.I.E., C.M.G., D.S.O., Governor of Bombay, who from the very day he took over the administration of this Presidency has shown most lively interest in the subjects of medical relief and medical education. It might be of interest to consider these changes in some detail.

1. Increased facilities for practical instruction in Midwifery.

When Sir Norman Walker visited Bombay in 1921, on behalf of the General Medical Council of Great Britain, the chief drawback noticed in the system of training here was the lack of suitable facilities for practical instruction in midwifery. Since then marked progress has taken place. The main hospital for the teaching of this subject is the Bai Motlibai Hospital. In 1922-23 we utilized, in addition, the Cama and Ables Hospitals for midwifery training of our women students. The Bombay Corporation came forward to help us and allowed our men students to be trained at the Corporation Lying-in Dispensaries.

In addition to this, the Newrosji Wadia Maternity Hospital, which was founded on 9th June, 1925, in Parel has been of great assistance to us. This hospital is the result of co-operation between Sir Ness Wadia, the donor, the Government and the Municipality, and in the words of Sir Norman Walker "can challenge comparison with any in the world."

During 1927, arrangements were made with this hospital for the training of our students in practical midwifery. The students attend this hospital in batches of two at a time, and the arrangements have proved satisfactory.

Owing to the increased facilities detailed above, the students are now able to complete the requisite number of midwifery cases in a reasonably short time, and there is no difficulty now in fulfilling all the requirements of the General Medical Council of Great Britain so far as this subject is concerned.

2. Increased facilities for Clinical instruction in Medicine and Surgery and expansion of Sir J. J. Group of Hospitals.

In the years immediately after the War, there was a great rush of students to the college. It was part of a phenomenon common in other countries also, e.g., Great Britain. The increased number was readily accommodated in the Departments of Anatomy, Physiology and Pathology, but there was considerable difficulty as regards clinical instruction in the wards. The ratio of beds per student became too small for efficient training. The congestion in the wards was felt keenly by the clinical teachers. The position was fully realised by the College and University authorities. To remedy this to a certain extent, the Gokuldas Tejpal Hospital was utilized as a teaching centre for students in medicine and surgery in 1924. We still send students there for clinical instruction and the arrangements have worked satisfactorily. At the same time, the number of admissions was limited to 120 per year in 1924, and since then, there has been a steady reduction.

The most important measures for providing increased facilities for clinical instruction, however, consist in the additional ward accommodation provided in the expansion scheme of Sir J. J. Group of Hospitals. In this connection, the Sir Leslie Wilson Hospital Fund has played an active part. The Yellappa Balaram Pavilion of 104 beds is now under construction. Another pavilion of 97 beds is soon to be erected. The Byramjee Jeejeebhoy Hospital for children of 100 beds is well on its way to completion. The foundation stone for new nurses' quarters for 99 additional nurses, which will be required for this extension, has already been laid by His Excellency Sir Leslie Wilson on 28th February, 1928, and the buildings are now under construction.

The total number of additional beds after the two pavilions and the Byramjee Jeejeebhoy Hospital for children are ready, will be 301. Counting the present number of 326 beds, the total accommodation in the J. J. Hospital will be 627.

Apart from this there is a scheme to add 27 more beds to the Sir Cowasjee Jehangir Ophthalmic Hospital. Expansion of Gokuldas Tejpal Hospital is also taking place.

4. Reorganisation and expansion of the Pathology Department.

For some time past we had felt the necessity of reorganising the Pathology Department. The Departments of Pathology and Bacteriology were isolated and housed in separate buildings at some distance from each other. The Pathology Museum was comparatively small and was located in the main college building away from both the Pathology and Bacteriology Departments. Besides, there were no facilities for research work. To remedy these defects, it was suggested in 1925 by Dr. V. R. Khanolkar, M.D. (Lond.), the then Professor of Pathology, that the two Departments of Pathology and Bacteriology be amalgamated with one head for the whole department. It was thought that the addition of a floor to the existing Pathology building would provide sufficient extra accommodation but the late Mr. Wittet, Consulting Architect to the Government suggested that it was more economical and convenient to consider an independent structure rather than a scheme of alteration and addition to the existing building. This suggestion was accepted. New plans were prepared by the late Mr. Wittet for an

The Byramjee Jeejeebhoy Hospital for Children.

3. Revision of the Medical Curriculum.

In 1923, the University of Bombay introduced new regulations for the M.B., B.S., degrees, the most important effects of which were that:—

- (a) The period of hospital training for undergraduates was raised from two to three years.
- (b) The standard of preliminary education required for admission to the college was raised from the Previous to the Intermediate Science Examination. (Group comprising Biology, Chemistry and Physics).
- (c) The standard for pass was raised in all the subjects.

Certain consequential changes took place in the college. Formerly when students were admitted after the Previous Examination, the first year of their training in the Medical College was devoted to the study of Biology, Chemistry and Physics, which were taught here. This comprised the Preliminary Scientific Examination. But after the introduction of the New Regulations, the training in these subjects was imparted solely by the Arts College, and there was, therefore, no necessity to maintain these departments here. The Department of Biology, which was housed in the Bacteriology building, was closed down, and the whole building was thus taken over by the Bacteriology Department. The Departments of Physics and Chemistry were still maintained, as the New Regulations provided instruction in Applied Physics and Applied Chemistry in the Medical Curriculum.

independent building which consisted of a total area of 25,814 square feet. There was, however, considerable pecuniary difficulty in carrying out the project. Dr. R. Row, M.D., D.Sc. (Lond.), who was appointed Professor of Pathology in 1926 approached Sir Dorab J. Tata, who showed his practical interest and sympathy in the scheme by offering a generous donation of about Rs. 2 lakhs towards its expenses. One of the conditions on which this offer was made was "that the building are to be commenced as soon as the financial exigencies of Government permit, but the buildings should be completed within a year and a half from date." This offer was accepted by Government, but it was agreed subsequently, that the period of one year and a half for the completion of the building should run from the date of the sanction of Legislative Council, from which date also the date of sanction of Government to the project will take effect. The Bombay Legislative Council gave its sanction on 28th July, 1927, with the proviso that a Committee consisting of official and non-official medical men should consider all the plans and estimates. This Committee was appointed.

This Committee met on 19th October, 1927, and carefully considered all the plans and estimates and suggested certain alterations, which were unanimously agreed upon. We have also had the benefit of the advice of Dr. Heiser and Dr. Carter of the Rockefeller Foundation and of certain experts in this branch at the Pasteur Institute, Paris. Administrative approval was accorded to the construction of the new laboratories at

an estimated cost of Rs. 3,92,972, half of which was to be made from the donation of Sir Dorab Tata, and the other half by the Government. The work of construction commenced on 11th January, 1928, and is progressing rapidly. The new building will house the Pathological Museum, the Bacteriological and Clinical Laboratories, and will have ample accommodation for post-graduate instruction and research work. This scheme also includes provision for an up-to-date refrigerator and mortuary and an animal house. We look forward to having a very fine and up-to-date institute in the grounds of the College by the middle of next year. Much credit for this is due to the enthusiasm of Dr. R. Row.

5. The Establishment of Sir Currimbhoy Ibrahim Memorial Dental College and Hospital.

A sum of Rs. 91,000 collected for the perpetuation of the late Sir Currimbhoy Ibrahim's memory was handed over at the suggestion of His Excellency Sir Leslie Wilson by the Memorial Committee to the Sir Leslie Wilson Hospital Fund for the purpose of establishing a Dental College and Hospital for the poor to be named after the late philanthropist. To this, an extra sum of Rs. 9,000 was added by the Trustees of the late Sir Currimbhoy Ibrahim Knighthood Memorial Fund, so that a round sum of Rs. 1 lakh was given by the donors. To this, the Government contributed an equal sum. The suggestion of a Dental College and Hospital appealed to all the parties concerned. Dr. J. J. Modi, Professor of Dental Surgery in the Grant Medical College, had on previous occasions urged the necessity of such an institution in the city. The Memorial Tablet of the hospital was unveiled by His Excellency Sir Leslie Wilson on 28th February, 1928. It will be built on the first floor terrace of the new out-patient department of Sir J. J. Hospital and will be the first institution of its kind not only in Bombay but in India.

In the Dental College, it is proposed to give instruction for qualification in dental surgery which will rank equally with the registrable dental qualifications in the United Kingdom.

6. Introduction of the system of staffing the Hospitals with Medical men working in an honorary capacity.

One important development in the system of staffing the institution has been the appointment in increasing numbers of highly qualified medical men, belonging to the independent medical profession in the allied hospitals, who work in an honorary capacity. The system was introduced in 1923-24, and has worked satisfactorily.

There are at present six physicians, including one Professor of Medicine (who is an I.M.S. officer and is also Superintendent, Sir J. J. Hospital) one Professor of Materia Medica (who is also Physician to Sir J. J. Hospital), one Associate Professor of Medicine, and three Honorary Physicians. On the surgical side, there are five officers, including one Professor of Surgery, one Professor of Operative Surgery, one Associate Professor of Surgery, and two Honorary Surgeons. In Midwifery and Gynaecology there are two officers, including one Professor of Midwifery and Gynaecology (who is an I.M.S. officer and in charge of Bai Motlibai and Petit Hospitals), and one Associate Professor of Midwifery. A lady doctor is also on the staff of the Dwarakadas Lalloobhoy Dispensary at Bai Motlibai Hospital, where she is in charge of a separate Antenatal Clinic.

In addition to the changes enumerated above, I may also mention the following:—

An up-to-date Embryological Laboratory was opened in 1926. It is well equipped and in full working order as part of the Anatomy Department. Formerly, the teaching in Human Anatomy was mainly topographical, but since the new University Regulations came into force in 1923, Embryology forms an important part of this subject.

The subjects of physiology and hygiene were formerly taught by one professor. In 1926, this system was abolished. A new Professorship of Hygiene was created, so that now the two subjects are taught by two different teachers. This was a very desirable piece of reform.

In 1926, arrangements were made for clinical instruction in mental diseases at the Mental Hospital, Thana, and the medical officer in charge of that hospital was made ex-officio Professor of Mental Diseases in the College.

Apart from the excellent ward laboratories now existing, a well equipped central clinical laboratory is being provided in the J. J. Hospital, under the charge of a clinical pathologist.

The Military Medical Pupils' Class has been abolished in the college since 1923.

The college library has been reorganised and is being extended.

The portrait gallery in the main college building has been brought up-to-date and we now have the portraits of all the principals who were in charge of the college, commencing from Dr. Charles Morehead, the first Principal in 1845.

TABLE I.

Showing the in-patient (bed) accommodation at the J. J. Hospital, Bombay.

Year.	Beds Medical.	Beds Surgical.	Beds Diseases of Children.	Beds Venereal.	Beds Ear, Nose and Throat.	Beds Orthopaedics.	Beds Tuberculosis.	Beds other special departments.	Total.	REMARKS.

Dieting the Corpulent.

By W. F. CHRISTIE, M.D.

The Practitioner, May, 1928 p. 306.

ANOSITY of simple or exogenous origin takes years to develop, an increase in weight of a pound a month being an average rate of progress. Since fat comes from food, the plump person need only diet to stop it—the sooner the better. The modern craze for a slender figure, however much we may disapprove of its adoption by normally proportioned people, is a sound hygienic measure for the fat.

The effect of carrying a burden of dead weight, upstairs and down, wherever we go, is seen by each branch of the profession. The physician condemns the strain which is thrown on the heart and circulation, the liability to lung affection, the development of diabetes; the surgeon finds difficulty in obtaining access to anatomical structures and is disturbed by the frequency of herniæ, gall-stones, pancreatitis and ptosis in fat people; the orthopaedist finds the bones, joints, ligaments and muscles strained and painful; the gynaecologist and others see cases daily in which the symptoms are purely referable to the obese state. There seems every reason

to applaud, therefore, the stout woman who wishes to reduce her form, even although her primary motive should happen to be the improvement of her looks, or merely a desire to wear ready-made clothes.

The onus of correcting over-weight in the general public falls naturally upon the family practitioner. To him, more than to any other, is addressed the question: "What is the surest, quickest and safest way of losing weight?" The answer must be: "Through dieting alone can the fat man lose his burden, though systems of exercise, Bergonie chairs, baths, spas, pills and potions may assist the process." Now diets, like dress clothes, need to be fitted to the owner.

The wise dietitian will consult his patient's wishes and constitution before embarking on any particular method. No one would, of course, attempt to reduce in weight those who are suffering from a wasting disease, such as tuberculosis, diabetes or cancer. The mentally weak, the melancholic or the markedly neurasthenic are not, as a rule, suitable subjects for a reducing cure. If it is clear that the patient will be happier, healthier and fitter at a lighter weight, that person ought to be reduced.

By a rapid reduction diet we mean one which is capable of causing a greater loss of fat than two or three pounds a week. Slow reduction diets aim at producing a loss of one to two pounds a week over a long period. Each type has its merits and demerits which are instructive to review.

Diets which Reduce Rapidly.

Because fat is laid down very slowly, its rapid removal must be unphysiological. Wrinkling and bagginess of the skin is apt to occur as the tide of fat subsides, while some muscular and cardiac weakness is inevitable. The devotee of speed in the game of losing weight neither looks so well nor feels so fit as the man who takes it off more slowly; of equal importance perhaps is the fact that he learns very little of the fat-forming qualities of the various articles of food, and is just as likely as formerly to put on weight after he has lost it.

Long Fasts.—The disappearance of ten to twelve ounces of fat per day can be accomplished by a person of moderate activity if he eats nothing at all; a week's total abstinence from food, therefore, reduces the weight by five to six pounds. If the water intake is also limited, which it never should be, the weight falls more rapidly, but the difference is regained within a few days after the return to a normal diet.

Absolute fasts from food of not more than seven days' duration appear in practice to be safe enough for healthy people, although acidosis from the incomplete oxidation of fat usually appears on the third day.

For the purpose of fat reduction, total abstinence from protein food is quite unnecessary, and is not without danger to the unfit; for instance, a lady weighing 17 stones, who had suffered occasionally from auricular fibrillation, had a threatened attack of cardiac failure at the end of a four-day fast, due doubtless to muscular weakness.

Since the loss of permanent weight after seven days' fasting is only five or six pounds, some dietitians recommend a fourteen days *partial* fast. During the first week, the patient is confined to bed on a diet of water, albumen water, clear soup, weak tea with milk but no sugar, and orange juice; while from the third day a limited supply of protein is added.

During the second week, the patient is allowed up, although not fit for much exertion. Headache, nausea and dizziness are indications of acidosis which necessitate a sudden stop being put to the course. In this way, some nine or ten pounds of fat can be lost in return for an even more heroic effort than the first.

Short Fasts.—Commencing with a dose of calomel or a blue pill at night, followed by a Seidlitz powder in the morning, no solid food is allowed for three days, but water is taken *ad lib.*; thereafter, one of two procedures may be adopted:

(a) After a few days on a diet which gets rid of the acidosis, a second fast is instituted, which is again stopped on detection of acetone bodies; by alternate fasting and dieting, in accordance with the state of the urine, it will be found that the body acquires the power, in an increasing degree, of oxidizing the products of breaking down fat, with the result that each successive fast can be lengthened.

(b) The patient may be weaned on to a slow reduction diet. True, very little fat can be lost in three days, but the rest given to the organs of digestion promotes a sense of well-being which many stout people have not experienced for years.

Semi-starvation.—Ready-made semi-starvation diets rise and wane perennially. The "milk and potato cure" has an approximate caloric value of about 750, being two-thirds less than the maintenance diet of an average woman; because it contains vitamins A, B and C, it is thought to be healthier than others.

The period of dieting lasts 21 days, is said to be best adapted for use during the summer months, and a loss of eight to ten pounds in weight is expected. It is carried out on the following lines:—

On waking.—The juice of three oranges and one lemon.

Breakfast.—A cup of tea without sugar or milk, but with a slice of lemon if desired.

Two or three slices of thin brown bread.

Lunch.—Three small baked potatoes or one large one, into which place a pat of butter and add salt. One tall glass of cold, fresh milk.

Tea.—One to three cups of plain tea, as before.

Dinner.—Potatoes and milk, as at lunch.

For the week following the course, food must be recommenced gradually—eggs, spinach, chicken, etc., and so to a normal diet.

Other examples of the rapid method might be cited. For those who are in a hurry to become thin, who are sound in body and strong in purpose, who have less than a stone of surplus fat to unburden, the rapid method has its appeal. It must be carried out under close medical supervision, which, owing to the unflinching disapproval of the patient's relatives and friends, is best done outside the home.

Diets which Reduce Slowly.

The corpulent as a class love their meals, although they will often tell you that "really" they "eat nothing at all." The merits of fasting, however brilliant the advocate, are rarely appreciated, for the nightmare of hunger lurks ever in its background.

A slowly-reducing diet gives quite enough to eat, especially if food is thoroughly masticated. Moreover, it is safe; those who follow it feel unusually fit throughout the period of dieting. Its effects, too, are likely to be permanent; because a considerable latitude in the choice of food is permitted, the reducer takes an interest in and learns to avoid those items which are particularly fat-forming. Very seldom do weights go up afterwards.

A loss of one to two pounds of fat per week is aimed at. If this is maintained over a sufficiently long period, it will be obvious that any amount can be dissipated. In practice, one advises the patient to return for a month to a maintenance diet after the loss of 18 lb.; thereafter, the reducing diet is resumed.

For those who possess a working knowledge of food values, the construction of a scheme for each fat patient is an easy matter. The diet should contain a full ration of proteins, vitamins, mineral salts, roughage and water, but the fats and carbohydrates are reduced a thousand or more calories below the maintenance standard of the individual.

Instead of cream, butter, oil, cheese, animal fats, yolk of egg, sugar, articles made with flour, etc., the holes and corners of an empty stomach are filled with fresh fruits, green vegetables, fresh salads, clear soups, bovril and other items of low caloric content. The diet must not only be balanced and the calories counted, but the menus should be suited to the patient so that he may find them attractive as well as efficient.

The art of writing a dietetic prescription for diabetes, a mere penalty of obesity, is taught in the medical schools, while the primary ailment is apt to receive little attention. Ready-made diets for the reduction of corpulence are, therefore, given to all types of people living under various conditions; like garments off-the-peg, some suit while others do not.

This difficulty can be overcome to some extent by the use of a "skeleton diet," to which may be added as occasion demands one or more items from a graded list of food-stuffs. The skeleton contains most of those elements which are essential for the maintenance of health and the repair of tissue, but its fuel value is greatly curtailed; if, while living on it, the body burns more of its own fat than two pounds a week, the diet should be augmented from the supplementary list, one item at a time.

A skeleton diet (value about 1,200 calories). High protein, low carbohydrate and fat content. $\frac{1}{4}$ lb. bread, 1 oz. butter, 4 oz. milk is the total quantity of these articles permitted during the day.

On rising.—A tumblerful of hot water.

8 a.m.—Half a grape fruit; a breakfastcupful of tea or coffee with milk, but no sugar (use saccharine if necessary); one egg, or a small grilled kidney, or fish as at lunch; toast one thin slice; butter, a scrape.

11 a.m.—A tumblerful of cold water, or a cup of hot bovril; lemon squash made without sugar, or barley water.

Lunch.—Fish: an average helping of any white fish; boiled, baked or grilled; cod, sole, haddock, plaice, whiting, perch, skate, flounders, bass, smelts, halibut, half a lobster. Bread, wholemeal or standard, one slice. Butter, $\frac{1}{2}$ oz., or two small balls. Fruit—eat it raw; choose one of the following: an apple of average size; a teacupful of raspberries, blackberries, cherries or mulberries; a large banana; two average-sized peaches; one orange; two slices of pineapple; a small bunch of grapes; an average-sized pear.

4 p.m.—Tea, as before; toast, one thin slice dry.

Dinner.—Oysters, six (if desired). Clear soup—beef-tea, strained chicken or mutton broth. Meat—cut off all the fat and eat the lean. Must be grilled, boiled, or occasionally roasted. No rich gravy or thick

sauses are allowed, but clear gravy, mint sauce, horse-radish, ketchup may be taken; an average helping of sweetbreads, kidneys, tripe, brains, veal, beef, mutton chops, lamb cutlets, chicken, grouse, partridge, pheasant, pigeon, quail or turkey; the pork butcher's products, including ham, bacon and sausages, are forbidden. Vegetables—two kinds should be available. Take a large helping of cauliflower, cabbage, brussels sprouts, leeks, spinach, mushrooms, tomatoes; but avoid those which grow in pods or underground. A fresh salad of lettuce, cucumber, radish, tomato, made with vinegar, pepper, mustard and a little salt (no oil or egg). Bread, wholemeal or standard, one slice. Fruit, as before. Coffee—black, without sugar.

On retiring.—A tumblerful of hot water, with a little fresh lemon juice added.

Supplementary List of Foods.

The following have much the same fuel value, viz., between 70 and 80 calories:—

Eggs, one.
Butter, one ball (1½ oz.).
Bread, wholemeal, 1 slice (1 oz.).
Bread, white, ½ slice (1 oz.).
Sugar, 4 small lumps (2½ oz.).
One glass of skimmed milk.
Half a glass of fresh milk.
Half a lobster (3 oz.).
Fish, white (4 oz.).
Potato, one medium, boiled (3 oz.).
Peas, green, average help (3 oz.).
Beans, broad, average help (3 oz.).
Jam, 1 oz.

The Treatment of Nausea and certain related Circulatory Sensations.

By ROBERT W. KEETON, M.D.

and

ESTHER S. NELSON, M.D.

(*Jour. Amer. Med. Assn.* March 3, 1928, p. 683.)

IN this paper, the authors discuss the control of nausea and certain closely related sensations. These sensations are variously described by patients as dizziness, lightness of the head, pressure in the head and neck, mental numbness and headache. They often appear associated with nausea, but frequently exist independently. In fact, an observing patient, even when questioned carefully, may be unable to relate such sensations to nausea.

The direct relationship to vomiting, however, has been shown. In a previous study, vomiting was divided into two stages, one of regurgitation in which the bowel contents are returned to the stomach, and a second one, of emesis, in which the stomach is emptied. These stages are separate and distinct. Each develops its sensory and motor pattern, and each may exist with or without the other. Further evidence of the participation of the duodenum and intestines in vomiting has been presented recently by others.

Nausea was considered a sensation resulting from abnormal duodenal motor activity, most probably duodenal antiperistalsis. The related sensations were considered phenomena secondary to the duodenal antiperistalsis, and were conditioned on the reflex spread of the stimuli into the cardiovascular fields. They were regarded, therefore, as of circulatory origin, but no attempt was made to analyze the mechanism further. It is well established that duodenal regurgitation of chyme occurs normally and is considered by some authors important in reducing the gastric acidity of the interdigestive phase. When such a normal process exceeds a certain degree of vigour, it becomes pathologic. If, however, the receptive field is hypersensitive, then an antiperistaltic wave of normal vigour may function as a pathologic one and produce the sensation of nausea. If, on the other hand, the circulatory mechanism is abnormally unstable, as in the cases of

so-called vasomotor instability (hyperthyroidism, menopause, dysmenorrhea, migraine and similar conditions) then a given antiperistaltic wave may induce circulatory sensations and the patient will complain of dizziness or other related sensations. From such reasoning it can be seen that a patient may experience, without nausea, any one of the related sensations.

In treating nausea and the related circulatory sensations (dizziness, lightness of head, pressure in the head and neck, mental numbness, frank headache), duodenal dysfunction (antiperistalsis) must be reduced quantitatively or changed into peristalsis.

To accomplish this, the reflexes involved must first be disorganized or separated from their central connections. Then a mild cathartic will re-establish peristalsis.

For this purpose they advocate the use of the bromide ion, and suggest the administration of a powder consisting of 15 grains each of sodium bromide, sodium bicarbonate and sodium phosphate.

Parathyroid Therapy.

(*From the Prescriber*, May, 1928, p. 165.)

THE work of Collip has placed parathyroid therapy on a rational basis, with the result that the literature now presents reports which add to the knowledge of the action of the parathyroid hormone. The effect of parathyroid hormone (Collip's extract) on the calcium balance has been studied by Hoag and co-workers (New York). Seven infants were observed: one normal, four rachitic, and two with infantile tetany. One normal infant and three of the rachitic infants showed distinct diminution of calcium retention while the extract was administered. One rachitic infant gave no evidence of either calcium removal or calcium deposition in the radius and ulna. Two patients with infantile tetany showed a slight tendency towards retention of calcium during the periods of parathyroid treatment. One rachitic patient with striking signs of disturbed calcium metabolism showed noticeable increase in retention of calcium. In these cases, the concentration of the serum-calcium was initially low and was not markedly raised by the extract, never reaching normal levels.

Tetany.—Leitch (Edmonton, Alberta) reports on the use of parathyroid hormone in eight cases of infantile tetany. The hormone was given subcutaneously at daily intervals. Four injections as a rule sufficed to cause cessation of symptoms, although the serum-calcium had not quite reached normal by that time.

Noehren (Buffalo) reports the case of a nurse who developed parathyroid tetany after an operation for thyroidectomy. Collip's parathyroid hormone was given hypodermically starting with 1 c.c. daily for a few days, then 0.5 c.c. daily. The symptoms rapidly disappeared. No record was taken of the blood-calcium content during her illness, but after the symptoms had gone this stood at 7.2 mg. per 100 c.c.—still somewhat below normal.

Hjort and Eder report on a case of adult tetany following thyroidectomy (strumipriva tetany) in which parathyroid hormone alone, up to 130 units daily, had practically no effect on the condition until the treatment was supplemented by oral thyroid therapy. Incidentally they remark that large doses (3 gm. daily) of desiccated parathyroid substance failed to influence the serum-calcium, even when thyroid was administered in conjunction with it.

Oedema.—Several cases have been recorded in which oedema disappeared under treatment with parathyroid hormone (*see Davidson: Prescriber*, 1926 May, 191; Mason: *ibid.*, 1927, May, 183). McCann (Rochester, U.S.A.) now reports its use in three cases of generalized oedema associated with severe disturbance of renal function. In all three the total serum-protein was rather low. The first case was apparently one of acute nephritis with no evidence of hypocalcemia. A very small dose (10 units or 0.5 c.c.) of parathyroid hormone initiated a diuresis which continued until the oedema was almost entirely gone and

persisted long after the transient elevation of the blood-calcium. The second and third patient had generalized oedema with hypocalcemia, but no evidences of tetany. In each of these cases diuresis was initiated by parathyroid hormone, and lasted for several days after a transient increase in the blood-calcium. McCann offers no explanation of this action, which does not appear to take place in non-oedematous subjects, and suggests that the question should receive further study.

Epilepsy.—Madsen is of opinion, as the result of treatment of five cases, that parathyroid hormone has a regulating effect on the ammonia metabolism of epileptics; in some cases, it is necessary to combine the treatment with calcium therapy. Calcium alone is not capable of producing this effect. Improvement in the patient's clinical condition was so noticeable that the benefits can hardly be ascribed to accident. In three of the five cases there was marked reduction in the number of attacks as well as improvement in the physical condition. These effects, however, are not proof that epilepsy is characterized by parathyroid insufficiency.

Hæmorrhage.—The property possessed by parathyroid hormone of raising the blood-calcium level has been taken advantage of in the control of bleeding. Allen, Compere and Austin noted that the hypercalcemia induced by parathyroid was accompanied by increased viscosity of the blood; and that bleeding even from large vessels stopped very quickly. They tried parathyroid hormone in three cases of prolonged menstrual bleeding, the patients selected being idiopathic bleeders. They found that in all cases the bleeding time and clotting time were definitely shortened, the number of days of menstrual bleeding and the amount of blood lost were appreciably reduced, and during the intermenstrual period the patients were not so reduced in strength and vitality. They think it possible that the hormone may act by ionizing the calcium, or in some way activating it so as to hasten the formation of clot.

Gordon and Cantarow (Philadelphia) used parathyroid extract (Collip) as a means for controlling hæmorrhage from various causes, such as pulmonary, gastro-intestinal, and genito-urinary bleeding, and operative incisions, also in jaundice and other conditions in which the clotting time of the blood was prolonged. The total number of patients with hæmorrhage was 347, and cessation occurred in 304, following one or more transient increases in blood-calcium. The best results followed the injection of from 10 to 15 units every 36 hours for one to three doses. As a pre-operative measure in jaundice it reduced the coagulation time to within normal limits and apparently prevented hæmorrhage. Unfavourable results occurred when overdosage and prolonged administration were employed, also in blood dyscrasia (puerperal hæmorrhage and hæmorrhagic disease of the new-born) irrespective of the size and number of doses, apparently because of certain local changes in the tissues.

Jaundice.—It being evident that the increased amount of bile pigments in the blood and tissues in jaundice results in a functional deficiency of calcium, Cantarow, Dodek and Gordon investigated the response to parathyroid hormone. Fourteen cases were selected; one was hæmolytic in type, three were due to arsenobenzene, and ten were of an obstructive nature. The serum-calcium values varied from 9.3 to 12 mg. per 100 c.c., but the calcium content of the whole blood showed a much greater variation 4.8 to 12 mg. per 100 c.c. Twelve hours after the administration of parathyroid hormone, the variation in the whole blood calcium of jaundiced and non-jaundiced patients was practically identical.

Zimmermann (Chicago), on the other hand, states that elevation of the blood-calcium by injection of parathyroid hormone did not have a constant effect on the coagulation time of the blood in normal or icteric patients, or in animals. He observed no demonstrable changes in the serum-calcium level as a result of common bile-duct obstruction, but a regular delay in coagulation time was seen in such cases. Injection of parathyroid hormone effected no clinical improvement

in the condition of icteric subjects, and he concludes that to increase the calcium concentration of the blood does not have any effect in diminishing the coagulation time, either in the presence or in the absence of jaundice.

Fractures.—In view of the findings of Stewart and Percival that parathyroid hormone increases the serum-calcium by drawing that element from the tissues, and probably also from the bones, it is unlikely that the administration of parathyroid substance would have any effect in the healing of fractures. French (Herrin, Ill.), however, claims that it has this effect, and reports two cases. He himself was struck by a car in the street, sustaining a fracture of both bones of the left leg below the knee, and was taken to hospital. While there he took desiccated parathyroid substance, 1/10 grain, three times a day. In eight weeks his leg was sufficiently healed to allow him to leave the hospital. His argument is that as he was 85 years of age the fracture would have taken six months to heal without parathyroid. He cites also the case of a lady of 87 who sustained a compound fracture of the thigh. Under the same treatment, the fracture healed in six weeks. In neither case is the argument in favour of parathyroid therapy very convincing.

On the other hand, Lehman and Cole (St. Louis) show pretty clearly that parathyroid has no effect in hastening the calcification of fracture callus. A series of carefully controlled experiments on animals with parathyroid extract demonstrated beyond doubt that so far from hastening the calcification of fracture callus, injection of parathyroid hormone rather tends to delay the process. This is only what might have been expected.

Dangers.—Hueper (Chicago) calls attention to some possible untoward effects of overdosage with parathyroid hormone. These include metastatic calcifications in various organs, notably the thyroid gland, lungs, heart muscle, stomach, duodenum and kidneys, the most marked effects being on the kidneys. Renal function is impaired by the gradual calcification of the tubular epithelial cells, the formation of calcium casts in the lumens of the tubules inducing retention of various components in the blood, with consequent deleterious effects to the organism. An increase of the blood-calcium to 10 to 15 mg. per 100 c.c. may be produced for some time without much risk, but a greater elevation will soon cause dangerous symptoms of the circulatory system, stomach and kidneys.

Dosage.—Parathyroid extract containing the active hormone as devised by Collip, known as "parathormone," "paracalcin," etc.—is standardized so that 100 units will increase the blood-calcium of a 20 kg. dog by 5 mg. in 15 hours. One cubic centimetre of the extract is equivalent to 20 units. In cases of true tetany, 20 to 30 units may be administered; in severe cases, this dose may be repeated if necessary twice or three times within the first 24 hours, the dosage being then diminished as indicated by the condition of the patient. In chronic cases, doses ranging from 10 to 25 units are sufficient to prevent recurrence of tetany.

The method of standardization originally proposed by Collip is based on the production of hypercalcemia in normal dogs. Hanson (Faribault, Minn.) recommends the use of parathyroidectomized dogs, which show abnormally low serum-calcium, the condition being restored to normal by administration of an active extract. Such animals show, 24 hours after operation, a drop of approximately 30 per cent. in the serum-calcium, without severe symptoms of tetany. An amount of extract is then administered that will increase the calcium level by 3 mg. in six hours—practically the normal level. His clinical unit is one-hundredth the amount required to produce a rise of 1 mg. under these conditions. His unit is thus much smaller—about 60 per c.c.—and his dose of 30 to 60 units, he claims, avoids the danger of hypercalcemia already referred to.

The employment of a "crystalline extract" soluble in water is described by Berman. This is prepared by extraction with acidified alcohol, removal of lipins and

proteins, and subsequent concentration. Dissolved in Ringer's solution and injected into the circulation, this substance has the property of definitely raising the calcium content of the blood, and at the same time reducing the electrical irritability of the nerves. Berman employs this action on the ulnar nerves as a means of estimating the strength of the preparation, in preference to determination of the serum-calcium. Injection of this crystalline substance (in solution) obviates the undesirable effects of parenteral protein introduction. Berman discusses the question of the effectiveness of parathyroid administered by the mouth, and quotes Hjort and Eder (*see above*), suggesting that the mode of preparation of the desiccated substance may have much to do with its efficacy or otherwise. He thinks that in the milder forms of parathyroid insufficiency, parathyroid by the mouth may be worth using.

Reviews.

MODERN MEDICINE: ITS THEORY AND PRACTICE.—By Sir William Osler, Bart., M.D., F.R.S. and Thomas McCrae, M.D., F.R.C.P. (Lond.). Vol. VI. Third Edition. London: Henry Kimpton, 1928. Pp. 964. Illustrated. Complete in six volumes. Sold in sets only. Price, £12-12 per set.

THIS is the sixth and last volume of this world-famous system of medicine. The first part deals with diseases of the nervous system and the second part with disease and abnormalities of the mind. Part I consists of nearly 900 pages; it is divided into 24 chapters, each of which is written by a specialist on the subject. Most of the contributors are American; there are four British contributors and one from McGill University. The whole subject of disease and abnormalities of the mind is dismissed by one contributor in 44 pages. This apparently unfair division at first surprised the reviewer. Presumably, the editor felt that the subject was too much that of the specialist to be given more space in a book of this nature. To the alienist, one can conceive, this chapter would not be of much assistance but to the student of general medicine the short but clear account of the various mental states given in this chapter is very helpful. General paralysis of the insane is dealt with in the first part of this volume under the heading of "Syphilitic diseases of the central nervous system"; the chapter is written by Dr. Sachs, whose name is so familiar, mainly in connection with the serum test for syphilis with which it is associated. It is rather surprising that he does not give more details of the malaria treatment about which he admits that he is enthusiastic. The only method of producing infection which is mentioned is by intravenous injection of the blood of a person suffering from malaria. The question of the species of plasmodium which should be employed is not discussed, nor is there any mention of the transmission of the disease by means of infected mosquitoes.

It is not possible to discuss the individual contributions to this famous "system." The reviewer has not had time to do more than glance through many of the chapters. They all appear to be well written, usually in excellent English; the printing, paper and binding are good; the book is expensive, but it is well worth the money.

L. E. N.

ACUTE APLASTIC ANÆMIA: ITS RELATION TO A LIVER HORMONE.—By A. Hayes Smith. London: H. K. Lewis & Co., Ltd., 1928. Pp. viii plus 80, with 3 illustrations. Price, 6s. net.

DR. HAYES SMITH's monograph is based on a single case of acute aplastic anemia. The author has given minute details of the case in the form of a day-to-day diary along with exhaustive pathological notes by Dr. C. J. Young, which must have entailed a considerable amount of labour and perseverance.

The consensus of present day opinion is that the Minot-Murphy treatment in cases of this kind by the oral administration of liver, either as a whole or in the form of a suitable extract, produces remarkably beneficial results. Nearly all the cases treated by this method seem to have responded kindly and readily to this treatment and few cases have relapsed. One of the immediate effects of giving liver extracts in these cases is a great increase of the reticulated red cells in the circulation.

The whole history of the case, the intelligent method of differential diagnosis supported by detailed laboratory evidence and the discussion on treatment form an instructive and interesting study.

In the opinion of the author, the present conception regarding the function of the bone marrow as an independent organ is erroneous. He holds that the bone marrow is a subsidiary organ dependent for the exercise of its function on a powerful hormone produced by the liver which helps to keep it in a state of functional tone, the deficiency or absence of this hormone being due to some toxin or "noxa" producing aplasia or death of the marrow.

The *modus operandi* of the treatment of cases of this nature by liver feeding, according to the author is explained by the "replacement" theory and is analogous to the treatment of myxœdema by thyroid medication.

J. P. B.

TUBERCULOUS INTOXICATIONS.—By Joseph Hollos, M.D. Edinburgh: E. & S. Livingstone, 1928. Pp. 132 plus ix. Price, Rs. 7-14.

THE main thesis of this work is that a large number of very diverse affections including neurasthenia, rheumatism, thyrotoxicosis and psoriasis are essentially of tuberculous origin. For the maintenance of this view, it is necessary to postulate two kinds of acquired immunity in tuberculosis—*antitoxic* and *lytic*. The former is demonstrable in those suffering from progressive tuberculosis, while the latter type is characteristic of cases showing hypersensitiveness to tuberculous infection without evidence of spreading disease.

The disturbances arising from this so-called "tuberculous intoxication" are in part due to a direct action on different organs; the greater number, however, result indirectly from the action of the tuberculous toxin on various endocrine glands. Treatment of these cases may, therefore, be either symptomatic or ætiologic: the former line of attack consists in supplying the deficient hormone or hormones while the latter aims at eradicating the tuberculous focus which is at bottom responsible for all the signs and symptoms. Specific or ætiologic therapy finds its chief application in the use of the immune blood treatment first discovered and described by Carl Spengler in 1908.

A large portion of the work is taken up with case histories illustrative of different arguments brought forward by the author in support of his main contention. The originality and boldness of Dr. Hollós' work make his book interesting reading. Whether his views will ultimately be accepted seems doubtful: it may be noted that it is now 20 years since Spengler's discovery. Even if one makes allowances for the disturbances incidental to the war period and for the traditional unreceptiveness of the medical profession, we still think that the treatment, if as successful as its protagonists claim, would be in more general use.

The printing and binding of the book are excellent and there is a good index.

J. M. H.

THE CLINICAL EXAMINATION OF THE LUNGS.—By E. M. Brockbank, M.D. (Vict.), F.R.C.P., and Albert Ramsbottom, M.D. (Vict.), F.R.C.P. Second Edition. London: H. K. Lewis and Co., Ltd., 1928. Pp. 112 plus viii, with 35 illustrations including 4 plates. Price, 5s. net.

THIS small book is intended to place before the student the salient facts in the routine examination of the lungs both in health and disease. The subject is treated on conventional lines and only the methods of

examination likely to be of real value to the reader are included. The book is adequate so far as it goes but under the heading of "Inspection" a description of Litten's "diaphragm phenomenon" might usefully have been given. In our experience, the mapping out of Kröning's lines demands a degree of clinical skill not possessed by the ordinary student.

A certain number of errors have crept in and it is hoped that these will be eliminated in future editions. On page 3; "Cartilage" should be "Cartilage"; on page 9; line 27, "of the" should be inserted after the words "Central portion" while on page 10, "diaphragm" lacks an "a." On page 6, the hypercritical might object to the use of the word "decently" with reference to chest expansion, but the point is a small one. The statement on page 43 that "the respiration rate is increased proportionately to the pulse rate in any febrile condition according to its severity" is open to criticism.

The four X-ray plates are excellent and there is a good index.

J. M. H.

NUTRITION AND DIET IN HEALTH AND DISEASE.—

By James S. McLester, M.D. Philadelphia and London: W. B. Saunders Company, 1927. Pp. 783. Price, Cloth, 86s. net.

IN this book, the learned author has ably dealt with the subject of nutrition and diet in health and disease in all its important bearings and in its various aspects, chemical, physical, physiological, pathological and economic. The book is a mine of carefully collected and well arranged information which, we are sure, will be found interesting and profitable reading by all students of food and dietetics. References to literature on the subject are most generous and would prove very helpful to a further and advanced study of the subject. The chapter dealing with "the nutritional factors of fundamental importance" contains a very interesting and critical review of our up-to-date knowledge in the matter of digestion, absorption and utilisation of the various nutritive principles of food. The question whether the animal organism is capable of utilising inorganic compounds of metals and non-metals, such as sodium, potassium, iron, calcium, phosphorus, iodine, etc., has been the subject of much interesting controversy. The author has ably discussed this subject, and by references to a large number of successful experiments carried out by numerous reliable investigators, has come to the conclusion, that inorganic substances can be utilised in the system, whether they are presented as such or in some inorganic combination.

We are in full agreement with the author in his estimate of the quantity of protein daily required by a healthy individual engaged in ordinary work. The author has fully discussed the subject and after giving due consideration to the opinions and observations of the two opposing schools (the German school headed by Voit and others, and the American school headed by Chittenden) has come to the conclusion that the estimate of the German school is approximately correct and that "to enjoy sustained vigour and to experience his normal expectancy, man must eat a liberal quantity of good protein. By liberal is meant an amount in excess of his theoretic needs, such an amount as the race, in its long experience, has instinctively chosen—say, 100 grammes daily, more or less. By good is meant proteins or protein mixtures which are of high biologic value, in which the proteins of meat or milk, preferably of both, find first place." We may incidentally mention here that the investigation into the diet of some of the races living in India conducted by McCay, MacCarrison and others strongly supports the author's conclusion as to the importance of a liberal supply of good protein in the daily diet for the maintenance of health, strength, and resisting power to infection. One of the causes of the poor health of the people of certain provinces in India, is, in our opinion, chronic protein starvation.

Much useful information as regards the proper selection of diet in various diseases (such as diabetes, gout, deficiency diseases, diseases of the kidney and of the

digestive organs, enteric fever, tuberculosis, etc.) is to be found in the portion of the book devoted to the consideration of diet in disease. Some of the old time and ill-founded notions on the subject have been successfully combated and the evils of a starvation diet in enteric fever have been prominently shown by the author. A good case for the liberal administration of milk in combination with food articles of high caloric value, such as butter, cream, eggs and cereals has been made out by the author in the treatment of typhoid fever. The chapters on diet in disease will amply repay perusal.

The book is a valuable contribution to our up-to-date knowledge of diet and nutrition and should find a place in the library of every student of medicine.

J. P. B.

DIAGNOSIS AND TREATMENT OF DISEASES OF THE STOMACH: WITH AN INTRODUCTION TO PRACTICAL GASTRO-ENTEROLOGY.—By Martin E. Rehfuess, M.D. Philadelphia and London: W. B. Saunders Company, 1927. Pp. 1236, with 519 illustrations, some in colours. Price, Cloth, 55s. net.

THE author says that he has written this book in the manner in which the subject appeals to him. He has certainly produced a very practical volume which will be a valuable addition to every medical library, and especially useful to the increasing number of Indian doctors who are taking an interest in diseases of the stomach. The word gastro-enterology does not come easily to us, but the subject as presented by Professor Rehfuess is very fascinating and his method has resulted in one of the most readable medical books we have perused for some time.

The approach to the study of gastric disease, Chapter II, explains the multitude of ways in which gastric disturbances can occur, and stresses their relation to diseases of other organs. We are reminded of the intimate functional association and close correlation of different segments of the digestive tract and of the influence of the ingestion of irritants or the effects of other substances acting indirectly through the nerve supply, vascular channels, or by elimination (morphia, emetine, etc.). Toxins, infections (e.g., influenza), infectious disease may so alter the irritability of the gastric musculature, suppress its secretions, or damage its mucous membrane that the causative lesion may be overlooked, and the possibility of disease in another part of the body or of a constitutional condition such as phthisis not considered. This theme is elaborated in Part III, where the relation of the stomach to diseases of the œsophagus, liver, gall bladder, pancreas, intestines and nervous system is discussed.

The earlier chapters contain a very full and complete account of the anatomy, embryology and physiology of the stomach, of physical examination and of gastric technique. The author's conviction that the well-trained gastro-enterologist should be able to carry out every investigation and procedure himself should be comparatively easy with his graphic and well-illustrated descriptions of modern technique. The chapters on the gastro-enterological laboratory, chemical technique and gastric analysis will be invaluable to the clinical pathologist, while that on X-ray examination is equally satisfying. Too often the reading of a negative, the most important part of X-ray work, is left to the radiologist and we agree that it is the clinician, trained by experience in interpretation, and fortified by information from a number of different sources, who is generally best able to reach conclusions. A series of radiographs, which must be taken in every plane, if an ulcer is insisted upon; and one realises the futility of the one or two exposures which are often expected to satisfy the demand for a radiological examination of the stomach. The value of fluoroscopy, not used nearly enough in our own clinics, and the facility obtained in interpretation by constant study and incessant practice is well demonstrated. Careful preparation with belladonna or atropine over some days is

advocated and will frequently "iron out" spastic phenomena, the presence of which may make a correct interpretation difficult or impossible.

Part II is concerned with organic diseases of the stomach and the discussion on the aetiology of ulcer is one of the most interesting we have read. Rogers' Indian statistics are quoted to support a claim that vegetarians are almost free from these conditions, but work in South India has shown that this is not correct and suggests that the universality of the disease is influenced by the poorly balanced diets of the people. The author's observations lead him to the following important indications for treatment:—(1) "To get rid of anything likely to induce acute ulceration, focal infection of whatever kind, toxins of every variety and description, and foods which are irritating or difficult to digest (2) To remove the factors producing chronicity, namely, free acidity, spasm, and retention, and toxæmias of every kind which might induce ulcer chronicity." Elaboration of these principles supported by experimental and clinical evidence gives the reader a very clear insight to the theory and practice of ulcer treatment. Every modern system is fully described. Indications for surgical interference are clearly stated and we could only add one, namely, the economic position of the patient, a very important factor with Indians and which calls for an earlier resort to surgery than is general in Europe. Evidence is quoted which suggests that malignant degeneration of an ulcer occurs more commonly than we supposed, though from our own experience we believe that cancer and perforation are both rare conditions in Southern India. Every teacher will agree that our students have been taught the regular text-book description of gastric carcinoma, and that almost every symptom in it is a death warrant to the patient. A latent period is said to last from four to eight months and is usually the vital period for diagnosis. The author calls for an expansion of the regular diagnostic surveys, such as life insurance institutions are practising, and demands a complete X-ray examination of the stomach and digestive tract, a method which he believes will reveal the evidence of a lesion in 96 per cent. of all cases. "In other words, not only is the public to be educated to the necessity of routine complete examination during the cancer age, but the physician must be educated to a knowledge of early and not late carcinoma." Space is found for a discussion of the work of Gye and Barnard in relation to gastric cancer.

In Part III, excellent descriptions are given of gastric crisis, the effects of diseases of the nervous system, while Dr. I. B. Deaver contributes a very clear account of the surgery of the stomach. A busy practitioner will consult with profit the concluding chapters. Under medical treatment notes on useful preparations, formulae and methods of value to the gastro-enterologist are given. Under dietary considerations the action of various foodstuffs and beverages on the stomach is fully discussed, and the final chapter contains useful diet and instruction charts. The research worker will find a full bibliography at the end of all important chapters, and stimulation to further investigation of these diseases in India in nearly every page.

GYNÆCOLOGY.—By Howard A. Kelly, A.B., M.D., LL.D., and Collaborators. New York and London: D. Appleton & Co., 1928. Pp. 1044, with 767 illustrations and 16 coloured plates. Price, Rs. 37-8 net. Obtainable from Butterworth and Co., Calcutta.

In the autumn of his life, Howard Kelly, the father of modern gynæcology, has produced this monumental volume in collaboration with the younger generation of American gynæcologists. Mere praise is not sufficient, for anyone who has a conception of the task of producing a book, will appreciate the time and energy expended by an author nearing the biblical age limit. Verily we can say, *Si monumentum requiris, circumspice*. For 18 of the 49 chapters are by Howard Kelly himself, written with that charm and balance of thought, which

has distinguished every production from Baltimore during the last 30 years.

For many years to come, this book will be a standard one, not merely because of the fame of its author, but for its illustrations, wealth of detail and pathological sanity; moreover, each section has the cachet of being written by a recognised expert, who not only gives his own views, but summarises the historical side of the outlook.

This book is not one for students, but for the post-graduate or interne, who is endeavouring after an extended course of anatomy, post-mortem and pathological work to become a specialist in gynæcology.

Among the younger generation, it is a common idea that knowledge of books rather than that of the dead house and its pathological aspects, is sufficient for him to call himself a specialist. To America, and especially to Johns Hopkins Hospital, we owe a debt of gratitude, for their insistence on advanced anatomy and pathology as part of the curriculum before any post-graduate comes on the interne specialist staff. The proof of this most excellent system is here before us in this book, and it would be a good day for India when every university in Great Britain made it a rule that before graduates of Indian Universities sought the cachet of a higher qualification, a certificate was necessary that a specialist revival course in pathology, anatomy, physiology and perhaps bio-chemistry had been undertaken, for then theory and practice would go hand in hand, and the qualifications mean something more than so many letters after a name.

Howard Kelly and the school he so nobly represents, was the pioneer of this idea, and in choosing his collaborators, this fact is pre-eminent. The whole field of clinical and pathological findings is wonderfully depicted and there is no method of investigation and treatment omitted, including protein therapy, radium, pneumoperitoneal roentgenography, ultra-violet radiation, psychiatry, etc.

In a book so extraordinarily well produced, it is difficult to pick out one chapter that is better than any other, but if the reviewer was asked which was the best, or which the one that gave most pleasure, he would say the chapter on the general principles of abdominal surgery written by Howard Kelly himself, 37 pages of great experience and wisdom.

Shadows are passing across the sun, but it can be no mean pleasure to the revered author of this book, to feel that wherever the English language is spoken and higher gynæcology is practised, his name and principles will continue to inspire the younger generation of gynæcologists.

V. B. G.-A.

THE PRINCIPLES AND PRACTICE OF OBSTETRICS.

—By Joseph B. De Lee, A.M., M.D. Fifth Edition. Philadelphia and London: W. B. Saunders Company, 1928. Pp. 1140, with 1128 illustrations on 923 figures, 201 of them in colours. Price, 55s. net.

THE name of Joseph De Lee as a master of obstetrics is too well known to need introduction, and the reviewer has no hesitation in saying that this fifth edition, the outcome of team work in the Chicago Maternity Hospital, is a splendid piece of work, for it bears the imprint of the clinician rather than the theoretician.

The population of Chicago is polyglot, and it is interesting to see and read of conditions in this great lying-in hospital, which are to be found almost any day of the week in Calcutta. It is difficult for the clinical obstetrician to say anything new about the fundamental art of his specialty, but Dr. De Lee not only says things in a new way, but takes care to rub in his point by most excellent illustrations, for instance, measuring the outlet, illustrating puerperal abdominal exercises, and his most excellent method of Cesarean section.

There are altogether in 1140 pages, 1128 illustrations, so that for the student, although the print is small, the reading matter is easy to follow.

It is interesting to note that the author has very little first hand knowledge of osteomalacia, having seen only

one case, and that an imported one, moreover, it would appear that the funnel-shaped pelvis is rare in Chicago. Both these facts tend to corroborate the reviewer's hypothesis that the funnel-shaped pelvis and osteomalacia are closely related to food errors in childhood or at puberty, for in America as is well known, the benefits of a proper dietary and sunlight have been long recognised.

It would be invidious to pick out any one portion of this most excellent clinical book, but if one may say so, the feature that strikes one most is the conservatism of the author, which is all to the good in its way, but it must be remembered that exceptional circumstances demand exceptional treatment. For instance, Dr. De Lee seems timid or lukewarm in his adoption or recommendation of Cæsarean section for placenta prævia, extended breech presentation, prolapse of the cord, post-maturity, and elderly primiparity: nor does the text indicate that the author himself has done the operation for any of these conditions.

Naturally, the reviewer turns to the portion of the book which deals with that type of Cæsarean section for which the author's name is exalted by all obstetricians in the East, namely, the low cervical method, for this is the ideal operation in India, considering that two-thirds of the patients that are seen with absolute indications for Cæsarean section arrive in hospital after multiple examinations and early rupture of the bag of membranes.

In Chicago, out of 620 operations only six died, and the reviewer's experience of a great many cases which in former days would have been treated by craniotomy, or hysterectomy is the same. He has no hesitation in reiterating that once the technique of this operation is mastered, all obstetricians in the East will agree that it is the ideal operation for the late cases seen in the East with the fœtus alive, and particularly in osteomalacia.

There is only one criticism the reviewer would make of the illustrated pages in the text of this book, and that is, that Dr. De Lee has not seen fit to mention a small but still a very great improvement in his operation, namely, the modification of Dr. Hendry of the Glasgow Maternity Hospital who first advocated that the incision in the lower uterine segment should be curved transversely, with its convexity downwards. This method of incision makes the emergence of the fœtus easier, the suturing easier and greatly diminishes the risk of injury to the bladder, or tearing of the uterus into the vaginal portion of the cervix or upper uterine segment.

Having done a great number of these operations according to the method of Dr. De Lee and also that of Dr. Hendry, the reviewer has no hesitation in earnestly recommending the important modification abovementioned.

There is just one little point in the text and technique which is new to the reviewer and which he intends to follow in the future, namely, to inject $\frac{1}{2}$ to 1 c.c. of pituitrin into a vein the instant the head is delivered, for although not common, on two or three occasions, the bleeding for a few moments has been somewhat alarming.

This is a book that should be on the shelf of every practising obstetrician from a teaching and reference point of view.

V. B. G.-A.

FIRST AID IN CHILD-BIRTH.—By Hon. Dr. U. Rama Rau. Published by Sri Krishna Bros., Madras, 1928. Pp. 79. Price, As. 4.

Dr. RAU is to be congratulated for the public spirit and enthusiasm he has shown in bringing out this little volume for the aid of mothers and midwives in rural India.

India is awakening to the fact that countless lives are sacrificed from ignorance of the first principles of child-birth, and one feels that if charitable bodies, municipalities and local governments would stir in the matter, the present apparent apathy would disappear, for there is no question that with the growth of education, the great public of India will demand a greater knowledge of obstetrics than it has at present.

Dr. Rau has quixotically entered the arena and has rendered in a small way and by a small beginning what may be a great service. He has put the proposition simply and without prejudice, and he tells us that this little book is to be translated into all the vernaculars in the Madras Presidency. It cannot help being of service to the expectant mother, and just as after the war in Europe, the general public began to grasp the importance of sterilization and surgery, so in like manner if this book, or others of its kind, is in the hands or at the disposal of the public, the effect will be not only to lessen infantile and maternal mortality, but equally important from an educational point of view, to raise the standard of knowledge, training, and equipment of all those who may be called to attend an expectant mother, either before or in labour.

V. B. G.-A.

A TEXT-BOOK OF ACTINO-THERAPY: WITH SPECIAL REFERENCE TO ULTRA-VIOLET RADIATION.—By D. D. Rosewarno, M.R.C.S. (Eng.), L.R.C.P. (Lond.). London: Henry Kimpton, 1927. Pp. viii plus 237, with 20 illustrations including one coloured plate. Price, 9s. net.

So many works have been written on this subject that one is inclined at first sight to look askance at any new publication. The present book under review, however, has points of its own to recommend it. In the first place, it has been written from the point of view of the student and general practitioner, and consequently, the language is simple and unaffected. Another point in which it differs from all other publications is in the omission of elaborate descriptions of apparatus. The main principles of the different types of lamps and arcs and radiators are concisely explained and the rest left to trade publications.

Another interesting point is the author's advocacy of the direct skin test. He asserts it to be the only reliable clinical guide and that it cannot be replaced by any other method.

An interesting feature is the chapter on auto-intoxication, for which the author lays stress on combined treatment. As he puts it, "Actino-therapy is not a cure for all human ills."

Here we have a book written from an entirely disinterested point of view, thoroughly up-to-date, and deserving of the highest commendation.

MENTAL DISORDERS: A HANDBOOK FOR STUDENTS AND PRACTITIONERS.—By Hubert J. Norman, M.B., Ch.B. (Edn.), D.P.H. (Edn. & Glas.). Edinburgh: E. & S. Livingstone, 1928. Pp. 463, with 57 illustrations. Price, Rs. 10-8. Available from Messrs. Butterworth & Co. (India), Ltd., Calcutta.

BEYOND affording the reader some idea of what the author imagines a text-book should be, this publication does not appear to be likely to serve any very useful purpose for it contains nothing new and a great deal that is very old. Dr. Norman thinks that most people who read text-books on mental diseases, "skip lightly over" any portion of the book which deals with psychology in order to get as quickly as possible to that which deals with psychopathology. For this reason, the book opens with a chapter labelled "Insanity and Conduct" and whatever there is of psychology comes much later. Indeed, one of the features of this book is its way of springing surprises on the reader through its utter lack of arrangement. For example, after 106 pages devoted to a discussion of some of the major psychoses, we reach a chapter entitled "Borderland." This is followed by a chapter on "Mental Deficiency" and then, (Shade of Charcot!), "Hysteria" leaps into view. Some idea of the archaic views of the author can best be illustrated by a reference to his discussion of what he terms the neurasthenic-neuropathic disorders. Under this heading he classes neurasthenia and psychasthenia. In discussing the differential diagnosis of neurasthenia, he states that it is to be diagnosed from, among other conditions, psychoses. He omits entirely to note from which particular psychosis, an omission

which is very unfortunate as one of the commonest errors of the general practitioner is to diagnose neurasthenia in early cases of dementia præcox. The author's treatment of psychasthenia leaves even more to be desired, for he applies his term to a variety of neuroses which have no relation to the condition which Janet first called psychasthenia. For example, he lumps together the hysterical phobias and all obsessional states as varieties of psychasthenia. And so the book goes bouncing on from one topic to another, until the reader, faint yet pursuing, gets a chance to regain his wind with a so-called "Historical Survey." Dr. Norman holds some rather exotic views on instincts and their perversions besides labouring under the misapprehension that the term "sadism" is derived from the name of Sacher-Masoch because he "first described it!" Having delivered himself of this piece of fiction, the author performs yet another somersault and lands into a dissertation on morbid anatomy. Then follows a chapter on treatment, after which the reader is invited to take a dive into a whirlpool of legal technicalities. But the end is now in sight, so that, after wading through the shallows of two appendices, the reader finds himself once more on comparative *terra firma* in the form of a bibliography.

O. B. H.

INTRODUCTION TO PRACTICAL BACTERIOLOGY.

—By T. J. Mackie, M.D., D.P.H., and J. E. McCartney, M.D., D.Sc. Second Edition. Edinburgh: E. & S. Livingstone, 1928. Pp. 416. Available from Butterworth & Co., Calcutta. Price, Rs. 7-14.

It seems only about a year ago that the writer had the pleasure of reviewing the first edition of this excellent little book. Apparently, three years have slipped by. The fact that a second edition was called for in so short a time is excellent testimony to the value of the book.

It will be observed that this book is going the way of all its kind—perhaps the right way and it appears to be the inevitable way—it has undergone considerable enlargement. Bacteriology is a rapidly advancing science and it is essential that further advances in our knowledge should be included in a book of this nature; in this matter, the authors have bowed to fate, but was it necessary to add to their troubles by enlarging the scope of the book? For the purposes of this book, the malarial parasite, the Leishmanias (the reviewer prefers "Leishmanias," but he is probably in a minority) and other protozoa are bacteria. The book is certainly not written for the trained bacteriologist; it should be a very valuable book to the student going in for an examination and on occasions one could conceive of its being used by a general practitioner who wanted to know something about an organism which he had seen referred to in a journal. But would it help any member of either of these classes to read the very accurate information given on the two small pages which are devoted to Leishmania? The reviewer is certainly prejudiced and is probably wrong. Perhaps after all, if a student were asked in an Edinburgh M.B. examination what he knew about the species of the genus *Leishmania* and he repeated this section word for word, he would get full marks for knowing more about the subject than did the examiner. Nevertheless, his knowledge would be of no practical value to him.

The reviewer has really nothing but praise to offer regarding this very valuable little book; the above remarks are mere quibbles. The book is of convenient size, it is excellently printed, well bound and is very good value for the money.

L. E. N.

AN ELEMENTARY LABORATORY GUIDE IN GENERAL BACTERIOLOGY.—By Harold J. Conn. Baltimore: The Williams and Wilkins Co., 1927. English Agents: Baillière, Tindall & Cox, London. Pp. 165 plus ix, with 27 figures in the text. Price, 13s. 6d. net.

This is easily the most expensive book, words per shilling, that we have ever had the pleasure of reviewing.

The main portion of the book consists of 137 pages of which 66 are blank. The remaining 71 pages contain numerous illustrations, so that this part of the book contains probably less than 24,000 words and the price is thirteen shillings and sixpence. It is only fair to mention that there is an appendix consisting of 20 pages printed on both sides of the paper.

The book is more suitable for the higher grade laboratory attendant than for the medical student, but should prove useful to the latter. All mention of specific organisms is most studiously avoided, presumably to prevent the beginner from attempting to run before he can walk; the idea is a good one.

The subject is clearly dealt with and the illustrations are very helpful.

The get up of the book is excellent, although, when space is to be left for notes, interleaving is, in our opinion, a better plan than that adopted in this book, namely, printing on one side of the page only.

L. E. N.

PERCIVAL'S MEDICAL ETHICS.—Edited by C. D. Leake. Baltimore: The Williams and Wilkins Co. English Agents: Baillière, Tindall and Cox, London, 1927. Pp. xiv plus 291, with 11 plates. Price, 13s. 6d. net.

DR. PERCIVAL was born in Lancashire in 1740. He practiced in Manchester. He was a distinguished physician who, amongst other things, introduced, or rather re-introduced, the use of cod-liver oil in the treatment of debilitating diseases. His name has not been, as far as the reviewer is aware, attached to any fracture, disease or sign, but he will always be remembered in medical history as the writer on sociological subjects and more particularly as the author of "Medical Ethics."

It is on this book that the medical ethics, or perhaps it would be better to say, "codes of medical etiquette," of the English speaking races have been founded. It is surprising how little of this code is not literally applicable to-day. Just as one realises how necessary it is to pass on Lord Chesterfield's advice in his famous letters to his son written in 1750, that when you have blown your nose you should not, in public at any rate, inspect your handkerchief to see what has happened, so in malaria-ridden Bengal at the present day one sees the wisdom of the following quotation from Percival:—

"The duty and responsibility of the physician, however, are so intimately connected with these points, that no dependence on the probity of the apothecary should prevent the occasional inspection of the drugs, which he prescribes. In London, the law not only authorizes but enjoins a stated examination of the simple and compound medicines kept in the shops. And the policy that is just and reasonable in the metropolis, must be proportionally so in every provincial town, throughout the kingdom. Nor will any respectable apothecary object to this necessary office, when performed with delicacy, and at seasonable times; since his reputation and emolument will be increased by it, probably in the exact ratio, thus ascertained, of professional merit and integrity."

It is a book that could with advantage be read by every member of the profession in India, or in any country; if his conscience is quite clear when he reads that, "No physician or surgeon should dispense a secret *nostrum*, whether it be his invention, or exclusive property. For if it be of real efficacy, the concealment of it is inconsistent with beneficence and professional liberality. And if mystery alone gives it value and importance, such craft implies either disgraceful ignorance, or fraudulent avarice," then perhaps he may have some qualms when he comes to the next page and reads, that he "should avoid all contumelious representations of the faculty at large; all general charges against their selfishness or improbity; and the indulgence of an affected or jocular skepticism, concerning the efficacy and utility of the healing art."

In the appendices the "Code of Ethics" and the "Principles of Medical Ethics" of the American Medical Association are reproduced. Although the book is

produced mainly for the benefit of the American medical practitioner it could be read with equal profit by and to practitioners of any country.

The format of the book is good and suitable.

L. E. N.

HOW TO START IN GENERAL PRACTICE.—By Isaac G. Briggs, M.R.C.S., L.R.C.P. London: John Murray, 1928. Pp. 158. Price, 6s. net.

THAT the modern medical curriculum is theoretically adequate along certain limited lines may or may not be true, the point is a debatable one. That it fails miserably to give the student an adequate insight into the thousand and one difficulties that beset the path of the medical man in the first few years after qualification, admits of no debate at all. The man fresh from school knows little enough about the common ailments that the general practitioner is called upon to treat; of such essential matters as equipping his dispensary or surgery, adapting his house or rooms to the requirements of his profession or the art of "handling" different types of humanity, he is abysmally ignorant and his ignorance is likely to cost him dear both in pocket and in reputation.

Dr. Briggs deals adequately and concisely with the very problems that are likely to confront the beginner in general practice—where and how to "set up," the technical and legal difficulties in so doing, the building and furnishing of the house or "rooms," the economical purchase of instruments and drugs and the storage and dispensing of the latter. We would strongly urge all those who intend to practice medicine—and after all general practice is the only real "practice of medicine"—to read this little book. It is wholly admirable.

Annual Reports.

LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE. REPORT ON THE WORK OF THE TROPICAL DIVISION FOR THE YEAR 1926-27.

THIS report is the last of the separate annual reports of the London School of Tropical Medicine in its old setting, for with the year 1927-28 other departments of the new big London School of Hygiene and Tropical Medicine were opened. It is a report which will interest the many former students of the School in India.

Dr. Andrew Balfour reports that the change in the D.T.M. to a 20 instead of a 12 weeks' course has been all to the good. Unfortunately, however, it means that batches of men from the Colonies can only be set free to attend the classes twice a year, instead of three times, as formerly. When the School moves to its new and commodious quarters, new arrangements may be possible. At the 1926-27 courses there were 69 students for the ordinary course, and 5 for the special course; at the March-July 1927 session, 72 students for the ordinary course, and 9 for the special course. One hundred and fourteen, out of 124 competing, passed the School examination; and 36 of them gained distinction; also 49 out of 96 competing gained the D.T.M. & H. (Eng.). The Lalca and Duncan Medals both went to Dr. H. W. Kumm, of the Johns Hopkins Medical School, Baltimore. Among the 155 students at the School during the year, 79 belonged to the colonial services, 1 to the R.A.M.C., 9 to the I.M.S., and 11 to different missions. A new departure of the year was the institution of a course of lectures in tropical hygiene and sanitation to I.C.S. probationers. A special course in malariaology has been arranged, in conjunction with the Mosquito Control Institute at Heyling Island and the entomological field station of the Wellcome Bureau of Scientific Research, but only one student put in for this course, which will not be given unless there are at least 6 applicants.

With regard to the staff a new Division of Medical Zoology was created, to include the departments of entomology, helminthology and protozoology, and Professor Leiper was appointed Head of the Division. New posts of Lecturer and Milner Fellow were created, and Dr. T. W. M. Cameron, Dr. J. T. Duncan and Dr. A. Robertson were appointed to them.

Turning to the different departments, there were many changes in the staff of the Entomology Department. Dr. Dudley Buxton writes of the necessity for concentrating teaching on a few types dealt with rather fully, rather than on trying to cover a more comprehensive schedule in three weeks. The most important event of the year was the opening of a field station at Farnham Royal, Buckinghamshire. Dr. Buxton's memoir on his investigations in Samoa was prepared for publication, whilst Dr. Wigglesworth investigated the process of digestion in the cockroach, a preliminary to a study of the digestive processes of blood-sucking insects—a subject about which extremely little is known. Dr. Mary V. Beattie studied the relationship between the thermal death point of the blue-bottle fly and atmospheric humidity, whilst Professor Nuttall and Mr. C. Warburton examined, overhauled and identified the collection of ticks.

In the Helminthology Department, Miss J. Leishman was appointed Milner Research Scholar and Demonstrator, and has carried out research work on the cercaria of *Schistosoma* and the development of *Trichinella* and *Strongyloids*; Dr. Cameron has continued his studies on the evolution of lung worms and hydatid. He has also given much attention to helminthic material collected from the London Zoological Gardens. Dr. Cameron also received the D.Sc., Edinburgh, during the year for a thesis on economic helminthology. In the Protozoology Department, Dr. J. G. Thomson comments on inadequate facilities for teaching. Major J. A. Sinton, V.C., I.M.S., spent about two months in the Department during the year. Dr. S. Annecke investigated the biology of the malaria parasites, and also the anopheline carriers of South Africa. He was further deputed to study and report on the antimalaria work carried out in Italy under the auspices of the League of Nations. A finding of importance during the year is that, whereas *Trypanosoma rhodesiense* soon becomes stabilised in virulence for laboratory animals, *T. gambiense* appears steadily to decline in virulence. A long list of trypanocidal drugs was experimentally tested during the year, and much work carried out on the pathology and parasitology of malaria.

In the Department of Tropical Pathology and Bacteriology, again, there were changes in personnel. Dr. H. B. Newham comments on the amount of time and labour which has to be given to teaching, and especially to the preparation for the practical classes and providing material. The phenomenon of sedimentation of the red blood corpuscles in different diseases was studied, and Dr. R. M. Morris obtained his M.D., London, together with the Gold Medal for his researches on the output of urobilinogen and urobilin in sprue. Dr. Duncan investigated the relationships of *Micrococcus melitensis* and *Bacillus abortus*—a subject upon which there is now an extensive literature. The museum is being added to, and every endeavour made to make it as representative as possible.

Clinical material is readily available at the London School from the Hospital for Tropical Diseases in Endsleigh Gardens, and the Seamen's Hospital Society's Hospital at the Royal Albert Docks. Dr. Manson-Bahr made a donation of a large collection of laboratory specimens from clinical cases under his care, and was having a series of X-ray transparencies with regard to the differential diagnosis of liver abscess from conditions in the lung prepared. The usual lectures by visiting lecturers were given; also special cinema lectures.

The Egyptian Government asked for Professor Leiper's services to be lent to them for a limited period as adviser with regard to the prevention of schistosomiasis in Egypt. Dr. Andrew Balfour and Dr. Manson-Bahr were appointed members of the new

Colonial Medical Research Committee, whilst the old students of the School continue to render loyal support in the way of sending material. The future museum in the new building is being organised, and received several valuable exhibits.

In the appendix to the report there is given a detailed list of the 62 papers, reports, etc., published by the staff of the School during the year.

In some ways one regrets that this is the last annual report of what was formerly the London School of Tropical Medicine, for the School was especially associated with the name of Sir Patrick Manson, and its record, both in war and peace, is a magnificent one. Its future, however, in the new building, as part and parcel of the new London School of Hygiene and Tropical Medicine, will be even more important, one realises, in the immense field of tropical medicine in the British Empire.

REPORT ON THE PRISON ADMINISTRATION OF BURMA FOR THE YEAR 1926. BY LIEUT.-COL. P. K. TARAPORE, I.M.S., INSPECTOR-GENERAL OF PRISONS, BURMA. RANGOON, SUPD.T., GOVT. PRINTING, 1927. PRICE, RS. 5.

THERE was no change in the number of central and district jails in the province during the year. A notable feature of the year, however, is that Government has approved of a proposal to construct an institution which will serve as a hospital for 100 tuberculous prisoners and 100 leper prisoners, with a common laboratory.

The daily average number of prisoners was 19,267, an increase on the previous year of nearly 2,000. The majority of newly convicted prisoners came from Rangoon—4,000; whilst Insein came next with 2,334. Seventy-one prisoners who volunteered for service in the Andamans were transferred there, and 21 to the Mental Hospital at Ranchi. No less than 85 per cent. of prisoners admitted during the year were Buddhists (Burmans, one supposes), which corresponds to the caste distribution in the province. The number of boys sent to jail shows an unwelcome increase, but "the question of the treatment of young offenders on reformed lines is still under the consideration of Government."

Seventy-three per cent. of prisoners admitted during the year were literate, 3.62 per cent. able to read, and 23.6 per cent. quite illiterate. During the year Government sanctioned, as an experimental measure, the provision of schools in jails to impart education to prisoners by paid teachers. The results so far have been satisfactory, and the scheme has been continued experimentally for another year.

There is a slight tendency in the figures to show that the courts are gradually reducing the number of short term sentences inflicted, but this serious question does not appear to have been really tackled as yet. Forty per cent. of prisoners admitted during the year were confirmed offenders and "habituals" constituted 35.27 per cent. of the total population.

Some 40 per cent. of habitual prisoners and 15 per cent. of casuals return to jail within three years of release. "As regards the enquiry into the age at which habituals start their criminal career, it was shown that about 30 per cent. were under 21 and about 70 per cent. under 30 years of age at first conviction. These figures would appear to indicate that the problem of habitual crime in Burma is that of the correct treatment of the young offender, and that our present methods of treatment of the young delinquent are far from satisfactory."

There were 12 escapes during the year, 1 from inside the jail, and 11 from extra-mural gangs outside the jail. The 12 recaptured included 2 who had escaped in a previous year. Several escapes of recent years having been effected by prisoners uprooting papaya trees and using them to scale the wall, a rule has been made that no papaya or plantain trees are to be planted within jail compounds, and those already there are to be removed. In Rangoon, a prisoner was sent to the General Hospital for emergent operation for acute intestinal obstruction and escaped; he was recaptured a week later, though no details are given as to what

treatment he received in the meantime! One prisoner had the audacity to escape in private clothing belonging to a sub-assistant surgeon who was on duty at the time, though he had only two more days' time to serve—an instance of misplaced enthusiasm.

Considering the great increase of the convict population, discipline was good throughout the year, and the total number of jail offences and punishments showed a substantial decrease. In this connection, Col. Tarapore makes the following pertinent remarks: "The opinions of most experienced Superintendents are unanimous that the present strength and quality of the staff makes it difficult to supervise the prison population efficiently, especially the habitual class from whom most of the 'bad hats' are derived. Practically all the serious assaults are made by 'bad hats' who need constant supervision. The remedy lies in isolating incorrigibles in a cellular jail, as is being done in the Madras Presidency, with a strong and capable staff."

The number of corporal punishments inflicted during the year diminished by about one half. During the year Government discontinued the experimental issue of tobacco to well-behaved prisoners who had been free from punishment for three months; the Director-General is of opinion that this is a mistake, for the issue tended to assist discipline.

Of the 35 offences committed within jail and tried by the criminal courts, 20 were for assault, 6 for escapes, and 2 for attempts at suicide. Twenty-three out of these 35 cases were among habitual prisoners. As a class, habituals are usually well behaved and accustomed to the routine of jail life; on the other hand, when they are obstreperous, they can make a prison Superintendent's life a very difficult one. At Insein jail the concentration of a large number of such convicts made it very difficult to manage them with the existing staff sanctioned.

Convict officers, both male and female, are still employed in the Burma jails, and there was actually a difficulty in finding a sufficient number during the year owing to the large number of prisoners of this class sent out on ticket-of-leave. Although the convict officer scheme is frowned upon officially, yet in actual practice it works well, and it is difficult to see how all prisoners are to be guarded by non-prisoner guards under existing conditions of financial stringency.

The daily number of under-trial prisoners increased during the year, and their average period of detention works out at 25.43 days. No less than 54 per cent. of such cases result in acquittal, and this antiquated system means not only that innocent men are kept in custody far longer than is necessary, but also increased cost to Government in their maintenance. The reason for this state of affairs is the inordinate time which it takes to settle cases in the Indian law courts. Four weeks' provisional detention for an innocent man appears to be rather a hardship.

With regard to finances, the total expenditure on the department during the year was Rs. 22,04,085, but the average cost per head was reduced, the large increase in the total number of prisoners being chiefly responsible for the increased budget. The cost of diets is likely to be seriously increased in future, since Government have rescinded the previous orders which allowed all articles shipped by Government steamers for jails to be carried free. The cost of clothing and bedding increased with the increase in the number of prisoners, and with the supply of bedding and clothing to ticket-of-leave prisoners. The issue of khaki uniforms to warders, whilst entailing an increased initial expense, is likely ultimately to save money, since three khaki suits are now issued every two years as against two blue suits per annum previously.

The jail gardens, as usual, continued to show a useful profit, garden produce to the value of Rs. 88,611 having been sold to the public after meeting the requirements of the jail population. The total cash earnings for the year on jail industries amount to Rs. 2,27,381. The prisoners in Mandalay jail have been put on to grinding wheat for the requirements of the Police Department,

but this industry is worked at a remuneration which only returns a yield of one anna per prisoner employed per day, for whereas the cost of grinding 100 lbs. in the open market would be Rs. 2, the allowance for grinding 100 lbs. in the jail is only 8 annas. A textile expert has recently been appointed to advise the department with regard to looms, weaving and manufacture of cloth in general. The manufacture of bricks in different jails has proved a most profitable source of income. "As a business proposition.....the average cash profit per prisoner sentenced to labour was Rs. 14-7 in the year under report," whilst the prison labour supplied for the construction of the jail at Tharrawaddy is estimated at Rs. 1,00,167.

Turning to vital statistics, there was a slight increase in the sick and mortality rates. The death-rate was 14.58 per mille as against 10.30 in the previous year. Akyab jail reported an extremely high death-rate—58.20 per mille—attributed chiefly to the admission of elderly prisoners, many of them confirmed opium eaters. Malaria and dysentery were the two chief diseases concerned. Pulmonary tuberculosis figures high in the mortality rates of the jails recorded. A special tuberculosis ward exists at Myingyan jail; 60 patients in all were treated there during the year. Capt. Be Thaw, I.M.S., is singled out for mention on account of his special care and attention to the patients in this ward, and the results are good; 17 per cent. cured, and 12 per cent. of deaths—the latter chiefly from among prisoners admitted in an already advanced stage of the disease. Anæmia, pneumonia and diarrhoea are some of the other chief causes of morbidity in the jails under review; and no less than 7 deaths were recorded from diarrhoea (possibly due to infection with Flexner's bacillus) in Akyab jail.

The year was entirely free from beri-beri, a most notable event, despite the continuous overcrowding which occurred, a fact which tends to discredit the "contagious" theory with regard to this disease. Influenza was unimportant during the year; there was only one case of plague, also one of hydrophobia in a prisoner admitted after he had been bitten. Nearly 10 per cent. of prisoners admitted were habitual opium consumers.

Of the 263 deaths that occurred during the year, no less than 122 were amongst prisoners who had been less than six months in jail. These figures are eloquent of the debilitated state of health in which perhaps the majority of prisoners are admitted to jail. Residence in jail in fact means the death of those who are already severely diseased, but improves markedly the general state of health and nutrition of those in ordinary health.

Burma is pre-eminent in crime, and an interesting investigation into this problem by Mr. J. J. Bennison, I.C.S., was carried out during the year. In India, 626 persons per million are annually admitted to jail; in Burma the corresponding figure is 1,640. Proportionately six times as many persons per million are admitted to jail for theft in Burma as in the rest of India. Robbery and dacoity also appear to be very much more prevalent in Burma than in India. Also the proportion of habituals admitted in Burma is on the increase. Whereas an average of 68 per million young offenders under 21 years of age are admitted to jail per year in India, the proportion in Burma works out at no less than 283. It is clear that Burma shares with the United States of America the notoriety of being a criminal-ridden country.

Of other features in the report, emphasis is laid on the persistent overcrowding in the jails in the province during the year; the experimental employment of Burmans as warders and head-warders in two selected jails; an increase in the cash earnings; and the inauguration of a project to employ large bodies of prisoners on the ticket-of-leave scheme.

Col. Tarapore is to be congratulated on an extremely interesting report, which will be studied with much interest by all prison superintendents in India.

BENGAL PUBLIC HEALTH REPORT FOR THE YEAR 1926. BY DR. C. A. BENTLEY, M.B., D.P.H. CALCUTTA, BENGAL SECRETARIAT BOOK DEPOT, 1928. PRICE, RS. 5.

THERE were several changes in the post of Director of Public Health, Bengal, during 1926. Dr. Bentley being on leave, Lieut.-Col. A. D. Stewart, I.M.S., acted until March 24th, when he also went on leave. Dr. R. B. Khambata succeeded him, and officiated until Dr. Bentley's return from leave on the 1st November, 1926.

The birth-rate per mille for the year, 27.4 per mille, was the smallest recorded from any province, though the death-rate—24.7 per mille—was seventh on the list of the ten provinces. The result is that the natural increase of population in Bengal—2.7 per mille—is almost less than half that of any other province, the Central Provinces heading the list with a figure of 11.7, and the Punjab coming next lowest to Bengal with a figure of 5.1. That this is a most unsatisfactory state of affairs does not need emphasising. The corrected rates, however, should be birth-rate 34.8 and death-rate 31.4 per mille, respectively.

The registration of vital occurrences in urban areas continues to be extremely unsatisfactory, and methods vary from one municipality to another, collecting sircars being employed in some, *dais* in others, rewards for reporting births and deaths being given in still others.

A graph on p. 9 shows how serious is the position with regard to the birth-rate in Bengal; even on the figures for the previous year the decline is 7.4 per cent. on the previous figure. Sixteen districts returned decreased birth-rates, and only 5 increased birth-rates; in Calcutta the rate was as low as 16.9. A still further factor in inaccuracy in reporting vital statistics is the failure of the courts to convict persons prosecuted under the Births and Deaths Registration Act; of 343 prosecutions undertaken, 59 were either withdrawn or struck off, whilst 81 municipalities did not prosecute a single offender.

The birth-rate in rural areas—28.1 per mille—was higher than that in towns—18.5 per mille. There was a slight improvement in the death-rate, perceptible in almost every district, except Calcutta and Howrah. With the exception of fevers, indeed, Calcutta shows a higher mortality from all other diseases than do the towns or rural areas, whilst anyone who has ever passed through that "salubrious locality" knows what a mass of slums constitutes Howrah.

Still-births in the province totalled 59,571. On an average 110 males die to every 100 females, and death-rates are higher among the Hindu and Mahommedan communities than amongst Christians and Buddhists. More than 50 per cent. of the total deaths occur in children of less than five years of age and persons above 50; only half the total mortality being in persons between the ages of 5 and 50 years. The death-rate is higher for females during the child-bearing period than for males of the same ages. The infant mortality rate was 196.8, an increase of 8.6 per cent. on the 1925 figures. The highest infantile death-rate is that recorded from Calcutta, a figure of no less than 372. In the rural towns the figure is better, 248.2, and in the rural *mofussil* areas better still, 194.4. Such figures show that, in spite of the vastly better facilities afforded in the big cities, such facilities cannot compete successfully with the growth of slums; registration, however, is much better in the cities than in the villages.

Cholera.—The year was characterised by a cholera epidemic, with 59,106 deaths and a death-rate 85.7 per cent. above that in 1925. The month of maximum incidence was, as usual, April. The quantity of cholera vaccine issued during the year was nearly five times that in 1925. As compared with only 16 districts in 1925, in 1926 inoculations were carried out in every district in the province with the exception of Darjeeling, where the disease is very rare. "It is satisfactory to note" runs the covering Government resolution "that

the inoculation is steadily gaining in popularity and has been universally admitted to be the best preventive of this fell disease. Besides, its immediate effects have captured the imagination of the public in a wonderful manner."

Small-pox.—The epidemic which started in 1924 continued into 1926, and persisted throughout the year, the total mortality from it being 25,548 as against a figure of 17,436 for 1925. The death-rate increased by 66.6 per cent. on the former figure, though the number of vaccinations showed a slight increase. As is not uncommon during an epidemic year the primary vaccinations decreased by a small percentage, whereas re-vaccinations increased by a large figure—20.1 per cent. The proportion of infants protected is only 273.4 per mille. In Calcutta, however, the corresponding figure is 500 per mille. The epidemic was at its height in May, and at its lowest in October, only to rise again towards December. Death-rates from small-pox were higher in all districts, except the Presidency district, in 1926 than in 1925. In some districts, such as Pabna, small-pox accounted for no less than 9 per cent. of the total mortality of the year. Half the total small-pox mortality was contributed by the six districts of Pabna, Murshidabad, Midnapur, 24-Parganas, Howrah and Burdwan.

Delayed notification was responsible for a severe outbreak which could not be stayed in Murshidabad district. The opposition of country *raids* and *kabirajs* to vaccination also militated against the control of the disease. In Calcutta and municipal areas it is reported that more than half the infants which had survived both the usual causes of infantile mortality and small-pox were protected.

Fevers.—The total mortality from "fevers" was 822,774, representing a ratio of 17.7 per mille. This mortality is highest in November and lowest in July. The increase in fever mortality seems to affect chiefly the western portion of the province, whilst there is a gradual decline in the death-rates from fevers in the towns and rural areas. Over 8,000 lbs. of quinine were distributed through the department during the year. Of experimental antimalarial schemes, the Banka Valley scheme had to struggle with an unexpected flooding by the river in August; the Singaran-Toposi scheme worked satisfactorily; the Jhangipur scheme has yielded excellent results since 1918—the spleen-rates having been materially reduced.

Kala-azar.—The total number of deaths reported—14,275 in all—showed a definite decline on the figure for 1925. Kala-azar accounts for only 1.7 per cent. of the fever mortality and 1.2 per cent. of the total mortality. Many centres report a falling off in attendances for treatment, and possibly the widespread measures now taken against the disease by official and voluntary agencies are beginning to tell.

Of other diseases, enteric fever showed a marked decline, but is definitely more prevalent in towns than in villages (perhaps owing to more accurate diagnosis in the former). Measles and relapsing fever were very unimportant; and there was no death from plague during the year in the province. Dysentery and diarrhoea accounted for a death-rate varying in different districts from 0.35 to 0.94 per mille of the population—figures which seem quite insignificant superficially, but which represent a big toll of life in the aggregate. Respiratory diseases accounted for a total death-rate of 0.66 per mille, or 30,589 deaths. Bites from snakes or attacks by wild animals accounted for 4,859 deaths and hydrophobia for only 349—a figure which shows how very unimportant hydrophobia is as a cause of death in the total mortality rate of India.

The public health laboratories continued to do a very big volume of routine work during the year, and published medical research papers which have already been commented on in our columns. One significant contrast is recorded in the table of samples examined. Of 535 samples of milk from the Carmichael Hospital for Tropical Diseases, which has an excellent milk supply, only 2 showed evidence of adulteration; of 283 samples from municipalities, no less than 166 or 58 per cent.

were adulterated. "Milk" is a very variable fluid in India and often a very different fluid from that yielded by the cow. In the School Hygiene Department 6,735 schoolboys were examined; only 15 per cent. are recorded as well nourished, 65 per cent. as fairly nourished, and 19 per cent. as ill nourished. Nearly 13 per cent. of children examined had defective teeth. Grants in aid were made to 100 training classes for *dais* in the province, and 1,094 village midwives received training during the year. The Publicity Officer of the department received a much needed assistant officer during the year. Some 300 lectures, attended by about 180,000 persons, were delivered during the year, 50 further sets of lantern slides prepared, and nearly a quarter of a million leaflets distributed. The department is equipped with 24 cinema reels on different diseases and aspects of public health, whilst its coloured posters have proved very popular. "The manner in which the work of this branch is developing and the pressing demand for such educative campaigns have once more made it incumbent on me to ask Government for sanction to conduct the work on a more extensive and intensive scale," writes Dr. Bentley.

The annual report of the Bengal Sanitary Board by F. C. Griffin, M. Inst. C.E., Chief Engineer, Public Health Department, Bengal, is also included in the volume. Twelve water-supply and drainage schemes were prepared and eight detailed projects of municipal water supplies and sewerage were drawn up during the year. Four water-supply and sewerage schemes were completed during the year, and others are in progress. Mr. G. Bransby Williams went on leave prior to retirement during the year, and "Government are confident that under Mr. Griffin the high standard of efficiency attained by the Engineering Branch of the Public Health Department will be fully upheld." With Mr. Bransby Williams' retirement, Calcutta loses a very efficient officer and a keen sanitarian.

FIFTY-SECOND ANNUAL REPORT OF THE CHEMICAL EXAMINER'S DEPARTMENT, BENGAL, FOR THE YEAR 1926. BY MAJOR T. C. BOYD, I.M.S., CHEMICAL EXAMINER TO THE GOVERNMENT OF BENGAL. CALCUTTA, BENGAL SECRETARIAT BOOK DEPOT. PRICE, Rs. 1-4-0.

As usual, Major (now Lieut.-Col.) Boyd's report contains much of interest.

Dr. Hira Lal Sinha, B.A., I.M.S., was in charge of the Department until September 27th, 1926, when Major Boyd returned from leave and took over charge. The volume of work has steadily increased, from a total of 3,141 articles in 1921 to 7,021 in 1926. Of the latter, 4,006 articles were from Bengal, the rest being sent in by the provinces of Assam, Bihar and Orissa, the Central Government, or private firms, etc. The regulations for the Calcutta University M.B. examination having lately been thoroughly revised, this will involve increased work in teaching in the Department.

In the general analytical department, 2,296 examinations were carried out. Thirty-four water samples were examined. Of 50 samples of ghee tested, only 7 were found to conform to the standards laid down, and only 3 out of 11 samples of mustard oil. Other articles examined were samples of cocaine and opium, articles in connection with note forging and counterfeit coming cases, and 211 examinations of explosive substances. The medical and scientific side of the department requires to be developed. Owing to the increase of work one of the store rooms was converted into an extra chemical laboratory during the year.

The following were some of the conundrums presented to the department during the year.

(1) As to the process of removing the hardness of tube-well water by subjecting it to the permutit system of softening.

(2) As to the existing tests for determination of the germicidal value of disinfectants.

(3) The question of the identification of pellets recovered from wounds.

(4) As to whether osmium tetroxide should be classed as a noxious and deleterious substance and fall under the Indian Post Office Act (No. VI of 1898) and also as to the advisability of its transmission through the foreign parcel post. (Referred by the Deputy Director-General of Posts and Telegraphs, Calcutta.)

(5) The question of toxicity in specimens of urea-stibamine which showed turbidity in solution. Further questions regarding toxicity of complex organic compounds will probably arise in the near future and can only be satisfactorily answered by the introduction of biological assay methods.

(6) As to whether there is any danger to human life in using potassium bromide as a substitute for potassium iodide. (Referred by the Commissioner of Police, Detective Department, Calcutta.)

(7) The cause of a solution of hydrarg. iodidum rubrum with potassium iodide turning black. (Referred by the Medical Store-keeper to Government, Calcutta.)

(8) The administration of a salt of copper as a possible abortifacient.

In the medico-legal department 2,212 cases were referred, an increase of no less than 316 on the figure for 1925. Of these, 1,192 came from Bengal, 849 from Bihar and Orissa, and 163 from Assam. The total number of articles examined was 4,725. Poison was detected in 168 out of 857 cases of suspected human poisoning, the most common poison being opium, followed by arsenic, oleander and aconite. In the majority of cases sent for analysis, the medical officers concerned withheld their opinion as to the cause of death. Poison was detected in 53 out of 108 cases of suspected animal poisoning, the chief poison used being arsenic. Blood was detected in 1,285 out of 1,917 articles examined, and proved to be human in 1,049 instances on examination by the Imperial Serologist. Seminal stains examined numbered 247.

Senior Assistant Surgeon Satyendra Nath Sen, M.B., contributes medico-legal notes to the report which show how important are the duties of the medico-legal department. Aconite was detected in the case of three persons who had drunk country *pachawai* together, and appears to be frequently introduced into country liquors in order to increase the drinker's thirst. Atropine is usually administered in sweetmeats. Cocaine was detected in a case from Bhagalpur, a district in which the cocaine habit appears to be common. In one instance a father poisoned his son and daughter, and then himself with potassium cyanide; whilst the same poison was detected in ten samples of whisky and brandy sent out as (forged) free presentation samples in Assam. Opium was detected in the viscera of a patient who was alleged to have died from snake-bite, and also in the viscera of two persons who were alleged to have died from hanging. Red lead, oleander and sulphur figure among the animal poisons detected. In a case stated to be one of rape, the blood present turned out to be that of a fowl (this appears to be a common procedure in India, the charge of rape being made, and the clothes stained with fowl's blood to simulate human blood.) Sulphuric acid in one case and hydrochloric acid in another were detected on mosquito nets; it is probable that these acids were thrown at the persons sleeping inside the nets.

The main feature of the year was the tremendous increase in the volume of work dealt with in every department. Captain J. K. Banerjee, M.B., was appointed temporarily as 5th Assistant Chemical Examiner during the year. Major Boyd laments the approaching retirement of Dr. Hira Lal Sinha, who for thirty years has rendered invaluable service in the Department. "The retirement of experienced officers is a serious matter to the satisfactory running of this Department," he writes, "and can only be met by a reorganisation scheme that will supply future assistant chemical examiners with the necessary practical experience as vacancies occur. Unless some such scheme is put into operation in the near future, it will be impossible to carry on the work, which is still expanding, without considerable delay, congestion and loss of efficiency."

THE CALCUTTA DENTAL COLLEGE AND HOSPITAL. ANNUAL REPORT FOR 1927-28. BY R. AHMED, D.D.S., PRINCIPAL.

This is the report on the seventh year's work of this institution, and the Principal is able to report that 54 past students are all practising as successful dentists in various parts of India, Burma, Siam and Ceylon. There were 38 students on the roll during the year, of whom 13 passed the final examination and received the diploma. The course of instruction lasts three years, and qualified medical practitioners who attend the College have now to attend for twelve, instead of nine, months as previously. The premises are sufficiently large for the present volume of work and number of students, but it is anticipated that they will soon become insufficient, if the work of the College continues to expand at its present rate.

During the year 2,987 out-patients were attended to, dental operations numbered 142, and there were 5,018 extractions, with much other work. The Secretary to the Local Self Government Department, Bengal, writes appreciatively of the work of the institution, and regrets that "had it not been for lack of funds, the Government of Bengal would have started a Dental College some time ago."

The audited balance sheet shows an income of Rs. 18,726, an expenditure of Rs. 13,283, and capital assets of value Rs. 13,204. Although it began in a humble way, the expansion of the work of the Calcutta Dental College shows how much an institution of the kind was needed in Calcutta.

ADMINISTRATION REPORT. STATISTICS AND PROFESSIONAL REPORT OF THE GOVERNMENT OPHTHALMIC HOSPITAL, MADRAS. FOR THE YEAR 1927. BY LIEUT.-COL. R. E. WRIGHT, B.A., M.D., D.P.H., I.M.S., SUPERINTENDENT. PRINTED BY THE SUPERINTENDENT, GOVERNMENT PRESS, MADRAS. PRICE, As. 12.

The report of the Government Ophthalmic Hospital, Madras, for 1927, is a record of continued progress in this important department of medical science. The total number of in-patients treated was 4,208 as compared with 3,898 in 1926: the out-patient figures also show a rise namely 25,899 as compared with 23,412 in the previous year. Operations on in-patients numbered 3,376 and on out-patients 3,042: no fewer than 1,652 cases of senile cataract were dealt with by operative procedures. A considerable reduction is recorded in the incidence of complications following this operation and the figures compare favourably with those of any first class ophthalmic hospital in the West. The vitreous loss rate is down, reaching the low figure of 0.73 per cent. in the straightforward cases. The iris prolapse rate is just over 2.1 per cent. Late formation of the anterior chamber occurred in 2.7 per cent. of the cases. The more important serious post-operative complications and causes of failure were, primary infections 8, of which 1 went on to panophthalmitis, choroidal hæmorrhage 3, turned sections 3, fundus disease 10, and marked glaucoma before cataract operation 15.

In connection with the iris prolapse rate, Colonel Wright explains that the figure quoted in last year's report namely 8 per cent., was a mistake in recording. This percentage, as also that in 1925, included not only iris prolapses but also impactions and drawing up of the pillars of face of the iris to the back of the section. A careful check of the records by several members of the staff showed that the actual iris prolapse rate in 1926 was 2.8 per cent. It is of interest to note also that the vitreous loss rate for the past 15 years has remained somewhere between 1 and 3 per cent.

The most important factors influencing the prolapse rate are those which, if present either singly or collectively, determine the expectation of success as "bad."

They are:—

(1) Intractable behaviour on the part of the patients associated with violent squeezing, uncontrolled movements, post-operative tampering with the dressing, wandering about the hospital, etc.

(2) Abnormal states of the iris as determined by old uveitis, the flabby irides associated with intense anæmia, irides which have been rendered parietic by the delivery or other manipulation.

(3) Conditions which are likely to be associated with post-operative increase in volume of the posterior segment such as glaucomatous types of eyes, or vascular disturbances in which the volume of the posterior segment is altered by actual hæmorrhage or engorgement.

Attempts have been made to find out if the more intense heat and glare existing in some parts of India is associated with greater frequency in the incidence of cataract. There is a general impression that this is so, but it is difficult to prove. Blindness in the Madras Presidency appears to be most prevalent in Ganjam, Malabar and North Arcot. The climatic conditions in two of them, Malabar and North Arcot are widely divergent. (The conditions in Ganjam most nearly approach North Arcot, but it is more humid.) In Malabar one finds a damp, green, thickly forested area with heavy rainfall, whereas in North Arcot the country is of a dry, arid, almost desert type with scanty rain. Assuming that the frequency of blindness and the frequency of cataract bear a direct relationship one to the other in S. India, one might perhaps have expected a greater frequency of blindness in those areas in which there was a preponderance of glare and bright light, i.e., where an infra-red or thermal lesion might be assumed to predominate. For this assumption there is at the moment no proof, but whatever its ætiology cataract is one of the chief causes of blindness in the presidency so far as the census return "blind" is concerned. Analysis of the hospital figures also shows that cataract heads the list, being approximately ten times more frequent than the next most common blinding affections.

During the year under review an important piece of research was undertaken by Major Verdon in conjunction with Major Newcomb, *viz.*, the investigation of the method of lowering intra-ocular tension by the intra-venous injection of hypertonic sodium chloride indicated by Duke Elder. Despite considerable technical difficulties interesting results were obtained, and these were embodied in a paper read before the Far Eastern Association of Tropical Medicine Seventh Congress, held in Calcutta in December, 1927. Major Verdon's conclusions may be summarised as follows:—

(1) Therapeutically the injection of strong sodium chloride solution is a valuable means of lowering the intra-ocular tension, effective in the great majority of cases and especially valuable as a pre-operative procedure.

(2) Following the injection, the intra-ocular tension falls and the osmotic pressure of the blood goes up, in spite of a large increase in blood volume, but it remains to be shown whether the fall in intra-ocular tension is more closely connected with the osmotic pressure or with other changes in the constitution of the blood.

During 1927, 2,416 cases were seen in the refraction room. Of these 1,980 were pure refraction cases, the great majority of which attended hospital for examination under a cycloplegic, and 436 were cases of fundus disease.

A series of models, specimens, photographs, charts, paintings, etc., from the hospital were on view in the ophthalmological section during the Congress of the Far Eastern Association of Tropical Medicine held in Calcutta in December, 1927. Those of us who were privileged to view the exhibit were unanimously of opinion that it constituted one of the most interesting and important contributions to the Congress.

During Colonel Wright's absence on leave for nine months, Major P. Verdon, I.M.S., officiated as Superintendent.

ANNUAL REPORT OF THE PRINCE OF WALES MEDICAL COLLEGE, PATNA, FOR THE YEAR 1926-27. BY MAJOR R. R. M. PORTER, I.M.S., OFFG. PRINCIPAL. SUPDT., GOVT. PRINTING, PATNA, B. & O. PRICE, As. 5.

THIS report shows the new Prince of Wales Medical College at Patna to be in a flourishing condition during

its second year of existence. Lieut.-Col. H. R. Dutton, I.M.S., was in charge of the College throughout the year, but left on leave in April, 1927, so that the present report is by Major Porter.

All departments were open during the year, and 76 students transferred from the Medical College, Calcutta, to Patna. Certain improvements were effected in the buildings, and certain changes occurred in the staff. Dr. E. W. H. Cruickshank, D.Sc. (Lond.), M.D. (Aberd.), M.R.C.P. (Lond.), joined the staff as Professor of Physiology during the year, and Major Porter succeeded Capt. S. N. Hayes, F.R.C.S., I.M.S., as Professor of Surgery. Forty students were admitted during the year, and 28 out of 38 who sat for the first M.B., B.S., passed. Twenty-two students appeared in the second M.B., B.S. of the Patna University, of whom 9 passed. Nine students appeared for the final M.B., B.S., of whom 6 passed (these were students who had been transferred from Calcutta to Patna). The College has not yet been recognised by the General Medical Council, but was visited during the year by Sir Norman Walker, as representative of that body for the purpose of inspection and report. Dr. W. S. Carter of the Rockefeller Foundation also visited the College during the year. The average daily attendance of students during the year was 164.6.

Owing to the vagaries of the Public Works' Department, the official opening of the College had to be delayed until the 25th February, 1927 (by which time it had been in existence as a teaching institution for some twenty months). The official opening was performed by H. E. Sir Henry Wheeler, on that date whilst several of the more prominent donors to the College were present.

Athletics played a prominent part in the life of the College during the year. football, tennis, and hockey being played regularly. Two country boats were purchased, and boating proved to be popular. The library now contains 1,033 books and 47 journals. The average cost of each student educated during the year was Rs. 1,844, and there are twenty-four scholarships awarded annually. Under the orders of Government, post-graduate classes for the training of Assistant Surgeons, lasting for three months, were opened during the year: 8 candidates attended and all passed the terminal examination. Twenty-four students were sent to Bangalore to receive training in midwifery. In the pathology department 20 new microscopes were purchased, and the grant for the establishment of a pathological museum fully expended. Sanction has been accorded by Government to the establishment of a provincial laboratory and of a provincial Pasteur Institute. The physiology department is still hampered by lack of space, assistants, and menials; whilst the post of biochemist, which has been sanctioned, has not yet been filled. The anatomical, biological, and pharmacological departments are now well equipped and in full running order, and an assistant surgeon was sent to the Medical College, Calcutta, for special training in museum work.

"The College is well equipped, but some augmentation of staff is necessary" writes Colonel Willmore, Inspector-General. "Proposals in this connection have been submitted to Government."

Correspondence.

THE RATIONALE OF MALARIA TREATMENT IN SYPHILIS OF THE CENTRAL NERVOUS SYSTEM.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—Malaria and many other forms of fever are beneficial in neuro-syphilitic conditions; an attack of kala-azar may improve a case of leprosy, while pneumonia has been known to effect a cure in kala-azar.

There is one factor in common to these conditions, *viz.*, that the secondary (curative) disease principally attacks tissues which are hardly affected by the primary

disease. Thus G. P. I. and tabes are diseases of the central nervous system, a part of the body unaffected by benign tertian malaria; leprosy is a disease of skin and nerves, kala-azar usually attacks tissues other than these; kala-azar principally involves the spleen while pneumonia has its special focus in the lung.

May it not be that the curative disease acts by depressing other tissues so that the organisms, causing the primary condition, are lured thereunto to assail a weakened fortress, but a fortress where, fortunately for the patient, the organisms are themselves either destroyed or their activities rendered comparatively innocuous? The theory may at first sight appear far-fetched but the following evidence may be adduced in support of it:—

(1) Novarsenobillon, as is well known, is quite useless in G. P. I. and tabes, yet after malaria it is of undoubted value, suggesting that the spirochaetes which had been lurking in tissues inaccessible to the drug had migrated to tissues into which the novarsenobillon could penetrate.

(2) Malaria does not remove the Wassermann reaction, on the contrary it is said that in certain cases of G. P. I. the serums which previously had been negative were rendered positive after malarial treatment (neuro-syphilis tending to become generalised syphilis?).

(3) No other explanation so fits the facts for if the good be attributed to protein shock (the generally accepted view) or to high incompatible temperature, or to leucocytosis, the question arises why should malaria only be of use in neuro-syphilis, and not equally beneficial in all late forms of syphilis?

(4) In the words of MacNalty "It is a truism of medicine that a disease is prone to attack an individual at the weakest or most fatigued point of bodily resistance." The above "migration" theory might be considered a reasonable corollary of such a statement.

(5) The extreme rarity of neuro-syphilis in India suggests that the spirochaetes prefer to attack and remain in the weakest tissues. The Indian as a rule is a fatalist and does not worry over so trifling a disease as syphilis, moreover the climate, his inadequate diet, malaria, dysentery, and a host of other devitalising conditions tend to keep his bodily resistance at a very low ebb without, at the same time, throwing any extra strain on his central nervous system. In consequence he escapes such diseases as G. P. I. and tabes. With the European exactly the reverse holds good. He is a man of comparatively good physique but to him venereal disease spells disaster. Sleepless nights and anxious days throw all the strain on his central nervous system—"the most fatigued point of bodily resistance" becomes the site of selection of the spirochaetes and he falls a ready prey to para-syphilitic diseases.

(6) The fact that dermal leishmanoid would appear to be fairly common as a sequel to other diseases of the skin, again suggests that the weakened tissues of the body are most likely to be involved by disease-causing organisms migrating thereto. Thus the one history, recorded in full in Col. Knowles' Introduction to Medical Protozoology (Page 217), is a case of a Hindu male adult who was treated for kala-azar and discharged as clinically cured. Two years later he contracted syphilis followed by an extensive generalised secondary eruption of so severe a character that it simulated small-pox—after 1½ years he developed dermal leishmanoid.—Yours, etc.,

PASTEUR INSTITUTE, KASAUJI.
17th July, 1928.

EYE-FLIES.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—I am very glad to see an article on these flies by Dr. D. N. Roy in the *Indian Medical Gazette*, July 1928. The fly has been a pest in India ever since 1881 when I first went to the country. I am now writing merely to point out that the numbers of these flies often vary from place to place suggesting that they breed principally in certain substances, which are not found everywhere, or in certain localities. Thus when I was

in Ceylon two years ago they were very numerous in most of the planters' bungalows, but I observed that they were nearly absent from one such bungalow and should like to have found a reason for this but had no time to investigate. Natives have told me that they swarm largely round "jack fruit," but I am not sure of this. When I lived in Bangalore many years ago, one of my daughters, who was then a child, had an extremely severe attack of ophthalmia from which she fortunately recovered completely. We thought the infection had been carried by "eye-flies" as Professor Strickland and Dr. Roy have noticed.

I agreed that, in the interests of the public in India, the subject should be thoroughly investigated.—Yours, etc.,

ANÆSTHESIA OF THE ABDOMEN.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—Reference the first two complications mentioned in Colonel Brayne's and Dr. Sen Gupta's article on "Anæsthesia of the Abdomen" in your journal of July 1928, viz., (a) Headache and (b) Temperature, my experience is that the former can be avoided or minimised by putting the patient during operation and during the post-operative treatment in bed with the head low or lower than the rest of the body, and that the latter is due to absorption of blood and tissue proteins let loose in the area of operation by the knife.—Yours, etc.,

A. F. W. da COSTA, F.R.C.S., D.T.M., L.M. & S.,
Civil Surgeon.

BILASPUR, C. P.,
21st July, 1928.

SODIUM CACODYLATE IN THE TREATMENT OF BOILS.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—I shall be glad if you will be pleased to publish this note in your esteemed paper.

With reference to my paper in your *Gazette* of March 1928, on page 128, the dose generally used is gr. iii for an adult. I generally inject it subcutaneously. In my article I used the word hypodermic which I now understand is a loose term for both subcutaneous and intramuscular administration. Recently I have tried soamin and this gives me better results.—Yours, etc.,

BIDHU BHUSAN GHOSE, L.M.F.

SHAHZADPUR,
PABNA DISTRICT.

COAGULATION OF THE PERITONEAL INFLAMMATORY EXUDATE.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—Some time ago I read in the *Indian Medical Gazette* that the fibrin of the peritoneal inflammatory exudate coagulates and causes adhesions within 24 hours after an injury. The following case illustrates that the adhesions can take place even earlier, i.e., within 14 hours.

A boy, aged 14, who fell from a jambul tree at 5 p.m. was brought to me at 7 a.m. next morning. A splinter of wood about ¼ inch thick at the tip and ½ inch behind entered the right side of his back just above the crest of the ilium about 3 inches from the spine, went through the abdomen and protruded 2 inches in the left groin just above the inferior spine of the left ilium. The protruded portion of the splinter was covered with faecal matter. The whole length of the splinter was 13 inches, 9 inches within the abdomen and 2 inches outside on either side. The abdomen was fully distended; no stool or flatus was passed; the urine was clear; there was no blood in it; temperature was

100°F.; pulse full and bounding, 100 per minute; respirations were normal.

Preparations were made for opening the abdomen and suturing the intestines where necessary. The protruded portion of the splinter was cut close to the skin and the remainder was withdrawn from the wound of entry at the back. Stinking gas gushed out with a noise and the abdomen completely subsided immediately. This proved that the punctured intestines were glued together and to the parietal peritoneum by the coagulation of the fibrin within 14 hours. Hence the gas in the intestines could not escape into the peritoneal cavity but was expelled outside. The wounds in the abdominal walls were simply dressed and bandaged. The boy made an uneventful recovery and was discharged cured in a week.—Yours, etc.,

K. V. KUBAL,
Medical Officer.

CHINCHANI, BOMBAY,
23rd June, 1928.

ESTIMATION OF CHLORINE IN BLEACHING POWDER.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—I beg the hospitality of your column for inserting the following observations which I would like to make upon the paper, "A simple method for estimating the available chlorine in bleaching powder" by Dr. R. B. Brahmachari, published in the *Indian Medical Gazette* in May 1927, Vol. LXII, No. 5, p. 251.

The method described in the paper is only an adaptation of the original method of Pinot (*vide Quantitative Analysis* by Clowes and Colmen, 11th Ed., page 162). It gives only the approximate amount of chlorine, as the amount of arsenious oxide prescribed is 10 grains instead of the theoretical amount of 9.75 grains to be dissolved in 16 ounces of water. The amount of soda carbonate given is 40 grs. This is, however, insufficient to dissolve the amount of arsenious oxide. It should be at least 50 grains, if not more.

The method is open to criticism on the following grounds:—(1) An ordinary mill doctor for whom this is intended, if he has no previous experience, will find it rather disconcerting to prepare the standard arsenic solution as described in the paper, as it has been found in the laboratory that it requires at least 2 hours' continuous digestion on the steam-bath to dissolve the amount of arsenious oxide in the alkaline solution. (2) The solution of arsenious oxide is highly poisonous and as such it cannot be entrusted to a layman. A better method of preparing starch solution is to make an emulsion of starch with cold water first and then to pour this into boiling water, as experienced in the laboratory has shown that if starch is heated at first with water to boiling point it more often than not happens that the test-tube cracks.

The method can be simplified still further. Instead of taking 6 test-tubes and putting 1 c.cm. of the arsenic solution in each tube, one 10 c.cms. graduated pipette and one test-tube only with 1 c.c. of the solution and a measure glass are all that is necessary for the test. Add 5 c.cms. of water and a few cubic centimetres of starch solution and a small crystal of potassium iodide to the test-tube. From the graduated pipette go on running the bleach solution gradually until the contents of the test-tube begin to turn blue. The amount of the bleach solution run in will give the accurate amount of chlorine instead of its possible range of values, according to the paper. The method of calculation will, of course, remain the same. The starch potassium iodide in this case can be used as an internal indicator in contrast to the original method of Pinot where this is to be used as an external indicator in the form of iodised starch paper.—Yours, etc.,

N. L. BANERJEE,
*Asst. Professor, School of Tropical
Medicine and Hygiene.*

CALCUTTA,
24th August, 1928.

Service Notes.

APPOINTMENTS AND TRANSFERS.

Lieutenant-Colonel E. W. C. Bradfield, C.I.E., O.B.E., M.B., F.R.C.S.E., I.M.S., First Surgeon and Superintendent, Government General Hospital, and Professor of Surgery, Medical College, Madras, is appointed to officiate temporarily as Surgeon-General with the Government of Madras in addition to his own duties, with effect from the afternoon of the 2nd August, 1928, and until further orders.

The services of Lieutenant-Colonel H. W. Acton, I.M.S., and Lieutenant-Colonel R. Knowles, I.M.S., are placed permanently at the disposal of the Government of Bengal, with effect from the 16th August, 1928, from which date they will cease to be members of the Medical Research Department.

Lieutenant-Colonel W. J. Simpson, I.M.S., an Agency Surgeon, on return from leave, is posted as Agency Surgeon, Bhopal, with effect from the 11th August, 1928.

The services of Lieutenant-Colonel I. M. Macrae, O.B.E., M.B., I.M.S., are placed at the disposal of the Government of Bihar and Orissa for employment as Inspector-General of Prisons, with effect from the 17th February, 1926.

Major R. L. Vance, I.M.S., an Officiating Agency Surgeon, is posted as Civil Surgeon, Quetta, with effect from the 1st August, 1928.

The services of Major J. P. Huban, O.B.E., I.M.S., an Officiating Agency Surgeon, are placed at the disposal of the Chief Commissioner, Delhi.

Major B. H. Singh, M.C., I.M.S., First Resident Medical Officer, Eden Hospital, Calcutta, is appointed temporarily to be the wholetime Resident Physician, Medical College Hospitals, Calcutta.

Major C. J. Stocker, M.C., M.D., I.M.S., Civil Surgeon, Pachmarhi, is re-posted to his former appointment as Civil Surgeon, Hoshangabad.

Major J. B. Hance, O.B.E., I.M.S., an Agency Surgeon, on return from leave, is posted as Chief Medical Officer, Western India States Agency and Residency Surgeon, Rajkot, with effect from the 22nd July, 1928.

The services of Captain R. T. Advani, I.M.S., are placed at the disposal of the Government of Bihar and Orissa for employment in the Jails Department, with effect from the date on which he assumes charge of his duties.

The orders regarding the appointment of Captain R. W. H. Miller, I.M.S., temporarily to the Medical Research Department and his posting as Supernumerary Officer to the Central Research Institute, Kasauli, have been cancelled.

The services of Captain M. A. Jafarey, I.M.S., are placed at the disposal of the Government of Burma for employment in the Jail Department, with effect from the date on which he assumes charge of his duties.

The King has approved the following appointments to permanent commissions in the Indian Medical Service, with effect from the dates specified:—

To be Captain (on probation).

Sydney Hartley, M.C., M.B., 30th April, 1928, with seniority 28th August, 1926.

To be Lieutenants (on probation).

Bijeta Chaudhuri, 2nd August, 1927.

Shankar Sahai Bhatnagar, 2nd August, 1927.

Charles Frederick John Cropper, 8th February, 1928.

Kenneth Hugh Athelsten Gross, M.C., 16th February, 1928, with seniority 26th July, 1926.

Everard Venn Claydon, 16th February, 1928, with seniority 20th December, 1927.

Victor Henry Sarland, M.B., 16th February, 1928.

John Acheson, M.B., 30th April, 1928, with seniority 24th June, 1925.

Edmund Aloysius O'Connor, M.B., 30th April, 1928.

John Patrick Joseph Little, M.B., 30th April, 1928.

Patrick Laurence O'Neill, 30th April, 1928.

Vincent Thomas Joseph Lynch, 30th April, 1928.

PROMOTIONS.

Subject to His Majesty's approval, the following promotions are made, with effect from the 7th July, 1928, *vice* Major-General A. A. Gibbs, K.H.P., I.M.S., retired:—

Colonel to be Major-General.

Colonel H. Boulton, C.B., C.B.E., M.D., V.H.S., I.M.S.,

Lieutenant-Colonel to be Colonel.

Lieutenant-Colonel James Fuller-Good, M.B., I.M.S.
His Majesty the King has approved the under-mentioned promotion, with effect from the 1st July, 1928:—

To be Brevet Colonel.

Lieutenant-Colonel E. A. Walker, M.B., F.R.C.S.E., I.M.S.

Majors to be Lieutenant-Colonels.

W. D. Keyworth, M.B. Dated 30th July, 1928.

B. Gale, M.B. Dated 30th July, 1928.

H. H. King, M.B. Dated 30th July, 1928.

R. E. Flowerdew, M.B. Dated 30th July, 1928.

A. J. Symes, M.B. Dated 1st August, 1928.

Captains to be Majors.

H. H. Elliot, M.B.E., M.C., M.B., F.R.C.S.E. Dated 5th April, 1928.

A. C. Craighead, M.B. Dated 9th August, 1928.

G. R. Oberai, M.B. Dated 19th August, 1928.

I. Chandra, M.B. Dated 21st August, 1928.

P. H. S. Smith, M.B. Dated 30th August, 1928.

H. J. H. Symons, M.C. Dated 31st August, 1928.

The following provisional promotion is made, subject to His Majesty's approval:—

Lieutenant to be Captain.

B. S. Nat, M.B., F.R.C.S., I.M.S. Dated 2nd May, 1928.

RETIREMENTS.

Major-General A. A. Gibbs, K.H.P., 7th July, 1928.

Lieutenant-Colonel H. Watts, M.B., on account of ill-health, 10th May, 1928.

Lieutenant-Colonel W. Lapsley, O.B.E., M.B., on account of ill-health, 24th July, 1928.

Lieutenant-Colonel G. O. F. Sealy, I.M.S., with effect from the 22nd April, 1928.

Lieutenant-Colonel F. W. Browne, I.M.S., with effect from the 16th July, 1928.

Lieutenant-Colonel A. Murphy, 27th June, 1928.

Major A. Seddon, M.B. (on account of ill-health), 8th March, 1928.

LEAVE.

Major-General F. H. G. Hutchinson, C.I.E., M.B., K.H.S., I.M.S., Surgeon-General with the Government of Madras, is granted, preparatory to retirement, leave on average pay for eight months, combined with leave on half average pay for twenty months, with effect from the 2nd August, 1928, or from such subsequent date as he may avail himself of it.

Lieutenant-Colonel D. P. Goil, I.M.S., Civil Surgeon, Howrah, is granted leave on average pay for one month and fifteen days, with effect from the 3rd September, 1928.

Major G. H. Mahony, I.M.S., is granted leave on average pay for five months, with effect from the 21st May, 1928.

Major M. J. Holgate, I.M.S., Civil Surgeon, Hyderabad, is granted leave on average pay for eight months, followed by leave on half average pay for four months, with effect from the 25th October, 1928, or date of availing.

MISCELLANEOUS.

Subject to His Majesty's approval and in supersession of all previous notifications, the undermentioned officers will be graded for seniority as shown below:—

Names.	Pension service to count from.	Date of rank as Captain.
W. E. R. Dimond ..	26-7-1916	26-7-1919
P. H. S. Smith, M.B. ..	30-8-1916	30-8-1919.
H. H. Elliot, M.B.E., M.C., M.B., F.R.C.S.E. ..	5-10-1916	5-10-1919.
R. S. Aspinall ..	19-4-1917	19-4-1920
P. M. Antia, M.B. ..	23-5-1917	23-5-1920
S. N. Hayes, F.R.C.S. ..	9-3-1918	9-3-1921.
G. H. Fraser ..	25-11-1919	25-11-1922
A. H. Craig, M.B. (Service for promotion from 23rd June, 1920.)	29-11-1919	23-6-1923
R. W. H. Muller, M.B. ..	9-4-1920	9-4-1923
P. A. C. Devenport ..	22-4-1920	22-4-1923.
D. P. Bhargava, M.B., F.R.C.S.E. ..	5-6-1920	5-6-1923.
R. McRobert, M.B. ..	10-6-1921	10-6-1924.
T. A. Doran, M.B. (Service for promotion from 22nd May, 1922.)	28-1-1922	22-5-1925
S. C. H. Worseldine. (Service for promotion from 14th April, 1924.)	27-2-1923	14-4-1927

NOTES.

AN INSTRUMENT DESIGNED TO FACILITATE THE FIELDS OF VISION WHERE THERE IS A CENTRAL SCOTOMA.

(Abstract of paper read at the Ophthalmological Society of the U. K. by N. Bishop Harman.)

FIELD-taking is difficult where the macula of one eye is out of action. The device shown gets over most of these difficulties.

•A tube is bent at a right-angle midway in its length, and the two arms are so arranged as to give the seeing eye a false fixation spot which will correspond in position to the real one marked on the perimeter or scotometer.

The figure shows the plan of the instrument in reduced scale. E is the eyepiece. At the knuckle there is a double circle marked H, for the reception of the handle. At the extreme right hand end of the tube is a plate, in the centre of which is cut a diamond-shaped

aperture. At the knuckle of the bend of the tube is a large hole covered with a hinged lid M, fitted inside with a plane mirror.

The patient holds the instrument before the eye which has fixation power. He sees the patch of light reflected from the mirror lid at the knuckle. The field of vision of the other eye and the scotomata are thereon mapped out. The instrument can be used for either eye.

The Scotograph is made by Messrs. Weiss. It is shown with the handle for holding in the hand of the patient, and this is the form generally preferred, but the makers are prepared to fit it with a crank arm to clip on to the upright of the perimeter.

MESSRS. H. K. LEWIS & CO., LTD.

MESSRS. H. K. LEWIS & Co., 28 Gower Place, London, have just issued a small pamphlet describing their various "services." Messrs. Lewis & Co., has now been in existence for 84 years. The student visiting London will be well repaid by spending a short time in this shop. One of the most outstanding features is their most excellent lending library.

"VAPOROLE" BRAND EPHEDRINE SPRAY COMPOUND.

MESSRS. BURROUGHS WELLCOME & Co., have issued a useful "Vaporole" preparation of ephedrine for application to the pharynx and nose by means of an atomiser. "Vaporole" Ephedrine Spray Compound consists of Ephedrine 1 per cent. Menthol, Camphor and Oil of Thyme of each 2 per cent. in a base of "Paroleine" (a high quality liquid paraffin). Such a spray enables ephedrine to be efficiently applied locally in hay-fever and congested conditions of the pharynx and nasal mucosa. It is stated that clinical trials of this new method are exceedingly satisfactory and promise to provide a very effective weapon for the symptomatic relief of hay-fever and of engorged and catarrhal conditions of the naso-pharynx. The product is supplied in 1-oz. bottles.

EPIDIDYMITIS.

EPIDIDYMITIS, in the opinion of A. L. Wolbarst, M.D., ("Gonococcal Infection in the Male") is, by far, the most frequent complication of gonorrhoea and of paramount importance sociologically, because of its remote consequences.

Acute epididymitis is usually accompanied by inflammation of the vas deferens of the affected side or by an inflammation of the corresponding testis or by both. There is tense swelling of the epididymis, and, not rarely associated inflammation with serous exudation in the tunica vaginalis. Occasionally, the pain in the vas is quite severe and radiates upward and backward through the inguinal ring to the seminal vesicles, which share in the inflammatory process. This referred pain may lead to the erroneous diagnosis of acute appendicitis.

Acute epididymitis should be treated by rest (physical and sexual) and elevation of the scrotum and the constant application of heat. Diathermy, according to Dr. C. Otis Rich ("Diathermy in Acute Epididymitis," Illinois Medical Journal) yields results which vary "from the most spectacular improvement to frank disappointment." Heat in the form of antiphlogistine dressings usually gives marked relief in these painful conditions. Thermotherapy with the aid of this endermic, bacteriostatic agent is essentially decongestive and relaxant, removing thereby the tension on the inflamed cord, at the same time preventing blood stasis in the affected area. Being plastic, adhesive, non-irritating and thermogenetic, the physician will find in antiphlogistine a distinctly convenient method for prolonged thermotherapy with complete absence of tissue irritation or toxic action.

REDUCTIONS IN THE PRICES OF STOVARSOL AND NOVARSENOBILLON (N.A.B.)

MAY & BAKER LIMITED, beg to draw attention to the considerable reductions which have recently taken place in the prices of the above two products.

For the convenience of Medical Practitioners and hospitals, large stocks of N.A.B. and Stovarsol are now carried at May & Baker's Indian Branches and Agencies established in the following centres:

CALCUTTA: 7, Esplanade Mansion,

BOMBAY: 16, Ballard Estate,

MADRAS: 3/4 San Thome, Mylapore,

RANGOON: P. O. Box 1071,

AMRITSAR: Golden Temple Chowk (Messrs. K. R. Dosson & Co.)

BOVRIL, LIMITED.

The 31st Annual Meeting of Bovril, Limited, was held in London, on 21st February.

Sir George Lawson Johnston (Chairman) said the profits for the year were £360,523. The same dividends were being paid as in the previous year, and £64,507 had been added to the reserve, bringing that up to £1,100,000. He added that not only had Bovril sales for the year broken all previous records, but that the actual increase in the 1927 sales over those of 1926 had been greater than in any year since 1921.

Every year since the War, their export sales had shown an increase over the previous year, and 1927 was no exception; again they had surpassed the previous records.

The Bovril Australian Estates, some 9,000,000 acres in extent, were situated in Northern Australia, over 1,500 miles from a big city.

The recently reported break-up of the drought would come as a great relief to those who had retained a good part of their stock, as no country could revive more rapidly than Australia, once given rain.

The remoteness of cattle from their final consuming market had even more to do with price than quality. Last season they sent a good portion of the Bovril Australian Estates steers to the West Australian Government works, and the price received for them was just about the price they received for a hide (taken off a steer of similar weight) at their factory in the Argentine; yet the price paid for butcher cattle in Melbourne or Sydney was quite as high as that paid by butchers for cattle in large Argentine cities.

They had ordered another river cattle carrier from Messrs. Thornycroft. It would take about 700 head and was to go out under its own motor power. From the cattle's point of view, it would be *de luxe*, with electric light, fans, water sprinklers for cooling the stock in hot weather, and it was, of course, fitted with drinking-water troughs. Not only did these things add to the animal's comfort, but they delivered him in better condition. He took that opportunity of confessing that they were paying more for this boat because it was British built throughout. If they had accepted even the engines from the Continent, instead of having a British make of semi-Diesel put in, they could, on those alone, have saved over £1,000; but in addition to being patriotic, the British article was he believed, worth while.

In proposing the election of the Duke of Atholl, Sir James Crichton-Browne said that there was one feature in the Report presented to them to-day which must, he thought, gratify them, not only from the shareholders' but from the patriotic and philanthropic point of view, and that was the record of the largely increased sales of Bovril, which was therefore contributing to that improved food supply of the people, which the Chief Medical Officer of the Ministry of Health declared to be the first essential in building up and maintaining the physique and stamina of the nation, and in increasing the resistance to disease. It was certain, Sir George Newman had said, that the most important factor in the decline of the death-rate from tuberculosis and some other diseases had been the rising standard in national nutrition.

Bovril was a factor in national nutrition, and so universal was now its consumption that it might almost be said to have become part of the British Constitution, while in the Dominions beyond the seas and in foreign countries it had established its reputation. Three thousand medical men from all parts of the country witnessed the making of Bovril in every stage, in October last, and they had since received from many of them emphatic testimony of their appreciation of the scrupulous care exercised in its production, and of the assistance it rendered them in their practice.

THE "ARTSUN" ULTRA-VIOLET RAY LAMP.

A NEW ultra-violet ray lamp at a very reasonable price £4 17s. 6d.—is the "Artsun" lamp manufactured by Brodie, Oakley and Co., 94, Gray's Inn Road, London, W. C. 1. Special features of this lamp are claimed to be: (a) the placing of the resistance behind the arc, in order that the infra-red rays generated thereby shall assist the deeper penetration of the ultra-violet rays; and (b) the co-ordination of all moving parts in a single adjustment. It is claimed that the special carbons supplied will last for approximately four hours, and will burn for twelve to fifteen minutes without adjustment. The lamp is suitable for either alternating or direct current.

The manufacturers state that they will be glad to supply further particulars.

THE SWINEY PRIZE FOR WORK ON MEDICAL JURISPRUDENCE OF THE ROYAL SOCIETY OF ARTS.

WE are asked to give publicity to the following notice with regard to this prize of value £100, together with a cup of equivalent value. It has been in existence ever since 1849. India is the land of medical jurisprudence, and some of our readers may be interested to know of the prize.

The Council of the Royal Society of Arts give notice that the next award of the Swiney prize will be in January 1929, the eighty-fifth anniversary of the testator's death. Dr. Swiney died in 1844, and in his will left the sum of £5,000 Consols to the Royal Society of Arts, for the purpose of presenting a prize, on every fifth anniversary of his death, to the author of the best published work on Jurisprudence. The prize is a cup, value £100, and money to the same amount.

The award is made jointly by the Royal Society of Arts and the Royal College of Physicians, and the prize is offered alternately for Medical and General Jurisprudence. If at any time the Joint Committee of the Royal Society of Arts and the Royal College of Physicians, which is appointed to submit a book to the adjudicators, is unable to find a work of sufficient merit in the class whose turn it is to receive the award, the Committee is at liberty to recommend a book belonging to the other class.

On the last occasion of the award, in 1924, the prize was awarded for General Jurisprudence. It will, therefore, be offered on the present occasion for a work on Medical Jurisprudence.

Any person desiring to submit a work in the competition, or to recommend any work for the consideration of the judges, should do so by letter, addressed to the Secretary of the Society, John Street, Adelphi, W. C. 2, not later than November 30th, 1928.

A SIMPLE APPARATUS FOR THE ESTIMATION OF BLOOD-SUGAR.

IN our issue for February 1928, there was described by Dr. J. P. Bose, Mitra Research Scholar in Diabetes, Calcutta School of Tropical Medicine, a simplified method and apparatus for the estimation of the blood-sugar in cases of diabetes. The method is very simple and gives results accurate enough for all clinical purposes, whilst no special laboratory training or technical skill is required to carry out the test, which can be

performed by any general practitioner in about half-an-hour.

It is to be regretted that many medical practitioners, even in big cities like Calcutta, treat their diabetes patients without even a preliminary blood-sugar test, which is often injudicious, if not dangerous. The whole modern treatment of diabetes turns upon estimation of the blood-sugar. Dr. Bose's apparatus places in the hands of general practitioners, and especially of those in the *mofussil*, a ready means for carrying out the test.

The Bengal Chemical and Pharmaceutical Works, Ltd., 15, College Square, Calcutta, have now undertaken to put the apparatus on the market, conveniently packed in a small portable cabinet. Full particulars with regard to it may be obtained from them.

THE HOLWAY DUAL CONTROL UNIT FOR RAPID RADIOGRAPHY.

THE busy radiologist may have often felt the want of some method of photographing instantly any abnormal condition which he sees on the fluorescent screen. When this is the case, he usually has to suspend his examination, whilst attending to the setting of his controls, in order to produce the radiographic current required, only to find when he studies the finished radiograph that the particular condition which he wishes to demonstrate is not apparent, such as e.g., a filling defect in the duodenum.

In order to give the radiologist an apparatus which is instantaneous, Messrs. Newton and Wright, Ltd., 471-472, Hornsey Road, London, N. 19, have put on the market the "Holway" Dual Control Unit, suggestions with regard to which had been made to them by Dr. H. C. Gage of St. Mary's Hospital, Paddington. The apparatus consists essentially of two main parts: (a) the floor pedestal and foot controls, and (b) the attachments to the vertical screening stand for speedily placing the sensitive film in position during exposures.

The method of operation is as follows:—The controls on the main switch board are adjusted so that the necessary current, say 60 milliamperes at 85 kilovolts, is produced through the tube. These controls are then left untouched; the patient is placed in position in the screening stands, the cassettes are loaded into the cassette-holder, and adjustment made on the dual control unit for the screening current, say of 3 to 5 milliamperes, as desired. Visual examination is now carried out, but exposure is made by depressing the "fluoroscopy" foot control instead of the usual hand-operated switch.

Immediately any abnormal condition is observed on the screen one of the cassettes in part (b), is instantaneously slipped into position, and the exposure made by depressing the "radiography" control, when the full exposure current is passed through the tube.

Provision is made in the foot control to close the filament circuit at the higher value before the high tension current is applied to the tube. The apparatus can be used in conjunction with almost any type of existing x-ray plant, and the two units (a) and (b) may be employed, if so desired.

The dual foot control (a) is listed at £25, and the photographic attachment with two half-plate cassettes and intensifying screens at £14-10-0.

THE ICHTHYOL FORMULARY.

ICHTHYOL is to-day a very well-known preparation. According to Squire it is a reddish-brown, syrupy liquid, obtained by the action of sulphuric acid on a sulphur-containing mineral oil distilled from peculiar fossil deposits, principally fish, and subsequently neutralised with ammonia.

Whatever its queer origin, ichthyol is used the world over by prescribing physicians, especially in the treatment of such conditions as chronic eczema, psoriasis, chronic rheumatism, pruritus and prurigo, and even in chilblains, and has come into very general use. It is

also administered internally in pulmonary tuberculosis and other conditions.

The manufacturers of ichthyol, the Ichthyol-Gesellschaft Cordes, Hermani and Co., Hamburg, have recently published a small brochure, entitled "The Ichthyol Formulary," which contains some 350 selected prescriptions of well-known authorities in which ichthyol is incorporated. Copies of this are available in India from R. Krishnaswami, P. O. Box 621, Bombay, Indian agents for the ichthyol manufacturers.

In addition to the original ichthyol, two other interesting preparations of the same firm are (a) Ichthargan. This is stated to be a compound of ichthyol with silver, and is especially indicated in the irrigation treatment of gonorrhoea, also in gynaecological practice generally. (b) Ichthoform. This is stated to be a product of the reaction of ichthyol with formic aldehyde, and is a blackish-brown powder, almost tasteless, insoluble in ordinary solvents, but intended for oral administration, when it is stated to be soluble in the alkaline contents of the small intestine. It is indicated especially in the treatment of tuberculous enteritis, and also in enteric fevers.

"NEOSTAM" STIBAMINE GLUCOSIDE.

(The Nitrogen-glucoside of Sodium *p*-amino-phenylstibinate.)

"NEOSTAM" is a new compound of antimony originated and issued by Burroughs Wellcome & Co., for the treatment of kala-azar and other conditions where tartar-emic has hitherto been used. The toxicity of "Neostam" is one-twentieth that of sodium antimony tartrate. (1) The results of clinical trials which have been reported suggest that it is a therapeutic agent of great value in kala-azar. (2) "Neostam" is administered by intravenous injection in the form of a four per cent. solution in water. The period of sterilisation averages a month, and the total quantity of "Neostam" necessary for a complete cure approximates 4 grammes per 100 lb. of body-weight.

Amongst other diseases which suggest themselves for treatment with "Neostam" are oriental sore, bilharziasis and filariasis.

"Neostam" is issued in hermetically-sealed phials of 0.05 gm., 0.1 gm., 0.2 gm., 0.5 gm. and 1 gm.

ANTI-GAS-GANGRENE SERUM.

AFTER the Great War it seemed as if the need for anti-gas-gangrene serum was at an end. But, thanks to a brilliant series of experiments continued over two years by an English physician at one of the great London hospitals, a wide field of application has been opened and the importance of this serum is fully recognised. The serum for the original researches was supplied by the Wellcome Physiological Research Laboratories. The product which is now issued for use by the medical profession is described as "Wellcome" Anti-Gas-Gangrene Serum (W) (*B. welchii*).

"Wellcome" Anti-Gas-Gangrene Serum has been successfully used in abdominal surgery for the treatment of toxæmia of acute obstruction and peritonitis with ileus; in certain cases of puerperal septicæmia following abortion; and as a prophylactic in grossly infected wounds such as may occur in road accidents. From 40 c.c. to 100 c.c. of the unconcentrated serum (containing approximately 100 "W" units of anti-toxin per c.c.) are generally given intravenously or intramuscularly for the treatment and 10 c.c. to 20 c.c. for prophylaxis; of concentrated serum from 20 c.c. to 50 c.c. (containing approximately 500 "W2" units per c.c.) are given intravenously to severe cases and in

smaller quantities intravenously or intramuscularly to cases of moderate severity. The serum in experiments is found to protect against both toxin and living culture.

The unconcentrated serum hitherto issued has contained 60 "W" units and upwards per c.c. Concentrated serum has now been prepared and shortly will be available in large quantities. A dose of 10 c.c. of the concentrated serum will be equivalent to from 50 c.c. to 80 c.c. of the unconcentrated serum previously used.

"Wellcome" Anti-Gas-Gangrene Serum (W) (*B. welchii*) is an all-British product prepared at the Wellcome Physiological Research Laboratories, Beckenham, England, and issued by Burroughs Wellcome & Co. in 10 c.c. and 25 c.c. hermetically sealed phials.

THE TREATMENT OF SCIATICA.

THE term sciatica denotes an inflammation of the interstitial tissue of the sciatic nerve or its roots. Dr. J. P. Martin, M.D., M.R.C.P., writing in the *Lancet* indicates four or five methods which may give early and rapid relief, if not complete cure, the choice depending on the severity and on the stage of the ailment. These are: (a) electrical methods; (b) use of oxygen; (c) injection of saline; (d) epidural injection of antipyrin; (e) surgical methods. With all of these methods, the general principles which govern the treatment of inflammatory conditions must be practised.

The patient must be kept at rest in bed and heat in some form should be applied to the affected limb. John H. Anderson, M.D., C.M.G. (*Lancet*, April, 1927), maintains that in this condition "heat is always grateful, either as a poultice, hot bricks or sandbags, radiant heat, antiphlogistine, hot air baths, or the humble hot-water bottle." In view of the fact that its active ingredients are readily absorbed, antiphlogistine has a favourable effect on the inflammation in the fibrous tissues, and by penetrating among them and loosening them it separates small inflamed surfaces and breaks down many minute adhesions.

As for the general treatment, in the early stage the first essential is, with the aid of simple hypnotics, to secure sufficient sleep for the patient, in order that he may not become exhausted. As soon as the acute phase has subsided the patient should have a general tonic. Debilitating factors such as infective foci, glycosuria or albuminuria should be sought for and constipation carefully treated. If the patient has pyorrhoea the extraction of the teeth is to be recommended at this time.

Publishers' Notice.

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles will receive 25 reprints *gratis*, if asked for at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions, Advertisements, and Reprints should be addressed to THE PUBLISHERS, Messrs. Thacker, Spink & Co., P. O. Box No. 54, Calcutta.

Annual Subscription to The Indian Medical Gazette, Rs. 16 including postage, in India. Rs. 18 including postage, abroad.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

KOLYNOS DENTAL CREAM

THE importance of oral hygiene and the value of the dentist to the community and the nation cannot be too strongly emphasized. A reputable, scientifically prepared dental cream is one of the dentist's best instruments in checking tooth decay, preserving the health of his patients, and in retaining a satisfied clientele.

Instruct your patients to prepare their mouths at home for treatment by brushing the teeth and massaging the gums regularly after meals. You will have the satisfaction of working in a clean mouth free of profuse gum bleeding and from which the removal of tartar is more quickly and easily accomplished.

Kolynos cleans the teeth, the gums—the entire mouth. Its germicidal ingredients destroy 80% to 92% of the mouth germs, leaving the mouth with a delightfully clean, refreshed feeling for hours afterwards.

On request our Distributors will gladly send you a dental package, free of charge.

ALLEN & HANBURY'S Ltd.,

LONDON,

**ACTUAL MANUFACTURERS OF
SURGICAL INSTRUMENTS & HOSPITAL FURNITURE.**

**AGENTS FOR
THE LONDON HOSPITAL CATGUT & LIGATURES.**

Our surgical Representative, Mr. B. W. Clark (late Wigmore St., London) is now continuously travelling throughout India, Burma and Ceylon with a complete range of samples of the very latest surgical Instruments and appliances.

We specialise in Instruments made of **STAINLESS STEEL.**

SURGICAL enquiries addressed to our Calcutta offices will at all times receive immediate attention.

Our new Complete Surgical Instrument Catalogue is nearing completion and will be issued shortly.

ALLEN & HANBURY'S Ltd.

(A. H. P. JENNINGS, Special Representative).

Clive Buildings, CALCUTTA.

Telegraphic address: "Bynogen," Calcutta.

Telephone: 5549, Calcutta.

FACSIMILE OF A LETTER RECEIVED FROM
MAJOR-GENERAL G. TATE, M.D., K.H.S., I.M.S., SURGEON-GENERAL
WITH THE GOVERNMENT OF BENGAL.

Far Eastern Association of Tropical Medicine
SEVENTH CONGRESS

3745
9/11/28

Patron: H. E. THE VICEROY AND GOVERNOR-GENERAL OF INDIA

President:

MAJOR-GENERAL T. H. SYMONS,
C.S.I., O.B.E., K.H.S., I.M.S.,
DIRECTOR-GENERAL, INDIAN MEDICAL
SERVICE.

Honorary Secretary-Treasurer:

F. E. A. T. M. FOR INDIA
ADDRESS: HEAD OFFICE.

HEAD OFFICE:

PASTEUR INSTITUTE
OF INDIA,

KASULI, PUNJAB,
BRITISH INDIA.

Vice-Presidents:

LT.-COL. J. D. GRAHAM, C.I.E., I.M.S.,
PUBLIC HEALTH COMMISSIONER,

LT.-COL. S. R. CHRISTOPHERS,
C.I.E., O.B.E., F.R.S., I.M.S.,
DIRECTOR, CENTRAL RESEARCH INSTITUTE.

General Organizing Secretary:

LT.-COL. J. CUNNINGHAM, I.M.S.
ADDRESS: HEAD OFFICE.

The 7th January, 1928.

Messrs. Bengal Immunity Co., Ltd.,
153, Dharamtollah Street, CALCUTTA.

Dear Sir,

On behalf of our Local Committee, I beg to thank your firm for their assistance during the Far Eastern Association of Tropical Medicine 7th Congress just concluded. The demonstrations at your laboratories were very much appreciated by the members who attended, who had an opportunity of seeing what local enterprise could do in biological research and production.

Yours faithfully,

(Sd.) G. TATE,

Major-General, I.M.S.,

Surgeon-General with the Government of Bengal.

Selected French Products

87.56%

of pure Quinine is contained in

QUINOFORM LACROIX

For the treatment of
MALARIAL FEVER

Results of which could be predicted in advance with Mathematical Precision:

**PAINLESS INJECTIONS AND
NEVER PRODUCES ABSCESSSES**

Because

This Basic Formate of Quinine is the most soluble of all the Quinine Salts, remains unaltered in the air, does not decompose, the aqueous solution being neutral to litmus, non-toxic and does not possess the injurious effects upon the kidneys. Therefore

It is now adopted

A PLEA FOR VAGINAL HYSTERECTOMY IN INDIA: ITS INDICATIONS AND TECHNIQUE.

A RECORD OF 150 CONSECUTIVE CASES.

By V. B. GREEN-ARMYTAGE M.D., F.R.C.P. (Lond.),
Lieut.-Col. I.M.S.,

Professor of Gynaecology and Obstetrics, Medical College, Calcutta, and Surgeon to the Eden Hospital.

WHEN I was working in Paris in 1904, I heard Professor Doyen use these words:—"No man can call himself a gynaecologist unless he can perform a vaginal hysterectomy in private."

Such a statement would appear sweeping, but there is a deal of truth contained therein, for whereas in hospital certain risks can be taken and a certain boldness acquired, it is altogether another matter when dealing with a private patient in a nursing home with no resident medical officer, for the operation of vaginal hysterectomy requires skill, courage, experience and perspicacity.

The surgeon having started vaginally, must be capable of finishing the operation by the same route, and he should be capable of dealing with any of the complications that may arise, for it is a confession of weakness and lack of diagnostic skill if after starting vaginally he has to terminate abdominally.

Historical.—Soranus, Aretæus and Paulus Æginata, circa 150 A.D., referring to the ætiology of prolapse, allude to an operation for extirpation of the uterus, and Alsaaravius the Arabian, circa 1080 A.D., directed that when attempts at reduction of the uterus fail, the organ should be removed from below.

It is possible, of course, that these ancients who advised operation for prolapse may have been considering a case of chronic inversion of the uterus, or one of those large pedunculated submucous fibromata of the cervix or uterus, which are so commonly seen in the East; but considering that Hippocrates, the Father of Medicine, 2,400 years ago described a case of procidentia which he saw "hanging down like a scrotum between the legs of a woman," I am inclined to think that the Arabian was the first to anticipate the modern operation, and that the first copyist of this operation of whom we have record, was Volkamer of Nuremberg in 1675. From this date onwards, the operation gradually became more popular and was advanced for cancer and fibroids of moderate size.

In the United Kingdom of Great Britain, Alex. Hunter of Dumbarton in 1799 was the first to perform the operation.

In the latter part of the nineteenth century, Paen and Doyen inaugurated morcellation and hemi-section of the uterus, and Schuchardt demonstrated the importance and success following a para-vaginal incision when extirpating the uterus in a difficult case.

Indications.—Mr. Herbert Spencer in the *British Medical Journal* of March 31st, 1928, writing on the subject of vaginal hysterectomy states, "The superiority of the recovery over that after abdominal hysterectomy is so marked that it is surprising that there exist gynaecologists who never perform the operation."

Eighteen years experience of this operation in India has led me to confirm this remark, for there can be no question that this operation is peculiarly valuable in this country, and for that matter in any country, provided the surgeon has the courage of his convictions, such digital dexterity as to be absolutely certain of his vaginal findings on examination, and is capable of co-ordinating his surgical skill and knowledge of anatomy. Wherefore, I make a plea for this operation, for amongst Orientals the idea of "cutting the stomach" strikes terror into many a patient, whereas if the operation can be done from below, consent is readily given.

It is contended by some that the abdominal operation is easier and permits perfect vision and a certain security from such risks as injury to the bladder or ureter and hæmorrhage, but for my own part I consider that in a suitable case such arguments are spurious and denote an inferiority complex, for we all realise that there is a subconscious element or structure of grandiosity which tends to make young surgeons prefer the panorama and joy of doing an abdominal operation before spectators, rather than as *they* say, "fiddling about in the dark"; although the immediate and remote results of a vaginal hysterectomy from the point of view of the patient, are far better.

As I have said above, the end all and be all of the operation is digital dexterity and diagnostic acumen, and after that *l'audace toujours* *Paudace*.

I have done 150 vaginal hysterectomies for the conditions appended with a mortality of 2 per cent., but I have never as yet performed morcellation or hemi-section in the course of the operation, for the reason that I consider the limit of size of a fibroid projecting from the body of the uterus or cervix is that of a cricket ball. If the tumour were above that size, I should perform abdominal hysterectomy.

It will be seen that a great many of the operations have been for *Fibromata* (36 per cent.) which is to be expected considering that in the tropics, fibroids are exceedingly common, and the excessive hæmorrhage which they give rise to brings them to the gynaecologist early.

In Western countries no doubt, large numbers of these cases would be treated palliatively or by electro-radiotherapy, but my experience of radium has not been fortunate, for though I can

give you no actual statistics, I have heard it stated by at least 20 per cent. of my patients, that they have been treated by radium or X-rays before seeing me, but nevertheless the hæmorrhage has continued or the tumour has increased in size.

Moreover, in 11 patients, four of them nuns, who had been submitted to radiotherapy, I have had to do an abdominal hysterectomy and remove large tumours of the uterus which had apparently rapidly grown after radium treatment, and in eight of them, either *post hoc* or *propter hoc*, malignant degeneration had occurred. In one, red degeneration was present.

Before undertaking vaginal hysterectomy for fibroids of, or less than the size of a cricket ball, it is important to elicit whether there is pain in the tumour or whether there have been attacks suggestive of localised pelvic peritonitis, for there may or may not be salpingitis or hydrosalpinx with cystic ovaries.

Careful vaginal and rectal examination will tell you whether the tumour is mobile or fixed. If it is fixed, the probabilities are that the rectum or intestines are densely adherent and vaginal operation is precluded. If I am in doubt on this point, I defer decision as to the route of operation until the patient is under the anæsthetic, for if the vagina is capacious and the tumour can be moved down or pushed up with a vulsellum on the cervix, I should not hesitate to go vaginally.

In at least 30 per cent. of the fibroids I have removed vaginally, there have been naked eye evidences of previous tubo-ovarian inflammation, and one has wondered whether the fibro-myomatous hypertrophy of the uterus was due to the tubo-ovarian disease; or whether the inflammation of the adnexa was secondary to the tumour, remembering what a witty Frenchman said "Fibroids are the reward of virtue, babies the reward of sin," inferring, of course, that fibroids are most frequently found in the sterile woman.

However, in fairness it must be stated that in 50 per cent. of the fibroid cases, the patients had had either abortions or one child, and that any such operation, spectacular and difficult as it may appear, is made much easier if the vagina is capacious and the pelvic diaphragm lax. So far, I have never had to make the Schuchardt paravaginal incision in order to remove one of these tumours.

The next most common indication for vaginal hysterectomy in the tropics, is undoubtedly *chronic metritis*, for this "clinically malignant" uterus, especially what Mr. Fletcher Shaw calls the *large sub-involution type*, with its excess of elastic and fibrous tissues microscopically, is, as one would expect in a country where ante-, intra- and post-natal care hardly exist, extraordinarily common.

The cause of this sub-involution type is of course a low grade degree of sepsis, either from

a lacerated cervix or an incompletely emptied or retroverted uterus after labour or abortion.

In a small proportion, the chronic metritis has been of the *hyper-trophic type*, that is, on section there has been an excess of muscle and fibrous tissue in the uterus, and its mucous membrane is like the pile of a Turkish carpet, soft and thick or villous. This type is very commonly found in the prostitute, and I think is seen (and will be seen more commonly in the future) as a sequel to the almost universal measures of contraception that are adopted nowadays.

In another type of which I have five specimens the uterus is small and thin and on section resembles the chronic granular kidney. This is the *arterio-sclerotic type*, and you will see the thickened blood vessels cut across looking like white millet seeds, and in the fresh specimen they projected on the cut surface. These are the cases which bleed furiously and are analogous to the so-called cases of renal epistaxis. They all have a high blood pressure, and in many there is generalised arterio-sclerosis. In 45 per cent. of my chronic metritis cases, curettage had been performed from one to three times previously by other surgeons.

Hæmorrhage with or without backache is the indication for operation, but before performing vaginal hysterectomy digital examination must exclude extensive tubo-ovarian inflammation, for, as I have said, puerperal low grade infection is the commonest cause of chronic metritis, and backward displacement of the enlarged uterus is the rule rather than the exception in these cases; but if the organ can be moved forwards, and with the forefinger in the vagina and the middle finger in the rectum, no great tubo-ovarian mass can be felt, the operator need feel no anxiety.

I particularly wish to stress such digital examination because many times my house surgeons or general practitioners, have doubted the feasibility of vaginal hysterectomy, but it should be remembered that it is almost the rule in these cases to find thickening of the postero-lateral parametrium and utero-sacral ligaments, which is a very different thing to finding dense adhesions in the pouch of Douglas between the uterus (or its adnexa) and the bowel.

Particularly do I wish to make a plea for vaginal hysterectomy in those cases of chronic metritis in India, for a great number of these poor souls come from distant places and run away if an abdominal operation is suggested, whereas if the gynaecologist is confident and dexterous, nine-tenths of these patients can be cured by hysterectomy from below. We should remember that every one of these patients who goes back home cured, is in her own way a missionary and gospeller of the advantages of expedient Western surgery, over the tinkering gynaecology she has hitherto suffered.

Of course I am aware many gynaecologists advise radium for these cases, but unfortunately there is no Government supply of radium in this

hospital or Province, and therefore, rather than permit poor patients who have come from a long distance, to suffer further expense, inconvenience and possible disappointment, in the treatment by radium, I prefer to do vaginal hysterectomy seeing that there have been no deaths out of 43 patients operated on for chronic metritis.

Moreover it must be remembered that radium used for chronic metritis, although ideal in a young woman with no tubo-ovarian disease, sometimes has been known to set up a violent exacerbation of old salpingo-oöphoritis, rendering the last condition of the patient worse than the first.

A proportion of my cases (33 per cent.) have been operated on because they had the so-called *precancerous cervix* (Howard Kelly) that is, a cervix lacerated, everted and eroded with deep infiltration of the mucosa and endocervicitis. In some of these cases the cervix was duck-bill-like, the lacerations extending right up to the vaginal vault and in a few, as high as the internal os,—the results of obstetrical injuries, forceps, pituitrin or precipitate labour.

These patients suffer from leucorrhœa, menorrhagia and backache, the backache being due to lymphangitis and swelling of the glands in the hollow of the sacrum.

The cervix is the tonsil of the pelvis, and just as in tonsillitis there is sub-maxillary gland enlargement, so in cervical inflammation the sacral glands are swollen and press upon the sacral nerves.

The cervical condition is a source of chronic inflammation and chronic irritation, and I am persuaded despite arguments to the contrary, that this condition is more often than not, a precursor of the cancer of the cervix which is so common in young multiparæ in Bengal. Moreover, in most of these cases there is a certain degree of chronic metritis due to the chronic sepsis in the cervix, therefore I am sure that the correct treatment of severe cases of this character is vaginal hysterectomy, an operation of comparative ease and subsequent gratitude. In minor conditions of course I employ the usual methods of amputation, trachelorrhaphy or electric cauterisation.

Of course, in some of these cases a high amputation of the cervix is both wise and permissible, but in the type of case for which I am advocating vaginal hysterectomy, such an operation as amputation would leave a chronically inflamed corpus uteri with but a small chance of future conception and a possible risk of continuance of the symptoms, or atresia or cancer.

Out of my 150 cases, it will be seen that in only 7 was the operation performed for *cancer of the cervix*. In three of these the patients were extremely fat, with flabby hearts, and locally there was an early condition of squamous-celled carcinoma, diagnosed beforehand by removal of a wedge of tissue.

One has been lost sight of, but two are following their vocations five and seven years after operation. In each of these cases, a large flap of vagina was removed along with uterus, tubes and ovaries.

Of the others, one had Graves' disease and is alive without recurrence seven years later, the other had second degree procidentia. The operation was extremely easy but she has been lost sight of, unfortunately.

In one other the patient died shortly after operation, the result of shock. She was almost ex-sanguine before operation due to excessive bleeding from an early cauliflower type of cancer, and the operation was performed not with the idea of a "cure," but to stop the hæmorrhage so that she might proceed to the radium institute 300 miles off.

For my own part, I would not advise vaginal hysterectomy for cancer of the cervix except in exceptional conditions such as the above, for I am convinced, speaking from a tropical experience only, that an operable case of cancer of the cervix is best treated by radium and then if desired, by abdominal hysterectomy, even though such an operation is made more difficult by the primary application of radium.

In one case of Wertheim's hysterectomy performed 18 months ago by me, after two radium applications, the patient was completely free of any signs of recurrence when seen last month. The parametrium in her case, when exposed was fibrous and made dissection of the ureters a very tedious business. The iliac glands, when examined microscopically, showed no evidence of malignancy.

In one case, vaginal hysterectomy was performed for cancer of the cervix in a patient three months pregnant. She was extremely anæmic from hæmorrhage and had a large spleen. The operation was easy, but six months later she was seen in the out-patient department with a recurrence. She had refused post-operative radium treatment.

In two cases the operation was performed, because at the time of a diagnostic curettage the material obtained was clinically that of a *cancer of the body of the uterus*. Both ovaries and tubes were of course removed. Both of these patients are alive three years afterwards with no sign of recurrence, the clinical diagnosis was confirmed by the pathologist to the hospital.

Out of 300 consecutive cases of operations for *prolapse of the uterus* vaginal hysterectomy has only been done on eight occasions, and the only reason for doing this operation was because there was marked enterocele as well as procidentia, and I was anxious to test the technique and confirm the results obtained by other surgeons in America.

In all cases the static results were excellent, but convalescence was somewhat tardy in 3 cases from oozing or sloughing of the posterior vaginal wall. I intend to do this operation on future

occasions more often, but shall reduce the size of the vaginal flaps and use interrupted rather than continuous locking sutures. The operation is an easy one and since it can be done rapidly, and practically bloodlessly, I am sure that in the type of case which is so frequently seen in India, namely, the old debilitated multipara, with shrivelled breasts and nates, it is followed by less shock than the Manchester school operation which is so ideal in strong and fairly healthy Western women, but which of course takes 45 to 60 minutes and is by no means a bloodless affair.

I intend to do the Mayo operation more frequently in suitable cases, but there is one difficulty that this operation does not adequately forestall, namely, post-operative cystocele—if the genital aperture is very enlarged. (It is possible that the technique of Lilian Farrar would have to be followed for complete success in such a case.)

Post-operative cystocele is no light matter to deal with after vaginal hysterectomy, for like congenital prolapse, the structural anatomy is defective. For this reason, as I have shown in a previous paper, I incline to advise the Fothergill, Watkins or Frank operations for 90 per cent. of the cases of prolapse we see in India, even though they are more difficult for patient and surgeon.

There was one case of *dysmenorrhœa* in a childless Indian widow aged 35, which had failed to react to any treatment at the hands of many physicians and surgeons. The uterus was small, there was no adnexal disease or evidence of endometrioma. The operation was easy, the uterus tubes and ovaries being removed.

TABLE OF OPERATIONS.

Disease.	Number of operations.	NATIONALITY.		Mortality.
		Indian.	European.	
Fibroids ..	49	33	16	1
Chronic Metritis	46	31	15	..
Precancerous Cervix.	36	16	20	1
Cancer of Cervix.	7	3	4	1
Cancer of body of the Uterus.	2	1	1	..
Prolapse of Uterus.	9	7	2	..
Dysmenorrhœa (very severe.)	1	1
TOTAL ..	150	92	58	3

As regards the actual operation, I need not describe the two common methods of procedure for they are so excellently illustrated in every large gynecological text-book, but there are a few practical points which experience has taught me, that may be useful,

(1) Always examine the patient carefully when under chloroform before commencing operation.

(2) If the patient is a nullipara, be sure that the vagina is capacious enough to permit access, and that the cervix can be pulled down. This is particularly important when dealing with fibromata.

(3) After making the vaginal cuff incision and pushing up the bladder, delineate the transverse white line of the peritoneal reflection, before boldly cutting the utero-vesical peritoneum. Then put in your anterior retractor.

(4) If in doubt, open up the pouch of Douglas first, and with a forefinger hooked forward, palpate the posterior surface of the uterus to see that it is free of adhesions, then pass the finger laterally so as to feel the broad ligament at the edge of the uterus. In this way you can make sure of the anterior peritoneum and that the bladder is pushed up and well out of the way before opening the utero-vesical pouch.

(5) Use reliable 21-day catgut from below upwards. The first two ligatures tie the cervical artery on each side. The uterine artery is tied twice, one ligature above the other on each side, but remember the principle of tying the first knot and then cutting the artery with scissors before tying the second knot. Once the uterine arteries are tied and cut (contained as they are in the cardinal ligaments), the cervix will descend to or beyond the vaginal orifice. Then the round ligaments are tied on each side and the tubes appear.

(6) When dealing with a fibroid tumour, it may not be possible as when dealing with a small or a "chronic metritis" uterus to remove both tubes and ovaries with the tumour, therefore I would advise you to clamp, each tube so that the tumour, now free, can be removed with ease first.

(7) Always expose both ovaries; if diseased, one or both must be removed, but should there be no indication for their removal, they may be left.

(8) Always remove both tubes whatever their condition. This is a perfectly simple procedure and is done by means of catgut on a needle and a long holder. If you do not remember this point a time will come, as it did to me in 8 of my first 50 cases, when you will find three weeks to six months after operation, a curious red and pointing soft mass at the top of the vagina projecting through the scar, giving rise to irregular bleeding (especially after coitus). This mass is a portion of prolapsed tube. It was this occurrence which first made me realise the importance of complete resection of the tubes whatever their condition, for a bleeding prolapsed tube is likely to make the patient or perhaps some general practitioner think that she has cancer at the vault of the vagina.

(9) Before closing the wound, that is suturing the anterior to the posterior folds of the

peritoneum, I always suture together with catgut the two broad and utero-sacral ligaments in such a way that the cut edges are downwards towards the vagina, and the peritoneal surface upwards, the ovaries on each side being sutured lightly to the peritoneal surface of the round ligament.

(10) As a rule before completely closing the peritoneum from below, I put a small gauze drain into the pelvis at one angle of the wound, which is removed in 24 hours. In perfectly dry and easy cases, the wound is completely closed at once without drainage.

(11) The patient is catheterised eight-hourly for the first 48 hours; she is placed in Fowlers' position, rectal saline is given and the bowels are opened by castor oil on the third morning.

(12) If you are in doubt of your ligature material, use silk twist leaving the ends long. For a few years I used silk-worm gut, but this caused irritation, discharge and sometimes bladder trouble. From the second day, whatever material is used, vaginal douches twice daily are always ordered. I have never used the "long clamp" method of operation.

(13) In only one case out of my 150 was the bladder injured, this was a case where there was a good deal of old parametritis in the left fornix; the injury did not show itself till the fifth day when the urine escaped due to sloughing of a small area at the base of the bladder. In one case only secondary hæmorrhage occurred. The ureter was never injured in any case. Intestinal obstruction due to adhesion of or kinking of a loop of intestine in the true pelvis has not been seen in this series of cases operated upon during the last seven years.

SUMMARY.

The advantages of vaginal hysterectomy are:—

- (1) The rapidity of the operation. I usually finish under the half hour.
- (2) Absence of shock.
- (3) Lessened risk of infection because the operation is extra-peritoneal.
- (4) No painful scar or risk of post-operative hernia.
- (5) The operation can be done on patients in India who would absolutely refuse any abdominal operation.
- (6) For this reason it is a life-saving operation for such a patient in India, bleeding from chronic metritis, small fibromata or very early cancer.
- (7) It is the ideal operation for the precancerous cervix and in certain conditions of prolapse in old women.
- (8) The patient is allowed up on the 10th day and she leaves hospital on the 16th day.
- (9) On five occasions, it has been possible to do myomectomy although the operation had been commenced with the idea of doing a vaginal hysterectomy.

Post Scriptum. During the time covered by this series of vaginal hysterectomies, that is

seven years, 229 sub-total and 180 total abdominal hysterectomies have been performed with a respective mortality rate of 6.1 and 13.3 per cent., that is a total mortality rate for both types of operation in this hospital of 9.2 per cent. in patients of all communities.

This mortality may seem high as compared with the 1 to 2 per cent. mortality of Great Britain. But it should be remembered that a great many of these patients arrive extremely ill from hæmorrhage, and have had intercurrent tropical diseases, such as kala-azar, malaria and dysentery.

I am indebted to Dr. M. Sirkar, Registrar of the Hospital for very kindly looking up the hospital and private records of these cases. 111 operations were performed in the Eden Hospital, 39 in nursing homes or private houses.

It is to be hoped that it will not be long before an efficient Radium Institute is established in Calcutta, for the proper treatment of many gynæcological conditions.

At present much suffering and expense is incurred from the fact that patients applying for treatment at the Eden Hospital are compelled to proceed to Patna if radium therapy is necessary.

PROSTATISM.

By SIR JAMES REID ROBERTS, C.I.E.,
M.B., M.S., F.R.C.S. (Eng.),

LIEUTENANT-COLONEL, I.M.S. (Retd.).

Nor merely has there been of late an improvement in the methods and technique of the operation of prostatectomy, but a recognition that the question of renal adequacy and the condition of the bladder must be gone into before a decision to operate is arrived at. The reduction of mortality of about 25 per cent. in cases undertaken in general hospitals to that of about 9 per cent. in special institutions in England is due in the main to the introduction of the operation in two stages, where renal inadequacy and cystitis are discovered to exist. In other words, it is *most important to test the renal function*, especially before proceeding to operate. In the majority of patients presenting themselves with "prostatism," i.e., frequency of micturition, difficulty in passing urine, dribbling of the stream and a varying amount of residual urine, it is important to remember that the kidneys have been subject to back pressure, and are either functioning badly or are damaged. Relief by constant catheterisation does not produce the same good effects as that of suprapubic cystotomy and drainage by means of a rubber-tube, self-retaining or otherwise, for a fortnight at least in order to relieve the back pressure and subject the cystitis to treatment by rest and irrigation of the bladder. This then is the method of operating in two stages; after the cystotomy the test of renal function is repeated and improvement or failure to improve is noted. It is remarkable, however, how quickly patients regain their renal adequacy

after the back pressure and residual urine are relieved. Many patients do not come for treatment until acute retention has supervened, though previous to this accident prostatic symptoms have existed. If the bladder is greatly distended and can be felt high up in the lower abdomen it is obvious that we have to deal with a chronic case, and experience has shown that it is dangerous to empty the bladder completely by catheterisation there and then. Anuria may supervene, so it is necessary to give relief by drawing off small quantities at a time every 4 hours, until the bladder is emptied during a period of 24 or 36 hours. The continuance of catheterisation for relief or of leaving a catheter in the urethra or bladder are both measures inviting sepsis sooner or later; so that after relief by catheterisation, it is a sound thing to proceed with a suprapubic cystotomy and permanent drainage. If, however, tests show that good renal function exists, the question of the complete operation in one sitting can be considered and undertaken.

Tests of Renal Function.—On the whole, the best test for the use of the practical surgeon in India is the *urea concentration* test, which is done by giving the patient 15 grammes of urea by the mouth, and then estimating the urea content of the urine during the first, second and third hours. If the percentage is over 2, the kidneys are acting normally; if, however, it is 1 per cent. or 2 per cent., they are impaired; if under 1 per cent., they are damaged and show a danger flag, and until the percentage is increased operation is contra-indicated.

The blood urea is another elaboration, and the tests acting on the principle of watching the excretion of certain dyes, viz., indigo-carmin or phenol-sulpho-naphthalein, need not be described as being of less practical value. One fallacy in the urea concentration test exists if polyuria is present, as a low concentration figure will be arrived at, so that the test is not of value in cases where more than about 130 c.c. of urine are passed in the hour.

The question after reading the above is how is one, as a practical surgeon in charge of a district hospital, to proceed in cases of suspected prostatism with or without enlargement? The case has probably been relieved by a catheter, and sounded for stone, both procedures of some risk; however, it has been done, and we have to make our diagnosis. The first thing to do, after our enquiry for the symptoms, is to make a rectal examination to estimate the size of the prostate, and to note any general, one-sided, or irregular enlargement and its motility or fixation when pressed upwards and sideways by the finger. Remember, that a full bladder is a handicap not permitting of estimation of the upper limit.

The next point to decide is that of the general health and the information to be gathered from our inspection and examination of the urine,

bearing in mind that in the case of being unable to carry out the urea concentration test it is important to look out for the following, as pointing to renal inadequacy:—Digestive troubles, loss of appetite, intense thirst, distaste for solid food, constipation or diarrhoea, dirty tongue coated in the centre, red at the tip, sometimes abdominal distension, hæmorrhoids, or prolapse; uræmic symptoms, such as headache, aching in the limbs, vomiting, hiccough, restlessness, bad dreams and hallucinations; general symptoms, such as loss of weight, dryness of the skin, in fact a cachexia simulating that of malignant disease all point to renal inadequacy.

The condition of the urine will indicate the degree of cystitis present, its reaction, alkalinity, mucus, pus, odour, and whether there is hæmorrhage, for spontaneous bleeding is not uncommon in enlarged prostate and often after instrumentation or rapid evacuation of the urine.

A case showing some degree of the above, or one in whom the signs are well marked, requires suprapubic drainage as an immediate procedure and it may be weeks before the bladder and kidneys recover sufficiently for the enucleation operation. There is, however, a good rule in advanced age; don't do more than establish permanent suprapubic drainage of the bladder. A self-retaining tube (Pezzer's) of rubber can be introduced, and removed every fortnight to clear off any deposit and replaced; the tight fitting of the tube in the wound prevents leakage, and the tube can be plugged, and the bladder emptied from time to time by the patient, or drained into a rubber apparatus. This means that the patient can get about, is independent, improves in health, and can be taught to irrigate the bladder with lotion from time to time and keep himself clean. No tube should be allowed to rest on the base of the bladder, as great irritation will ensue. Some old men become quite satisfied with this permanent drainage and it is ever so much better than constant catheterisation, with the urethral irritation this is apt to produce, and the danger of sepsis always at hand.

If the patient is of moderate age, and especially if he has a large adenomatous prostate after suprapubic drainage, and even without this preliminary procedure if the renal adequacy is judged to be good, enucleation can be proceeded with.

The cystoscope is a useful adjunct to genito-urinary surgery; but it is not a necessity for prostatic enlargement diagnosis. That it will become more and more an item of equipment in Indian hospitals I am certain; but, with 3 sizes of Sir H. Thomson's sounds, it is surprising what information they can be made to give in practised hands, with the point rapidly moved from side to side of the bladder by twisting the handle, and reversing the point to examine for any post-prostatic pouch, stones, trabeculæ, diverticula, the size and protrusion into the bladder of the prostatic middle lobe can all be identified.

There is a condition which it is as well to be thoroughly acquainted with; it is described as prostatism without enlargement. A patient comes with all the symptoms of a prostate; he has a large distended bladder with residual urine and he may have had an attack of retention, yet no enlargement can be felt per rectum, and there is no obstruction to the passage of a catheter. This is apt to be called atony of the bladder due to distension; true this has produced a stretching of the muscle fibre until it is unable to act, but the obstruction is at the neck of the bladder, and is due to the so-called fibroid prostate without obvious enlargement. The condition has been produced as a sequela of a prostate due to gonorrhoea years ago, leaving behind a gland infected with staphylococci in its tubules, and the seat of a chronic imperceptible prostatitis. With the contraction of the fibrous tissue urinary obstruction results. This class of case is nowadays dealt with by fulguration, i.e., diathermy, by means of an electrode burning a path through the prostatic bar, or by the diathermy punch; or the case is subjected to complete enucleation. I have found that the introduction of a lithotrite into the prostatic urethra, and stretching the part by separating the blades, gives a good result lasting for some weeks or months. The operation is simple and is quickly performed. The recovery of the over-distended bladder has to be dealt with, or the result expected will be subject to disappointment. This is a useful operation for any district surgeon, and can be repeated as he is not likely to have the diathermy apparatus alluded to. One thing I would advise is always to have a couple of Pezzer's self-retaining tubes in the hospital equipment ready for suprapubic drainage. A wooden plug inserted into the tubal opening can retain the urine in the bladder for about 2 hours or so, allowing the patient to get about, and the bladder to function; meanwhile a rubber urinal which straps to the leg can be ordered.

THE NUTRITION OF THE LENS AND VITREOUS.

By HENRY SMITH, C.I.E.,

LIEUTENANT-COLONEL, I.M.S. (Retd.),

"Blenheim," Main Road, Sidcup, Kent.

I USE an analogy as introduction which I shall appeal to later on.

What are the functions of the rhythmic contractions of the uterus during pregnancy? It is granted that these exist and are so marked in twin pregnancies as to cause oppressive flushings of the face in the later months; a lot of crude mechanical theories exist to explain them which have no sound basis. The one I advance has, I think, not been advanced by any one else.

A limiting membrane separates the placental sinuses from the uterine sinuses. Through this limiting membrane the nutrition of the foetus

passes in and the waste passes out. The nutrition is presented on the outside of this membrane by the blood stream in the uterine sinuses. Considering the small area of the sinuses, the force conveyed from the heart has not enough power to drive the blood forward into the veins. The uterine contractions come into play, pressing the blood between the relatively incompressible foetal sac and the muscular wall, periodically driving it forward into the venous circulation; hence the periodic flushings are observable. This mechanism under the control of the nervous system periodically fills up the sinuses, leaves the blood long enough in contact with the membrane to become deoxygenated and to take over CO_2 and is then flushed on. These contractions are thus respiratory and nutritional and on them the life of the foetus depends.

In the case of the eye, we have the lens and vitreous each enclosed in its limiting membrane. The nutrient medium for both, I think we are all agreed, is the aqueous humour to which their limiting membranes are exposed, also that the aqueous is secreted by the gland-like cells of the ciliary body. Theorists, of course, dispute whether it is the result of osmotic action or whether it is a true secretion as much as bile is a true secretion. The true secretion view I hold. It admits of the mechanism going out of order and then supplying a pathological pabulum, and hence disease which we know does occur. The osmotic view would necessitate constancy in composition and hence exclude nutritional disease apart from the fact that it would not provide a specialized pabulum.

There is no reason why the lens and vitreous should not take their requirements from the aqueous and give back their waste to it through their limiting membranes, in the same manner as the foetus does to the blood in the uterine sinuses.

This method of nutrition requires a regular circulation of the aqueous. The so-called pump-like mechanism, so clearly demonstrated by Professor Thompson—muscular fibres of the ciliary body acting on the scleral spur and through it on contraction drawing open the slit-like openings of the canal of Schlem and on relaxation admitting it to fall together like a valve—I prefer to call the "sluice-like" action. In principle its action should be periodic to be economic, allowing the nutrient medium a certain time for diffusion and then to pass it on and admit a fresh supply; this the sluice-like action above-mentioned under the control of the nervous system would supply.

I hold that senile cataract and glaucoma are local starvation diseases due to the mechanism which secretes their special pabulum having gone out of order and thus supplying a pabulum which is not physiological. I have demonstrated in a number of papers that an intense hyperaemia induced over the ciliary region re-establishes the function of that mechanism as evidenced by the clearing up of the lens in the early stage of

cataract. I hold that glaucoma is due to a different disorder of the function of that secreting mechanism, supplying a pabulum which induces oedema of the vitreous which, in turn, presses forward the structures in front of it and in this way puts the sluice-like mechanism out of gear—hence intra-ocular tension. If this tension is not controlled, it dominates all other factors. At the present time the treatment of glaucoma is the treatment of the one symptom of pressure and is aimed at nothing else. In practice it is fairly successful. What is its real though not recognised rationale? The organism in health secretes against a pressure of roughly 20 m.m. of mercury; an iridectomy or trephining reduces tension for a number of days much below normal by propping open an artificial sluice gate; Nature endeavours to put up normal tension and cannot do it—hence enormously increased secretion of aqueous which implies the induction of an intra-ocular hyperemia of the secreting mechanism which, in turn, re-establishes its physiological condition. This view, if accepted, would alter fundamentally our conception of glaucoma and its treatment. A mechanical drain for the performance of a physiological function does not appeal to me; if it is too large we have a soft eye, if too small we have a hard eye. We have no means of determining the exact size which will maintain physiological tension. I hold that when iridectomy or trephining is successful, it merely acts until physiological equilibrium of the nutrient mechanism has become re-established after which they have no *raison d'être*.

The view put forward above might imply in glaucoma the induction of an intense hyperemia over the ciliary region, controlling tension, as often as necessary, by tapping the anterior chamber until equilibrium had become re-established.

I now suggest to those in a position to do so:—

(1) To make a careful record of the pulsations of the aqueous, if any, and to compare them with the cardiac pulsations,

(2) a careful analysis of the aqueous in health,

(3) a careful analysis of the aqueous in the early and immature stage of cataract and in acute and chronic glaucoma in the living subject—the pathology of the living; this can be done without the slightest risk to the patient.

NOTES ON THE USE OF CERTAIN PREPARATIONS IN LEPROSY.

By JOHN M. HENDERSON, M.B., Ch.B. (Glas.),

Temporarily in-charge, Leprosy Research, The School of Tropical Medicine and Hygiene, Calcutta,
and

S. P. CHATTERJI, L.M.S.,

Physician to the Albert Victor Leper Hospital, Gobra.

A. *Copper chloride-p-diazoiminobenzene hydrochloride*, prepared by the Wellcome Chemical Research Laboratories.

The use of copper salts in the treatment of leprosy has been advocated by various workers. Takano (1916) records favourable results with Cyanocuprol. Sugai (1916) (1918) treated a number of cases with copper cyanide and with potassium cupro-cyanide with apparent benefit. Matta and Devoto (1922), Rho (1924) and Urbino (1925) claim to have effected decided improvement in their cases from the use of cuprocyan and cuprioidase.

Copper chloride-p-diazoiminobenzene hydrochloride is stated to contain 14.3 per cent. of metallic copper. It undergoes decomposition if kept for any length of time in strong daylight; it is readily soluble in N. saline but the solution is unstable and it must be freshly prepared; moreover the solution cannot be sterilised by heat. It is claimed that the salt itself is sterile and it is recommended that the solution be made up by dissolving gm. 0.02 of the salt in 10 c.c. sterile N. saline: the adult dose is from 1—10 c.c. (representing gm. 0.002—0.02 of the salt given intravenously twice or thrice weekly).

A supply of this copper salt sufficient to test its action on 9 cases was received from the makers. The average duration of treatment in the group was 6.6 weeks with a minimum of 1.7 and a maximum of 19.0 weeks. The results are shown in Table I:—

An analysis of the table reveals the following facts:—

(1) Copper chloride-p-diazoiminobenzene hydrochloride in relatively large doses has the property of stimulating the onset of leprosy reactions. (Cases 2, 3, 5, 6, 8 and 9).

(2) In small doses it is occasionally effective in relieving certain of the local manifestations of the leprosy reaction particularly nerve pains. But this action is apt to be inconstant (Contrast cases 1, 4, 6 and 7). This difference in the action of small and of large doses of the copper preparation with respect to leprosy reactions is one which is apparently common to the heavy metals and similar findings have been demonstrated after the use of antimony and gold.

(3) Apart from its reaction producing power, the particular copper salt tested appears to have no action on the course of the disease even after prolonged and relatively heavy dosage (Cases 2 and 5).

No toxic effects directly attributable either to the immediate or cumulative actions of the preparation were detected during the course of the experiment.

Careful bacteriological examinations carried out before, during and after treatment did not reveal any changes in the numbers or staining reactions of the organisms such as would suggest any direct bactericidal action of the preparation.

B. *Succinol*.—The precise chemical composition of this preparation has not been revealed: it is stated by its originator to be "a complex

TABLE I.
Results of Treatment with Copper chloride-p-diazoiminobenzene hydrochloride.

	Case.	Type.	Dosage.	Total dosage.	Notes.
1	(L. M.)	B ²	gm. 0.004—0.018 thrice weekly.	gm. 0.08	Had persistent pain in both ulnar nerves; this cleared up under small doses of the copper salt. No febrile reactions. Bacteriologically positive at the end of treatment.
2	(I.)	B ²	gm. 0.002—0.02 thrice weekly.	gm. 0.82	Signs and symptoms of leprosy reaction after maximum doses. Bacteriologically positive at the end of treatment.
3	(De la, B.)	B ³	gm. 0.002—0.01 thrice weekly.	gm. 0.08	Signs and symptoms of leprosy reaction after doses above gm. 0.01. Bacteriologically positive at the end of treatment.
4	(C.)	B ² —A ₂	gm. 0.002—0.004 thrice weekly.	gm. 0.06	Persistent leprosy reaction prior to treatment. This reaction proved resistant to the copper salt. Remains bacteriologically positive.
5	(D.)	B ²	gm. 0.002—0.02 thrice weekly.	gm. 1.0	Signs and symptoms of leprosy reaction after maximum doses. Clinically improved, but remains bacteriologically positive.
6	(De. S.)	B ² —A ₂	gm. 0.004—0.008 thrice weekly.	gm. 0.03	Persistent ulnar nerve pains prior to treatment. Unaffected by doses of the copper salt. Signs and symptoms of leprosy reaction in doses above gm. 0.008. Remains bacteriologically positive.
7	(F.)	B ³	gm. 0.004—0.008 thrice weekly.	gm. 0.17	Signs and symptoms of leprosy reaction prior to treatment. These subsided after 3 injections (each of gm. 0.006) of the copper salt. Remains bacteriologically positive.
8	(H.)	B ³	gm. 0.002—0.008 thrice weekly.	gm. 0.03	Signs and symptoms of leprosy reaction after doses above gm. 0.008. Remains bacteriologically positive.
9	(D. T.)	B ²	gm. 0.002—0.02 thrice weekly.	gm. 0.16	Slight local and general reactions after maximum doses. Bacteriologically positive at the end of treatment.

organic compound containing succinic acid." It probably also contains lactic and tannic acids, benzo-quinone, cane sugar, and urea with potassium and calcium in combination.

The preparation is dissolved in sterile distilled water in the proportion of gm. 0.05 per 1 c.c. and the dosage recommended is gm. 0.01 up to gm. 0.2 increasing "according to the strength of the patients and the duration of the disease." The frequency of dosage is not stated: organic

diseases of the heart, lungs, and arteries contraindicate the use of Succinol.

We tested the effect of this preparation on 9 advanced cases of leprosy: intravenous administration was given twice or thrice a week according to the tolerance of the patient. The average duration of treatment in the group was 8.5 weeks with a minimum of 5 and a maximum of 12 weeks.

The results are shown in Table II:—

TABLE II.
Results of Treatment with Succinol.

	Case.	Type.	Dosage.	Total dosage.	Notes.
1	(Z.)	B ³	gm. 0.01—0.2 thrice weekly.	gm. 1.75	Slight flattening of lesions. Bacteriologically positive at the end of treatment.
2	(S. K.)	B ³	gm. 0.01—0.16 thrice weekly.	gm. 4.71	Signs and symptoms of leprosy reaction after first few doses of gm. 0.16. Later doses failed to cause reaction. Bacteriologically positive at the end of treatment.
3	(D. K.)	B ³	gm. 0.01—0.2 thrice weekly.	gm. 3.75	Signs and symptoms of leprosy reaction in doses above gm. 0.08. Bacteriologically positive at the end of treatment.
4	(B. H.)	B ³	gm. 0.01—0.2 thrice weekly.	gm. 5.19	Prolonged leprosy reaction induced after 17 maximum doses. Some clinical improvement. Bacteriologically positive at the end of treatment.
5	(V. M.)	B ²	gm. 0.01—0.2 thrice weekly.	gm. 4.47	Slight clinical improvement. Bacteriologically positive at the end of treatment.
6	(K.)	B ²	gm. 0.01—0.18 thrice weekly.	gm. 1.64	Signs and symptoms of leprosy reaction after every injection. Remains bacteriologically positive.
7	(A. W.)	B ²	gm. 0.01—0.2 thrice weekly.	gm. 3.70	Signs and symptoms of leprosy reaction after every injection. Bacteriologically positive at the end of treatment.
8	(S. Z.)	B ² —A ₂	gm. 0.01—0.2 thrice weekly.	gm. 3.00	Slight leprosy reaction after doses above gm. 0.12. Bacteriologically positive at the end of treatment.
9	(S. D.)	B ²	gm. 0.01—0.2 thrice weekly.	gm. 3.70	Signs and symptoms of leprosy reaction after every injection. Bacteriologically positive at the end of treatment.

Analysis of the table together with a careful scrutiny of the patients' treatment cards brings the undernoted facts into prominence:—

(1) Succinol has the property of inducing leprous reactions (Cases 2, 3, 4, 6, 7, 8 and 9).

(2) No marked clinical improvement could be detected at the end of treatment in any of the cases: there was however slight clinical improvement in 3 cases (Nos. 1, 4 and 5).

(3) All the cases remained bacteriologically positive at the end of treatment: careful bacteriological examinations carried out before, during and after treatment did not reveal any changes in the numbers or staining reactions of the organisms, such as would suggest any direct action of Succinol on *M. lepræ*.

(4) There were no toxic effects directly attributable to the preparation.

C. *Fibrolysin*.—This is a compound of thiosinamine and sodium salicylate manufactured by E. Merck & Co. of Darmstadt: it is claimed for it that it has the property of softening scar tissue. Its use in leprosy has been recommended in a recent communication from Dr. Otto Krause of Bloemfontein. More than two years ago one of us (J. M. H.) in complete

ignorance of Dr. Krause's work carried out a short trial of the preparation on a few selected cases from the Leprosy Out-patient Department of the School of Tropical Medicine, Calcutta, without obtaining any very striking results.

On theoretical grounds only it seems reasonable to imagine that Fibrolysin by breaking down the fibrous tissue surrounding individual lepromata might lay the latter open to the action of anti-leprotic drugs and that hence it might be an important adjuvant in treatment: we determined therefore to carry out a more extended series of trials.

Fibrolysin is put up in ampoule form ready for use (after warming slightly): the dose recommended is 1 to 2 ampoules (2.3 to 4.6 c.c.) twice weekly by intramuscular injection. The preparation was tested on 17 different patients at the School of Tropical Medicine and at the Albert Victor Leper Hospital. The group of cases selected was a representative one comprising patients in all types and stages of the disease. The average duration of treatment in those who finished the course (14 in all) was 8.2 weeks with a minimum of 7 and a maximum of 10.

The results are shown in Table III:—

TABLE III.
Results of Treatment with Fibrolysin.

	Case.	Type.	Total dosage.	Notes.
1.	(M.)	A ₁	29.9 c.c.	Given with potassium iodide gr. 240 twice weekly. Headache, giddiness and pain lasting 24 to 48 hours after 2 ampoules of Fibrolysin. No other local or general effects.
2.	(P.)	A ₁	46.0 c.c.	Ditto.
3.	(S.)	B ²	(a) 52.9 c.c. (b) 82.8 c.c.	This patient though strongly positive bacteriologically has never shown signs of reaction under any treatment. Course (b) combined with potassium iodide gr. 240 twice weekly: no local or general effects. Bacteriologically positive at the end of treatment.
4.	(M. A. S.)	B ²	23.0 c.c.	Two ampoules twice weekly caused rise of temperature up to 100°F. for 1 day with tremors and giddiness. Left hospital before completing treatment. Remaining bacteriologically positive.
5.	(K. B.)	A ₂	32.0 c.c.	Given with potassium iodide gr. 30 to 60 twice weekly. Fibrolysin alone caused pain and giddiness. Potassium iodide alone no giddiness. Discharged before treatment completed.
6.	(S. P.)	B ³ —B ³	59.8 c.c.	Given with potassium iodide gr. 8 twice weekly, caused reaction and temperature of 101°F. for 1 day. Fibrolysin 2 ampoules alone no reaction pain or giddiness. Potassium iodide alone—reaction and temperature of 101°F. Remains bacteriologically positive at the end of treatment.
7.	(C. M.)	B ³ —A ₂	27.6 c.c.	Given with hydnocarpus oil 7 c.c. twice weekly, caused reaction and temperature 100.8°F. for 4 days. Fibrolysin alone—no reaction but pain and giddiness. Bacteriologically positive at the end of treatment.
8.	(D.)	B ²	4.6 c.c.	Given with potassium iodide gr. 6 twice weekly. Giddiness and pain after injection. Treatment cut short on account of hæmorrhoids and anæmia.

TABLE III—(contd.).

	Case.	Type.	Total dosage.	Notes.
9.	(R. D.)	B ³ .	55.2 c.c.	Given with potassium iodide gr. 12, caused temperature of 100°F. for 1 day. Fibrolysin (4.6 c.c.) only, no rise of temperature. Pain and giddiness after injection. Bacteriologically positive at the end of treatment.
10.	(Mn.)	A ₂	62.1 c.c.	Given with potassium iodide gr. 240 twice weekly, caused headache, sickness and vomiting. Potassium iodide alone gr. 240 twice weekly, no symptoms. Fibrolysin alone (4.6 c.c. twice weekly), caused vomiting and headache. No change clinically.
11.	(A.)	B ³	20.7 c.c.	Given with potassium iodide gr. 5 twice weekly, caused reaction and temperature of 100.2°F. for 2 days with giddiness. Fibrolysin alone caused rise of temperature up to 100°F. for 1 day with weakness and giddiness. Bacteriologically positive at the end of treatment.
12.	(G. S.)	B ³	41.4 c.c.	Given with oil of <i>Hydnocarpus wightiana</i> 8 c.c. twice weekly and potassium iodide gr. 240 twice weekly. No reaction, pain or giddiness. Still slightly positive bacteriologically at the end of treatment.
13.	(B. M.)	B ³ —B ²	27.6 c.c.	Given with potassium iodide gr. 30 to 45 twice weekly. No fever: giddiness and vomiting especially after 2 ampoules. Bacteriologically positive at the end of treatment.
14.	(S. A.)	B ²	52.9 c.c.	Given with oil of <i>Hydnocarpus wightiana</i> 8 c.c. twice weekly. No fever: pain and giddiness especially after 2 ampoules. Bacteriologically positive at the end of treatment.
15.	(A. F.)	B ³	59.8 c.c.	Given with oil of <i>Hydnocarpus wightiana</i> 7 to 9 c.c. twice weekly. No fever: giddiness and vomiting after 2 ampoules. Flattening of nodular lesions. Bacteriologically positive at the end of treatment.
16.	(R. D.)	A ₂	39.1 c.c.	Given with potassium iodide gr. 240 twice weekly. Fever on one occasion, 101°F. for 2 days. Giddiness, headache and occasional vomiting after injection.
17.	(B.)	B ²	41.4 c.c.	Given with potassium iodide gr. 10 twice weekly. Caused reaction with temperature of 102°F. for 1 day. Fibrolysin alone, no fever but giddiness after each injection. Bacteriologically positive at the end of treatment.

A study of the table reveals certain features of interest.

(1) In only two cases (Nos. 4 and 11) could Fibrolysin be said to have any direct action on the foci of the disease, as evidenced by signs and symptoms of leprous reaction.

(2) Its action as an adjuvant to potassium iodide in breaking down leprous granulation tissue is negligible. Cases showing signs and symptoms of leprous reaction under a combined course of Fibrolysin and potassium iodide failed to show such manifestations when the latter component was omitted: when potassium iodide alone was employed, the same signs and symptoms appeared as with the combined treatment. It is obvious therefore that potassium iodide is the active constituent (Cases 6, 9 and 17). The same is true of the combined use of Fibrolysin and hydnocarpus oil: the latter is the active constituent.

(3) Cases in the non-reacting phase of the disease when under treatment with other

preparations did not pass into the reacting phase when Fibrolysin was added. The claim that this preparation by breaking down fibrous tissue renders resistant cases accessible to treatment does not therefore appear to be substantiated.

(4) Fibrolysin has no direct action on *M. lepræ*: bacteriological examinations carried out before, during and after treatment showed little alteration in the numbers, size, shape or staining reactions of the organisms.

(5) Fibrolysin in many instances manifests certain undesirable side effects such as pain, vertigo and vomiting, especially in doses of 2 ampoules and upwards (All cases except Nos. 3, 6 and 12).

Summary and Conclusions.

(1) The results obtained at the School of Tropical Medicine and Hygiene, Calcutta, and at the Albert Victor Leper Hospital, Gobra, from the use of three different preparations have been briefly recorded and analysed.

(2) Of the three preparations in question, Copper chloride-p-diazoiminobenzene hydrochloride and Succinol appear to have some power inducing the onset of leprosy reactions when used in relatively large doses. In virtue of this "lytic" effect on the leprosy granulation tissue they may be of some assistance as adjuvants in the treatment of the disease. Their reaction producing power is however definitely inferior to that of potassium iodide. Fibrolysin in the amount and frequency of dosage used by us appears to be without action on leprosy granulation tissue.

(3) None of the preparations has any direct action whatsoever on the organismal cause of this disease—*M. lepræ*.

(4) No toxic effects directly attributable to either preparation were noted in the cases of the copper salt and Succinol: the use of Fibrolysin, however, causes certain unpleasant sequelæ, viz., pain at injection lasting up to 48 hours, headache, vertigo, vomiting and sometimes tremors.

We are indebted to Dr. T. A. Henry, the Wellcome Chemical Research Laboratories, London, for a supply of the copper salt and to Dr. Misra of Darbhanga for a generous consignment of his preparation Succinol.

A SIMPLIFIED BED-SIDE BLOOD-SUGAR METHOD.

By HARENDRA NATH MUKHERJEE, B.Sc., M.B.,
 D.L.C. (Lond.),

(Biochemical Department, Carmichael Medical College,
 1, Belgachia Road, Calcutta.)

THE introduction of micro-chemical methods during recent times, combining both simplicity and accuracy, for the estimation of blood-sugar, has rendered this important test available to the medical profession. But even so, practically all the blood-sugar methods require considerable laboratory facilities and are not suitable for application at the bed-side and in the mofussil.

Since the introduction of insulin and the modern developments in the diagnosis and treatment of diabetes, the estimation of blood-sugar has become essential in this disease. The blood-sugar question is, thus, of such importance in medical practice that it is considered worth while to evolve a method which could be applied at the

bed-side requiring no other apparatus but what a medical practitioner is expected to possess.

In the present paper a method is described which meets the above purpose. In this method advantage has been taken of the new blood-sugar reagents recently introduced by Folin (1928) of whose method it is a modification. The sugar is oxidised with alkaline potassium ferricyanide and the ferrocyanide produced is measured colorimetrically as Prussian blue. The colour obtained is nearly 5 times as deep as the colour obtained with the alkaline copper solutions.

The results obtained by the present method are fairly accurate for clinical purposes and the technique is so simple that it can be easily mastered in a short time. The quantity of blood necessary for the test is extremely small and can be conveniently drawn from a finger prick by means of a hæmocytometer pipette (up to 0.5 mark only).

Reagents.

1. Tungstic acid reagent:—This is prepared by diluting a mixture of 20 c.c. of 10 per cent. sodium tungstate and 20 c.c. of 2/3 N. sulphuric acid to a volume of 1 litre with distilled water. Add a little toluene as a preservative.
2. Potassium ferricyanide solution:—0.2 per cent. solution in distilled water. The solution should be kept in the dark.
3. Sodium cyanide-carbonate solution:—Prepared by dissolving 8 gms. of anhydrous sodium carbonate and about 1.5 gm. of sodium cyanide in 500 c.c. of distilled water.
4. Ferric sulphate solution:—30 gm. of gum arabic is dissolved in about 600 c.c. of water by heating on the water bath. 5 gm. of ferric sulphate is dissolved separately in 75 c.c. of 85 per cent. phosphoric acid and 100 c.c. of water by means of heat. Allow the solutions to cool and then mix them together and dilute to a volume of 1 litre with distilled water.
5. Standard glucose solution:—0.1 per cent. solution of chemically pure glucose in saturated solution of benzoic acid in water. A little toluene may be added to it.
6. Distilled water.

All these reagents, if kept properly, have good keeping qualities. They can be easily prepared in any chemical laboratory and stocked for later use.

Apparatus.

1. Test-tubes 4
2. 25 c.c. graduated cylinders—(of the same size and make) 2
3. One mark capillary pipette with attached rubber tubing and mouth-piece 1
 (The pipette in Sahli's hæmoglobino-meter or a hæmocytometer (W.B.C.) pipette will do).
4. An aluminium vessel or an ordinary glass beaker to serve as a water bath.
5. One spirit lamp with tripod stand.
6. Strips of filter paper.

Estimation of blood-sugar.

With the pipette draw the standard sugar solution (0.1 per cent.) up to the mark. (If a hæmometer pipette is used it is quite sufficient to draw up to the 0.5 mark). Wipe off the outside of the pipette with a piece of filter paper. Blow out the sugar solution completely on a small piece of filter paper. Put this piece of filter paper in a test-tube marked "S." It is not necessary to wash the pipette after this. With the same pipette draw blood up to the same mark in the usual way from a finger prick. Wipe off the blood on the outside of the pipette with a piece of filter paper. Then blow out the blood completely on another small piece of filter paper. Put this piece of filter paper in a test-tube marked "U." We have now exactly the same volumes of the standard sugar solution and of blood in the two test-tubes "S" and "U." If the pipette of Sahli's hæmoglobinometer is used this volume is only 20 c.mm. (i.e., 1/50th of a c.c.).

Put the two test-tubes "U" and "S" in the boiling water bath for 2 minutes. Then with a graduated cylinder add about 5 c.c. of the tungstic acid reagent to each of the test-tubes. Allow to remain in the boiling water bath for 5 minutes. Then take them out and by means of a glass rod or a clean piece of wire remove the pieces of filter paper. Care is taken to remove as little of the liquid as possible with the filter paper. Not more than 3 or 4 drops are lost in this way which is negligible from a practical standpoint. To each of the test-tubes then add with a graduated cylinder 1 c.c. of the potassium ferricyanide solution and 1 c.c. of the carbonate cyanide solution. Put the test-tubes in the boiling water bath again and allow to remain for 7 to 8 minutes. Then remove and cool. Add 3 c.c. of the ferric sulphate solution to each of the test-tubes. Mix by gentle shaking and let them stand for 5 minutes when the colour of Prussian blue develops.

Pour the contents of the test-tube marked "S" into one of the graduated cylinders and mark it "S." Similarly pour the contents of "U" into the other cylinder and mark it "U." Dilute both "S" and "U" up to the 10 c.c. mark by adding a few drops of water if necessary.

The intensity of colour in each cylinder is proportional to the amount of sugar present.

Calculation.—The sugar is determined colorimetrically by what is known as a "test-tube colorimeter"—a well known procedure when a regular colorimeter is not available. If the colour of the solutions in "S" and "U" match each other exactly when made up to the same volume, then "U" contains the same amount of sugar as the standard "S," i.e., the blood-sugar in this particular case is 0.1 per cent. If the colour of "U" is deeper than that of "S" then go on diluting "U" by adding water drop by drop carefully till the colours of "S" and "U" match

correctly. The blood-sugar is given by the following formula:—

$$\text{Blood sugar (in per cent.)} = \frac{x \text{ (dilution or total vol. of solution in "U")}}{10 \text{ (total vol. of solution in "S")}} \times 0.1$$

Example.—If "U" had to be diluted up to the 22 c.c. mark to match correctly with "S" (vol. 10 c.c.) then blood-sugar = $22/10 \times 0.1$ per cent. = 0.22 per cent.

In diabetics having blood-sugar contents higher than 0.25 per cent., i.e., when the colour of "U" even after diluting up to the 25 c.c. mark is still deeper than that of "S" proceed as follows: Dilute "U" up to the 25 c.c. mark then discard half of the liquid (12.5 c.c.) and again go on diluting till exact colour match with "S" results. In this way the unknown "U" can be diluted 2×2.5 times and we can estimate a blood-sugar content up to 0.5 per cent. For still higher blood-sugar contents the unknown should be diluted even further.

In normal individuals and in hypoglycemia when the sugar content of "U" will be less than 0.1 per cent. go on diluting "S" till the colour of "S" matches exactly with that of "U,"—"U" being kept at the original volume of 10 c.c. The blood-sugar is given by the following formula:—

$$\text{Blood-sugar (in per cent.)} = \frac{10}{x \text{ (dilution in "S")}} \times 0.1$$

Example.—"S" had to be diluted to the 20 c.c. mark to match correctly with "U" (Vol. 10 c.c.) then blood-sugar = $10/20 \times 0.1$ per cent. = 0.05 per cent.

RÉSUMÉ OF THE METHOD.

Standard ("S").

(1) With a capillary pipette draw 0.1 per cent. glucose solution up to mark (a Sahli hæmoglobinometer pipette or a W.B.C. pipette will do). Blow out the solution on to a piece of filter paper and put this piece of filter paper in a test-tube marked "S."

(2) Put test-tube "S" in a boiling water bath for 2 minutes. Then add about 5 c.c. of the tungstic acid reagent and let remain in boiling water for 5 minutes more.

(3) Remove the piece of filter paper with a glass rod and add 1 c.c. of the potassium ferricyanide solution and 1 c.c. of the carbonate cyanide solution and let remain in boiling water for 7 to 8 minutes more. Then take out and cool.

(4) Add 3 c.c. of the ferric sulphate solution, let stand for 5 minutes and then pour the contents of "S" into cylinder marked "S" and dilute to 10 c.c. mark.

Unknown ("U").

(1) With the same capillary pipette draw blood from a finger prick up to mark. Blow out the blood on a piece of filter paper which is then put in a test-tube marked "U."

(2) Steps 2 to 4 same as in the left hand column. The contents of test-tube "U" are finally transferred to a cylinder marked "U" and diluted to a volume of 10 c.c.

Then compare "S" and "U" colorimetrically by means of what is so commonly known as a "test-tube colorimeter."

Summary and Conclusion.

1. A simplified blood-sugar method applicable at the bed-side and in the mofussil is described.

2. The advantages of this method are:—

- (1) No special apparatus is necessary.
- (2) A very small amount of blood (about 1/50th of a c.c.) from a simple finger prick is sufficient.

Milking or squeezing the finger for blood is not only unnecessary but should be avoided as the blood becomes mixed with tissue-fluid.

(3) The collection of the blood with the capillary pipette is extremely simple and familiar to most practitioners. A W.B.C. pipette can very well be used for the purpose.

(4) The manipulations are quite simple and can be mastered easily.

(5) The results obtained are quite accurate for clinical work.

AN EASY METHOD OF DRAINING IN-ACCESSIBLE SUPPURATING CAVITIES.

By S. RAMA IYER, L.M. & S. (Mad.).

Viceroy's Honorary Assistant Surgeon, Civil Surgeon, Thaton.

Method.

Fit the nozzle of a 4 oz. or 8 oz. glass syringe into a Jacques' catheter of the required size and charge the catheter and the syringe with weak iodine solution. Introduce the catheter into the bottom of the cavity to be drained. Inject the solution slowly into it and draw the contents of the cavity into the syringe. Take the syringe out, leaving the catheter still in the cavity, and throw out its contents into a bucket close by. Charge it again with the iodine solution and refit the syringe into the catheter now in the cavity and draw out its contents again into the syringe and throw them out into the bucket. Repeat the process 6 to 8 times until the contents drawn from the cavity are nearly of the same colour as the solution injected. While so doing, it may be necessary to withdraw the catheter a little and change its direction to ensure thorough drainage of the cavity. Before drawing out the catheter finally, see that some solution is left in the cavity to prevent sudden withdrawal of pressure on the blood vessels and other structures which are in relation with the cavity. This precaution is especially necessary when one is dealing with pus in the pleural cavity to prevent air from being sucked into it.

It is needless to state that the catheter, syringe and the solution should all be sterile and the operation carried out with strict attention to surgical cleanliness.

The strength of the iodine solution used is 1 in 80. For practical purposes, it is enough if the dilution made is of faint brown tint.

How the Method evolved.

Case No. 1.

On 13th May 1927, a Chinese boy, 15 years old, called Eng Soung was brought in a country cart to the Civil Hospital, Thaton, with a big penetrating wound of the pleura. It was 4 inches long and 2 inches broad and extended transversely from the middle line of the chest in front at its upper part towards the right. The 1st and the 2nd right intercostal spaces were involved in it. The whole thickness of the 2nd right rib and the right half of the sternum were cut into.

The wound tailed off for three inches at its right end. There was copious extravasation of blood into the pleural cavity and air was entering and escaping noisily. To control bleeding and prevent air from being sucked in, the wound had been wrapped up with dirty clothing. The boy was wounded by dacoits about 11 hours prior to his admission into the hospital. His condition on admission was alarming. His pulse and breathing were bad and he was low. His dying declaration was arranged to be taken immediately. The wound and its neighbourhood were scrubbed with spirit and painted with tincture of iodine. The blood in the pleural cavity was sponged. Edges of the wound were everted and carefully cleansed. To arrest bleeding from the 2nd intercostal artery, the wound was packed on the principle of Desault's method. Two days later, this plug was removed and the wound sutured. But the sutures gave way in a couple of days and the wound began to discharge pus and it became a case of empyema of the right pleural cavity. Pus had accumulated up to the middle of the scapula behind. The patient was too low to stand resection of the rib. A drainage tube to reach the bottom of the cavity was introduced and as much pus as possible was withdrawn by fitting a glass syringe into the outer end of it. The wound was dressed by leaving the tube inside the cavity besides introducing alongside it long strips of gauze for purposes of drainage. The patient was also given his own pus internally.

Mr. John, Sub-Assistant Surgeon, who used to dress the case improved the withdrawal of pus by replacing the rubber tube with a Jacques' catheter of suitable size. The patient, however, did not benefit much from this treatment. His condition grew worse and the temperature began to rise steadily and his breathing became hurried and difficult. A desperate attempt was therefore made to resect the 8th rib in the mid-axillary line under local anaesthesia consisting of cocain, morphia and adrenalin hydrochloride in order to establish free drainage at the dependant part, but it was in vain since the patient developed signs of cocain poisoning. The operation was stopped and the patient was with great difficulty revived.

These circumstances led to the adoption of the method described above and the result was very gratifying. The temperature began to go down, discharge of pus became reduced, the patient's condition steadily improved and he was eventually discharged completely cured on 22nd September 1927, with a big depression below the right clavicle. The breath sounds over this depression and the remaining part of the right side of the chest were, however, quite audible, the only difference between the right and left sides of the chest being that the patient was exercising the muscles of the left side more than those on the right side.

Encouraged by this result I started applying this method in other cases also, and I give below notes of some of them. The results obtained were excellent and happier than those I used to get, especially in the case of joints, by making a counter-opening and flushing them with lotions, such as eusol, weak iodine, normal saline, etc.

Case No. 2.

Muthukarapan, Hindu, cultivator, 22 years old, was admitted into Thaton Civil Hospital on 30th November, 1927, for multiple severe *dah* cut wounds. One of them was on the top of the right shoulder, 7 inches \times 4 inches, communicating with the joint. The tip of the acromion process had become severed. The wound was stitched and an India-rubber tube put in at the dependent part for drainage. Pus formed in the joint in a couple of days.

Flushing the cavity every day through this tube with eusol solution and two intravenous injections of iodine solution given every third day did not have much effect on the temperature which was ranging in the evening between 103.4° and 102.0°F. till 9th December, 1927, when the Thaton Hospital method of draining inaccessible cavities was adopted with the result that temperature began to fall, discharge became less and the wound healed up completely before 6th January, 1928.

Case No. 3.

Panu, an Oriya cooly, who was working in Mokpalin stone quarry in Thaton District, met with an accident on account of a landslip while working at a height of about 25 feet from the ground and hurt his knee. On admission into Thaton Hospital on 12th June, 1928, he had besides two minor injuries on his left leg a triangular-shaped lacerated wound in front of his right knee with its apex directed upwards. Its sides were each 2 inches long and its base was 3 inches long. It was communicating with the interior of the joint. The ligamentum patellæ was torn. The lower end of the patella and the tip of the external condyle had become detached. In spite of thorough cleaning of the wound pus appeared in the joint on the second day after admission. Draining of the joint after the Thaton Hospital method was immediately started. Temperature became reduced and disappeared altogether in a

fortnight's time. The wound became filled up with granulation tissue by 7th July, 1928. The patient was thereafter kept in the hospital for the wound to become completely dry and to help the patient to get the full use of the joint.

THE DIAGNOSTIC VALUE OF A MONOCYTOSIS.

By H. R. DUTTON, M.R.C.P. (Lond.),
LIEUTENANT-COLONEL, I.M.S.,
D.T.M. & H. (Camb.),

Professor of Medicine, The Prince of Wales Medical College, Patna.

FROM a perusal of many works on differential diagnosis and leucocytosis, I have been struck with the insignificant place given to an increase in the monocytes of the blood as an aid to diagnosis, whereas in actual practice I have found this feature of a blood picture of very great diagnostic value either as (1) being a sign of a protozoal infection, or (2) in its absence as an indication that no protozoon is present. The fact that an increase in the monocytes occurs in protozoal diseases is well known but probably several factors have operated to militate against its more extended use as an aid to diagnosis. Foremost amongst these is the classification of the non-granular or hyaline cells. These include lymphocytes, large mononuclears and transitionals (Ehrlich). Confusing the issue are many names, such as "pro-monocytes" (Hittmair) "monoblasts" (Ferrata), "monocytes" (Wright). For the purpose of accurate differentiation it is essential for the observer to have a definite classification and to maintain this in all counts. The method I have found most satisfactory is to group the large mononuclears and the transitionals together as monocytes, owing to the difficulty sometimes of determining the differences between them. The normal standard count for large mononuclears can be taken as 1 per cent. and transitionals 2 to 4 per cent. (Ehrlich). A normal percentage of large mononuclears and transitionals combined should not exceed 4 per cent. (Stitt). Not less than 300 leucocytes must be counted and great care is needed to distinguish between large lymphocytes and monocytes. 5 per cent. and over of monocytes will constitute monocytosis, using as a stain any modification of Romanowsky. The distinctions between large lymphocytes and monocytes are as follows:—

Large lymphocytes—the cytoplasm is a clear translucent pure blue; it may contain pinkish granules known as azur granules, but these are of rather large size and do not mar the glass-like appearance. They are from 12 μ to 15 μ in diameter and possess a round nucleus taking a fairly deep rich violet stain.

Monocytes—these are large round irregular or oval cells with a nucleus which is frequently irregular in outline or shows indentations or is sometimes horseshoe-shaped. There is not that sharp distinction between nucleus and cytoplasm that exists in lymphocytes. The cytoplasm gives

the impression of opacity, as if it were frosted glass instead of clear glass and is pale washed out lilac in colour. The nucleus does not stain well and is of a washed-out violent shade (Stitt).

The large mononuclears are considered to have great phagocytic activity and the terms "clasmatoocytes," "macrophages" and "fibrocytes," have been applied to these cells. In the tropics, therefore, where protozoal diseases are so prevalent it can be readily understood why there should be a monocytosis, this being a direct offensive attack of the body reacting to the stimulus of a protozoal infection in contradistinction to a polymorphonuclear leucocytosis reacting against bacterial infection.

A monocytosis having been established it now remains to discover the particular protozoon giving rise to it. It must not, however, be forgotten that in variola, in dengue, about the 4th day in cholera, normally in infants, in diphtheria, in measles, in acute rheumatism, in German measles, in paratyphoid fever about the 10th day (Piney and Berrie), and in exophthalmic goitre (Piney) some degree of monocytosis occurs, varying from 8 to 50 per cent. I need not point out that all these conditions and diseases have definite clinical manifestations and, therefore, present no difficulty or doubt whilst the active disease is present, but when the temperature still persists, it may be only a degree or two, after the active disease has ceased or in any other obscure condition when a monocytosis is present, a protozoon may be suspected and should be searched for. It is common knowledge that any active disease may cause a latent protozoon to develop, the commonest in India being probably the malarial. Numberless blood films may be searched and no malarial parasites be found, yet a judicious administration of quinine will quickly bring the temperature to normal and it will stay there. If this does not happen it may be leishmaniasis in which case there will be some leucopenia in addition to the relative monocytosis, and the "urea-stibamine test" will be positive, or amœbiasis when the reaction of the faeces will be acid and either the vegetative forms or cysts of the *Entamœba histolytica* will be found and possibly some Charcot-Leyden crystals. Again how often one sees cases complaining of pain in the right hypochondrium and on examination finds some hepatic enlargement. The absence of a monocytosis definitely excludes amœbic hepatitis, although, often a history of "dysentery" is obtained, whereas the presence of a monocytosis is eminently suspicious of a protozoal infection and a further search will bring the cause to light.

An example of this has recently been under my care of severe pain in the right flank and right hypochondrium with a patch of pleurisy over the centre of the lower part of the middle lobe of the right lung. A differential leucocyte count showed only 2, i.e., 1 per cent., monocytes. The stool contained a small quantity of mucus, and the daily temperature varied between 100 to 102°F. The injection of 4 grs. of emetin

showed no result whatever. Had the cause been *E. histolytica*, a definite amelioration of symptoms would have taken place. As a matter of fact the case proved to be one of pyelonephritis and staphylococcal septicæmia. In another case there was severe pain over the right hypochondrium, slight daily rise of temperature, pyelonephritis and the passage of much mucus with the stools. Daily examinations for many weeks of the stools failed to reveal the *E. histolytica*, although there was a definite history of previous attacks having been stopped by injections of emetin. A differential leucocyte count showed only 3.5 per cent. monocytes. In spite of this, emetin injections, emetin periodide and Stovarsol were given without any improvement whatever. The case proved to be coli pyelonephritis and cystitis and mucous colitis. In another case with splenomegaly, leucopenia and some anæmia with the "urea-stibamine" test positive, but the "formol-gel" test negative, monocytes were only 1 per cent. The case proved to be splenic anæmia.

As a routine measure, a differential leucocyte count is carried out in all my cases in the wards and I daily demonstrate the proof of the diagnostic value of a monocytosis occurring in uncertain fevers, enlarged spleens, anæmia, diarrhoea, headache, abdominal pains, neuralgias and many other conditions of doubtful origin, by finding the protozoon responsible and giving the appropriate parasiticide. Often a valuable pointer is given to the "accès pernicieux" of subtertian malaria, which may simulate heatstroke, coma, epileptic convulsions, delirium, apoplexy, appendicitis and cholera. Timely quinine will save the case where nothing else would and after all is said and done a differential leucocyte count does not take very long or overmuch skill.

In conclusion I again emphasize the value of a differential leucocyte count and especially of a monocytosis, 4 per cent. being considered the healthy average, 5 per cent. suspicious, and 6 per cent. and over proof, except in certain specified conditions, of a protozoal infection.

A SIMPLIFIED TECHNIQUE FOR CULTURING MALARIAL PARASITES AEROBICALLY.*

By R. ROW, M.D. (Lond.), D.Sc. (Lond.), M.R.C.P., O.B.E.,
Professor of Pathology, Grant Medical College, Bombay.
From the P. D. Petit Laboratory, Byculla, Bombay.

To Bass belongs the credit of demonstrating for the first time that malarial parasites can be cultured in vitro: Bass and later on Bass and John's technique being complicated, the author of this memoir devised and published the details of a simplified technique for culturing hæmosporidia where one could operate even with small quantities of infected blood. Later, Sinton described a similar but a more elaborate method

* This paper forms a part of the investigation undertaken under the auspices of the Indian Research Fund Association "1927-1928."

where he used hydrocele fluid in the place of blood serum. All these methods yield only one good culture, and although a continued sub-culture appears theoretically simple, in practice, it always ends in failure; the reason for this will be described in a separate memoir. A satisfactory growth of the parasites even in the first and the only culture, being the important thing for an accurate study of the developmental and

was a relief to find that although with a constant temperature of 40°C. one could obtain various stages of development with almost mathematical accuracy, the laboratory temperature yielded cultures, which, while of distinctly slower growth, were otherwise quite good both in richness and quality.

This slightly delayed development was found to be even of some advantage as it gave one

Fig. I. A & B.

FIG. I: *Plasmodium falciparum*.

Fig. I. C.

- " A. 48 hours culture.
 " B. 72 hours culture.
 " C. 72 hours culture, phagocytosis.

All these were seen in one field.

other details, it was found desirable further to simplify the technique in such a way that one could plant the culture tubes even at the bed-side and handle the culture subsequently at ease. The first thing to ascertain was if one could do away with the use of uniform temperature, e.g., that of the incubator, and depend on the laboratory temperature in Bombay, 87° to 90°F., and it

more time and greater ease for observation; thus the malignant tertian parasites took 72 hours or more, from the ring stage to complete schizogony, instead of 48 hours, and the benign tertian required 48 hours or more instead of 32 hours, when left outside the incubator.

The second more important detail was to see the effects of eliminating the anærobic part of

the apparatus and putting up the culture in a stand and to our surprise this procedure had hardly any deleterious effect on the yield or quality of the culture. The essential requisites for a culture are the flat-bottomed micro-culture tubes, described in the previous memoir, and an adequate mixture of glucose solution in the nutrient medium which consists of a serum not necessarily fresh or autogenous.

The flat-bottom in a culture tube seems to afford the best chance for the blood corpuscles to be deposited in a thin layer where the parasites develop better in open formation than in the crowded and dense deposit as is obtained in

FIG. II.

FIG. II: *Plasmodium falciparum* 24 hours.
All seen in one field; chemiotaxis.

FIG. III a.

a round-bottom test-tube. Further, the leucocytes which are inevitably introduced get far less chance for phagocytosis of developing forms when they are sparsely distributed on the surface of this parasite-laden layer, than when massed together as they are in a test-tube; and the shape of the culture tubes is admirably suited to give the largest surface for the deposit with the best economy of the glucosed blood serum.

The following is the method in detail:—

1. Prepare previously (one or two days or even longer) a series of culture tubes ready for planting, i.e., by charging these with glucosed serum $\frac{1}{2}$ inch deep.

2. Puncture finger and with a pipette collect 3 or 4 drops in a sterile test-tube; shake this vigorously so as to defibrinate the blood taken.

3. Introduce one or two drops of this defibrinated blood into each of the micro-culture tubes. Set these upright in a stand, and put this stand away in a dark place.

All manipulations are to be carried on aseptically.

The deposit is ready for examining 12 to 24 hours, etc., after the planting.

FIG. IIIb.

FIG. III: *Plasmodium vivax*.

PLASMOQUIN IN THE TREATMENT OF MALARIA.

By PASUPATI BHATTACHARYYA,
D.T.M. (Bengal),

Bacteriologist, Police Hospital, Calcutta,
and

S. P. ROY CHOWDHURY, L.M.P.,
House Physician, Police Hospital, Calcutta.

THE Calcutta Police staff, like the Calcutta public, are not free from attacks of malaria, and more than 10 per cent. of all the cases admitted into the hospital with fever prove to be malarial infections. Although it is more common among the new recruits who generally come from up-country, it is also found to occur among such members who have not been out of the city for years together. Some of these get relapses in spite of treatment and have to be admitted into the hospital again and again. To avoid these relapses the routine treatment adopted here for every case is to give an initial purge and then a course of quinine or cinchona febrifuge, 30 grains daily in three doses for seven days, the fever generally subsiding within a day or two, and then after a period of interval for 3 or 4 days without quinine, another purge followed by a

second course of quinine or cinchona treatment in similar doses for about 7 days, before the patient is discharged. One cannot keep these people off-duty for any great length of time, so this plan of treatment was introduced by Major J. C. De to get the maximum effect within a minimum amount of time, and in most cases it answered very well. Of course, all possible precautions were taken to see that the quinine was actually taken in each case. The mixtures were administered by the compounders often in the presence of medical officers and each patient's urine was tested for quinine by Major De himself. There was no escape from taking quinine because everybody knew that he would be punished if his urine was found to contain no quinine. Relapses were now fewer than before, but yet there were cases that would relapse in spite of all precautions. These were generally benign tertian (*P. vivax*) infections. Since such promising reports were published about Plasmoquin and its superiority over quinine in the treatment of benign tertian and quartan malaria and their relapses, and also about its effects on the malignant tertian crescents that are not amenable to quinine (*Ind. Med. Gaz.*, August, 1927), it was at once decided to test this drug in our hospital only in suitable and selected cases, such as the obstinate relapses and the crescent-carriers. For this purpose, only the pure Plasmoquin tablets

gr. 1/3 each, were used. Each case was definitely diagnosed before being chosen for trial and the results were recorded by regular temperature charts and repeated examinations of blood in thick and thin films. Some private patients were also treated in the same way later on by one of the writers and the results were recorded, being of special interest. The reports of these cases are given here in tabulated form, the temperature charts have been intentionally omitted, and notes on cases of special interest are given below the tables.

Case No. 1 had been admitted 5 times for relapses and parasites were found each time in spite of regular treatment. He had enlargement of liver and persistent jaundice each time. During the last relapse, Charcot-Leyden crystals were found in the stools, and besides the quinine treatment he was given 18 injections of emetin gr. ½ each. The fever still continuing, 2 injections of quinine bihydrochloride grs. 10 each, intramuscularly, and later on 3 more injections were given. After all this, the fever dropped but jaundice persisted. Plasmoquin was now given and the jaundice gradually disappeared after this. He has had no relapse of fever since then.

Case No. 10 was suffering from fever for about 2 months and was treated for kala-azar in the mofussil on clinical diagnosis. Blood examination revealed the presence of benign tertian

25	H. M. 35	Indefinite		8	..	8 "	1	No relapse.

trophozoites. Plasmoquin was given for 3 days only. On the 5th day she took it on an empty stomach in spite of warning, and began getting violent cramps in the abdomen. Plasmoquin was discontinued forthwith and the pain disappeared. It was tried again after 2 days and the cramps appeared again. The treatment was, therefore, abandoned and no quinine was given, but she has had no more fever since then. The patient was of marked neurotic temperament.

Case No. 15 was originally a case of kala-azar and was being treated with injections of ureastibamine. He had a latent malignant tertian infection which flared up with a sharp rise of temperature towards the end of treatment when he had been altogether afebrile, and malignant tertian rings and crescents were found in the peripheral blood. The total W.B.C. count at this time was 3200 per c.mm. After giving him quinine for 4 days, Plasmoquin was administered for 10 days with an interval of 3 days, to get rid of the crescents. After Plasmoquin, the W.B.C. count rose to 6200 per c.mm.

Case No. 20 came in for treatment of blackwater fever that had followed a dose of quinine. After the usual measures and alkaline treatment, this condition was cured but he began getting fever again. He was given half a tablet of Plasmoquin Co. (Plasmoquin g. $1/24$ + Quinine gr. $\frac{1}{2}$) every 6 hours, and the dose was cautiously increased till after 3 days he could tolerate 3 tablets at a time thrice daily without showing any symptoms.

The fever was normal from the 5th day and this dose was maintained for two weeks without any break.

Case No. 23 a child was brought with history of fever for 4 months, intense anæmia, spleen and liver $++$. He had had no quinine treatment so far and would take no bitter medicine. Numerous benign tertian trophozoites were found on examination and one solitary ring was seen which was taken to be a benign tertian ring. He was given Plasmoquin $\frac{1}{2}$ tablet thrice daily for 14 days with a break of 3 days. The fever dropped very quickly but a week after the treatment had stopped, he began getting fever again, and many malignant tertian rings were now seen in the peripheral blood. He was given two intramuscular injections of quinine grs. 5 each, and the temperature dropped with no further relapse.

Conclusions.

From our experience in the course of a year regarding the effects of Plasmoquin in the cases cited above and also in several other unrecorded cases we can conclude that—

(1) Plasmoquin has its own sphere of action in the treatment of malaria. It can cure a case of benign tertian or quartan infection more quickly, more steadily and more easily than quinine. All our cases responded very quickly to the treatment and none had any recurrence of fever afterwards. It acts in very small doses, and being tasteless can easily be

taken by children. In these respects it has a great future in this country, but its value may not be fully appreciated until the use of the microscope becomes more popular and the different types of malaria are properly diagnosed.

(2) It cannot claim to replace quinine. It has no action on the asexual forms of malignant tertian parasites as has been conclusively shown in case 23. It has been observed that if there is a malignant tertian infection super-imposed upon a benign tertian or quartan infection and this is overlooked, Plasmoquin will fail to produce the desired effect.

(3) Hence only those who have facilities to distinguish the different types of malaria by the examination of blood, can make a choice between quinine and Plasmoquin for the respective cases. For the mofussil doctor who depends upon clinical diagnosis it is not safe to rely upon Plasmoquin alone. He can use it in addition to quinine and would surely get better results than with quinine alone, specially in the subacute and chronic cases so commonly met with, which are generally benign tertian infections, either pure or mixed. It is in those cases of characteristic tertian and quartan types of fever where the one day or two days' periodicity is kept up with clock-like regularity that Plasmoquin can be used without blood examination. But even then it is not always wise to judge the nature of the infection by guess work.

(4) In cases of malignant tertian infection also, it may be given along with quinine. The crescents that are generally formed in these cases before long, are destroyed and the spread of the infection checked. If it is universally used in addition to quinine the continuous infection and re-infection in the endemic areas would be materially reduced as there would be very few gametocytes for the mosquitoes to carry.

(5) The drug may be used without much risk. In none of the cases under our observation was there any untoward effect or toxic symptom noticed after its use except in a neurotic patient where there were cramps in the abdomen on the 5th day of its use.

(6) The Plasmoquin Co. tablets, containing both Plasmoquin and quinine, are meant to act like a double-edged sword for the undifferentiated and mixed cases of malaria. These can be given in such cases where blood examination is not possible, where a bitter mixture is abhorred and where there is no urgency for vigorous treatment. In cases of blackwater fever these are well worth a trial. As these tablets contain very small amounts of quinine and Plasmoquin, the dose can be cautiously regulated and increased and the intolerance gradually overcome. In cases of idiosyncrasy to quinine, these may also be of considerable value.

Our grateful thanks are due to Major J. C. De, I.M.S., who took an active interest in these investigations and to Major Malaya, Police Surgeon, for his kind permission to publish the reports.

A Mirror of Hospital Practice.

TYPHUS-LIKE FEVER. (COLONEL MEGAW'S TICK-TYPHUS?)

By G. GHOSE, M.B., B.S., D.T.M.

Lukerganj, Allahabad.

Case No. 1. Mr. F. G. J., aged 20 years, an English missionary from Mirzapur was admitted to the European Civil Hospital at Allahabad, on the 28th March, 1928. He came to India in October, 1927, and has been working in the B. C. M. S. mission at Mirzapur. On his arrival in India, he had a prophylactic inoculation of T. A. B. vaccine.

On Friday, the 23rd March, 1928, he felt a bit out of sorts and found that he was unable to carry on his usual work. On Saturday he had headache and was feeling seedy and found that he could not read on account of pain in his eye-balls. On Sunday morning he woke up with a temperature of 102.6° and felt "a chilly tremor up and down the body." The temperature gradually rose till on Tuesday evening it reached 104° . He was suspected to be suffering from malaria and was given two intramuscular injections of quinine by the doctor of the mission at Mirzapur. The injections did not bring the temperature down. He noticed a rash on the dorsum of his hands and wrists on Wednesday and came to Allahabad the same day and was admitted to the European Civil Hospital, here.

On or about the 20th March, 1928 (the patient does not exactly remember the date), he was bitten by some insect on the inner aspect of his left leg. The site of the bite was inflamed and tender for some days. (See the accompanying photograph).

Fig. 1.—Mr. J., 9th day. Left leg showing the site of bite.

He has four dogs and lives away from the city (Mirzapur) proper, where he says, lots of grazing cattle roam about.

Condition of the patient on admission:

1. *General appearance.*—Face flushed, temperature 102.2° . Patient complained of headache and pain all over his body. Eyes slightly red.

2. *Alimentary system.*—Tongue—very thickly coated.

Bowels—regular; no tympanites.

Spleen and Liver—not palpable.

3. *Respiratory system.*—Nothing abnormal.

4. *Urine.*—Colour—deep amber.

Sp. gravity 1028

Reaction acid

Albumen nil.

Sugar nil.

5. *Circulatory system.*—Heart sounds—normal.

Pulse—slow, as compared with temperature.

Blood Examinations.

(a) No malarial parasites found.

(b) Differential count—

Polymorphs .. 57 per cent.

Lymphocytes .. 40 "

Large mononuclears .. 3 "

Eosinophiles .. 0 "

(c) Total white blood count—12,000 per c. mm.

(d) Blood for Widal was taken on 31st March, 1928.

Result—completely negative to *B. typhosus*, *B. para A* and *B.*, in all dilutions.

Rash.—The rash appeared on the 4th day of

Fig. 2.—Mr. J., 9th day

the disease and was at first noticed on the dorsum of the hand and wrist. During the course of a day or two the rash spread over the whole body. Some spots of the rash were round while others were oval. The size varied from 2 m.m. to 8 m.m. in diameter. The rash was partially macular, partially papular (i.e., slightly raised from the general surface of the body so that the spots could be felt by the fingers with eyes closed). They were scattered all over the body and were discrete. In the early part of the disease they faded on pressure but later on, some of them did not fade on pressure and were definitely petechial in character. On the face there were only a few spots. With the subsidence of fever the rash began to fade and disappear. The patient left the hospital on 11th April, 1928, when the rash was still visible as brownish red on purplish pigmented spots.

Case No. 2.—A European lady, Mrs. R., aged about 50 years and living in Allahabad, got fever on Friday the 2nd March, 1928. About a week before this she was bitten by some insect while

she was sitting on her verandah at about 3 p.m., on the lateral aspect of her right arm about 2 inches above the elbow. The site of the bite became extremely painful, red and angry-looking and in a day or two the right axillary glands swelled a little and were tender on pressure. A painful cord-like swelling could be felt from the site of the bite right up to the axillary glands on

Fig. 3.—Mrs. R., photograph taken on the 16th day of the disease.

Fig. 4.—Mrs. R., 16th day.

the same side. The patient could not say what insect bit her. She is very fond of animals and has 7 long-haired dogs. The house where she lives is surrounded by trees and a garden, and is situated away from the city (about 2½ miles).

The fever was accompanied by rigor and pain all over the body. The pain was worst in the wrist joints (both). The fever on the first day was 101° and gradually it rose to 104° in the course of a few days.

Rash.—A macular rose-red rash appeared on the 5th day of the disease (Tuesday, 6th March, 1928), over the extremities and in the course of a day or two, spread all over her body, there being only a few spots on the face. The spots at first faded on pressure but later on many of them became petechial in character. The size varied from 2 m.m. to 12 m.m. in diameter.

Condition of the patient on 8th March, 1928, (7th day of the disease).

1. *General appearance.*—The patient seemed to be drowsy and was said to be sleeping all the time. Face flushed. Eyes very much congested and red. She complained of photophobia and pain in her eye-balls. Temperature—103.6°. Whole body covered with a rose-red macular rash. Some of the spots were slightly raised and partially papular in character. Many of them were petechial in character.

2. *Alimentary system;*
Tongue—very thickly coated.
Spleen and liver—not enlarged.
Bowels—regular.

3. *Respiratory system.*—A few crepitations at the bases of lungs.

4. *Circulatory system.*—A systolic murmur heard at the apex. Pulse 90 when temperature was 103°.

Blood Examinations.

(a) No malarial parasites found.

Temperature to be marked in —

Pulse to be marked in - - - - -

(b) Differential count—

Polymorphs	..	61 per cent.
Small mononuclears	..	32 "
Large mononuclears	..	6 "
Eosinophiles	..	1 "

(c) Total white blood count—about 11,000 per c. mm.

5. *Nervous system.*—The patient was drowsy. There was pain all over the body. She complained of pain in her eye-balls, photophobia and severe headache.

6. *Site of bite.*—A dark, reddish-brown, tender area could be seen, which was covered with a scab; it was about $\frac{1}{4}$ inch in diameter and was situated on the lateral aspect of the right arm, about 2 inches above the elbow. A tender cord-like thickening could still be felt extending from the site of the bite to the right axilla. The axillary glands were slightly enlarged and tender on pressure.

Course of the Disease.—The temperature came down to normal on the 18th day of the disease by lysis. The marks of the rash persisted for a long time and some of them are still visible on the extremities as brownish-red pigmented spots. During the course of the fever she bled profusely from the nose 2 or 3 times. She was last seen on the 12th of April, 1928.

(A third case of typhus-like fever described by Dr. Ghose, was incorporated in the article entitled "Tick-Typhus and other Sporadic Fevers of the Typhus Group." By Col. Megaw and published in the June 1928 issue of this journal. Editor, *Indian Medical Gazette.*)

CEREBRAL SYMPTOMS ASSOCIATED WITH FILARIA.

By THA MYA, M.B.

Assistant Surgeon, General Hospital, Mandalay.

MAUNG WE, a Burmese Christian, aged 40 years was admitted into the Mandalay General

Hospital on 20th June, 1928, for unconsciousness of four hours' duration. No history was available and the following conditions were found on admission. The patient was unconscious and restlessly rolling in bed. The right arm was flexed, twitched now and again, followed by stiffening of the extremities for a short while. There was no lock-jaw nor any injury to the head. Temperature was 98.4, pulse 64 and respiration 24. Heart sounds normal; lungs clear; liver and spleen not palpable below the costal margin. Pupils equal and reacted to light. Passed urine in bed. Blood examination—no malarial parasites were found. Urine drawn by catheter showed—reaction neutral, albumin and sugar nil. Blood pressure could not be taken properly as the patient was very restless. Lumbar puncture was performed and the fluid, which came out under pressure, was bloody. About 20 c.c. of the fluid was removed. The patient became more quiet. Blood pressure was taken with the following result:—Systolic pressure 160 m.m. of Hg. and the diastolic 90 m.m. of Hg. It was provisionally diagnosed as a case of cerebral hæmorrhage. Ice-cap was applied continually to the head. Calomel grs. v was given by mouth and retained. Enema was given and a large amount of fecal matter was passed. The patient lay quiet in bed on his right side. On 21st June, 1928, right-sided hemiplegia present. Patient was semi-conscious. He half opened his eyes when called and again went off to sleep. Temperature sub-normal, pulse good, 80. Patient quiet in bed. Takes feeds. Passed urine and feces in bed.

On 22nd June, 1928. Condition same. Catheter passed twice.

On 23rd June, 1928. Patient restless, turning constantly from side to side in bed, head retracted, no Kernig's sign present. Temperature 103 per rectum, pulse 108, respiration 28, in the forenoon. Ice-cap applied continually.

In the afternoon patient still restless, temperature 101, pulse 114 and respiration 70. Râles heard all over the lungs on both sides. Heart sounds normal. Lumbar puncture performed and the fluid that squirted out under pressure was bloody. The fluid was sent to the hospital laboratory for examination. After lumbar puncture the patient became more quiet. Enema given with good result. Ice-cap continued. Blood pressure taken and systolic pressure was found to be 160 m.m. of Hg.

Patient died at 12-45 a.m. on 24th June, 1928.

Laboratory reported that filarial larvæ were found in the fluid. No other micro-organism present.

I am grateful to the Civil Surgeon, Mandalay, for kindly giving me permission to publish this case.

TOXIC SYMPTOMS FOLLOWING ADMINISTRATION OF CARBON TETRACHLORIDE.

By A. C. MITRA,

Sub-Assistant Surgeon, Motihari Jail, Motihari.

PRISONERS of Bihar and Orissa Jails, on their admission, are treated by carbon tetrachloride till they are free from ankylostomes. On 20th July, 1928, a batch of six prisoners was given carbon tetrachloride, 45 minims each at 7 a.m., an hour and a half after their early morning meal of *ketchhri*. One of them, a prisoner of good health with hard labour, weighing 116 lbs. with a height 5 feet 4 inches and 30 years of age, felt nausea one hour after the administration of the drug and in a few minutes he commenced vomiting. He was seized, soon after, with a colicky pain in the abdomen and was restless. Perspiration started on the forehead, pulse was soft and slow and respiration laboured. Urticarial eruptions on the body appeared 20 minutes after the colic, these were at first discrete but soon became confluent and the whole body was bloated up. All these happened within two hours after the administration of carbon tetrachloride.

The prisoner was at once put to bed and pituitrin 0.5 c.c. injected, and mag. sulph. $\frac{1}{2}$ oz. in solution given by the mouth. The pulse improved after the injection. The prisoner had a good action of the bowels by 11 a.m. and was relieved of colic. The eruption disappeared completely by 2 p.m. and he was all right and returned to work the same evening. On examination of the stool, ankylostoma and round worm ova were found.

As none of the prisoners, a little over three thousand, treated by me ever exhibited such signs and symptoms, I beg to enquire if such a thing has been noticed before and what it was due to. Was this due to idiosyncrasy of the man to the drug or to the presence of a mixed infection? Several cases of mixed infection have been treated by carbon tetrachloride without such manifestations.

(We have shown the above paper to Dr. P. A.

Maplestone, Hookworm Research Department, The School of Tropical Medicine and Hygiene, Calcutta, who comments as follows:—

"The symptoms reported in the above case are somewhat atypical of carbon tetrachloride poisoning, especially the severe colic and the extensive urticaria. These symptoms are occasionally associated with ascaris infection. It therefore seems probable that the carbon tetrachloride stimulated the ascaris to emit a toxin, which caused the symptoms. As the above report points out, it is difficult to see why this should occur in one case infected with ascaris and not in all. This is no more capable of explanation in our present state of knowledge, than why, when ascaris infection is very common, it is very rare to meet cases with signs of toxæmia definitely due to this infection, although there is no doubt that such cases occasionally occur."—EDITOR, *Indian Medical Gazette*.)

DIGITALIS WITH SPECIAL REFERENCE TO AURICULAR FIBRILLATION.*

By P. V. KARAMCHANDANI,

CAPTAIN, I.M.S.,

Officer Commanding, Indian Military Hospital, Pishin.

THE essential feature in auricular fibrillation is over activity in the cells of the sino-auricular node, resulting in a machine-gun-like multiplicity of stimuli passing in such quick succession that only a few are effective in stimulating the atrio-ventricular node and ventricular contraction. The rate of ventricular contraction depends upon the degree of sensitiveness of the atrio-ventricular node and its power of response to the stimuli.

Our object, therefore, in such cases should be to decrease the sensitiveness of this node and thereby produce a sort of partial block, in order that while the auricles may continue to fibrillate the ventricles may slow down. This ensures better myocardial circulation and in course of time helps the auricles to recover as well. The effect of digitalis in such cases for the time is immediate, but the ultimate prognosis depends upon the myocardial condition.

The dose of digitalis varies in different cases, but it may be remembered that in cases of fibrillation, it has to be pushed to the physiological limit. Out of 5 cases, the following case in which as much as 1/10th grain of digitalin by injection and dr. 1 of digifortis (Parke, Davis and Co.) had to be administered per diem, will illustrate the above statement.

No. 6413, Sepoy J., was admitted to this hospital on 23rd March, 1928, for lobar pneumonia. On admission, his heart was regular, beating 120 times per minute. On 25th March, 1928, at 9 a.m., he developed auricular fibrillation with the result that his pulse which could be felt at first, became very irregular and subsequently it was quite imperceptible, the apex was beating 208 times per

* Published by kind permission of the Director of Medical Services in India.

minute. Subcutaneous injection of 1/50th grain of digitalin with dr. ½ tinct. digitalis by mouth along with detoxicating treatment of pneumonia, restored the heart and the pulse to rhythmic regularity.

The temperature came down to normal on 1st April, 1928 and on 9th April, 1928, it was 98.4°F, pulse 72, respirations 18 per minute. There being no contraindication, the patient who was clamouring for other diet than milk, was permitted bread, vegetables, chicken and fruits, on 11th April, 1928. On 13th April, 1928, at 8 a.m., he suddenly developed auricular fibrillation. I was summoned immediately and when I saw him he was at his last gasp. Dyspnoea was intense, respirations being about 64 per minute, the chest was full of congestion crepitations, the surface of the body was cold, perspiration was profuse over the forehead, the pulse was imperceptible and the apex was beating over 275 per minute, there was intense thirst and the conjunctivæ were ashy in colour. I at once gave him digitalin grain 1/50th subcutaneously and tinct. digitalis dr. ½ orally, and within half-an-hour he turned the corner and all symptoms of heart failure disappeared dramatically. The pulse rate, however, continued to be 125 per minute. He was given digitalin grain 1/10th in 5 doses of grain 1/50th by injection, and dr. 1 of digifortis (Parke Davis and Co.) in 3 doses of m 20. The injections were continued up to next mid-day (14th April, 1928), when they were stopped as it was considered that digitalis orally should have commenced operating. He developed a third attack at 8 p.m. on 14th April, 1928, but it yielded to the injection of digitalin which had to be continued, grain 1/50th 5 times a day. The pulse rate, however, never came down below 120 per minute.

He had a fourth attack at 10 a.m. on 16th April, 1928, and the fifth and last at 10 p.m. the same evening. Two hypodermic injections of 1/50th grain digitalin at 10 p.m. and 12 midnight failed to produce any effect, the patient became unconscious at 1-30 a.m. and died at 2 a.m. on 17th April, 1928. It may be noted that he showed no symptoms whatsoever of toxicity, drowsiness, headache, nausea, vomiting or diarrhoea arising from overdose of digitalis. How digitalis actually acted in this case may be explained as follows:—

When the heart showed signs of failure, the lack of circulation in various organs made them raise a cry, which, reaching the heart through the sympathetic, increased the rate of its beats. But this increase in the rate of beats decreased the efficiency of the heart by shortening the period of recovery or recharging of vital energy in the cell, thus establishing a vicious circle. The less the efficiency of the heart, the less the amount of blood in the organs, the greater therefore their cry and the greater the sympathetic stimulation resulting in still more rapid action of the heart and a still further lowering of its

efficiency. Digitalis at this juncture by counteracting the sympathetic effect gave time to the nodal cells to recover, which brought about slowing of the heart with consequent prolongation of diastole. The rapid and inefficient cardiac contractions were replaced by slow and efficient ones and the patient recovered. Of course, the ultimate recovery depended upon the condition of the myocardium and in this case it being degenerated, digitalis ultimately proved powerless.

A CASE OF RENAL CALCULI AT THE WEST HOSPITAL, RAJKOT.

By J. F. HENRIQUES, L.M. & S., B.M.S.,

Officer-in-charge, West Hospital, Rajkot.

A YOUNG Hindu woman, age 20 years was admitted for a supposed tubercular sinus on the left side of her waist. Carious bone was felt on probing and it did not seem to be connected with the spine. The sinus was enlarged and a portion of the rib resected which seemed to be necrosed. Anteriorly there was still felt on probing some hard object and on digital exploration calculi were found, six entire uric acid stones were removed and a couple were brought out in pieces. The entire kidney seemed disorganised. The wound was very foul and septic and there was a urinary discharge from it, after the operation; but it is now granulating. It may leave a sinus or necessitate removal of the bad kidney, at some future date. It was strange there was no urinary discharge from the sinus before the operation, nor any history of renal colic.

A CASE OF "ECLIPSE BLINDNESS."

By S. C. SEN GUPTA, L.M.F.,

Resident Medical Officer, Lakhipara Tea Estate, Banerhat P. O., Jalpaiguri District.

W. C., a Hindu male, aged 28 years, clerk, came to me for treatment and expressed himself as follows:—

"I lost my wife 1½ months ago. Since then on account of constant weeping my eyes became weak. A week back I went along with my friends to the river to see the solar eclipse. I looked towards the eclipsed sun pretty constantly four or five times with unprotected eyes. Soon after my last attempt to see, my vision became burred and after a couple of minutes all was dark, and I became totally blind.

I consulted a native *hakim* and after 3 days treatment my vision improved a bit, so much so that I could walk about and find my way. But since then a black object looms in front of my eyes and is surrounded by a bright circle in which I sometimes see rainbow colours. Objects in front of my eyes are obscured by that dark spot, but through the bright circle I can perceive things on the right and left very dim."

Objective examination in the daylight revealed nothing.

Subjective examination.—The patient was asked to read test type; he could not read, but could perceive a hand when moved in front of his eyes at a distance of 2 feet. There was no central vision.

He was examined in the dark room after dropping atropine solution, 2 per cent; with indirect ophthalmoscopic examination, the blood vessels entering the optic disc were seen to be somewhat congested. In the region of the macula-lutea a definite reddish brown discolouration was seen, except which there was nothing worthy of note.

The *diagnosis* of eclipse blindness was made from the—

- (1) History of seeing a solar eclipse.
- (2) Loss of central vision.

Treatment adopted. General.—The patient was confined to an absolutely dark room, and told to wear smoke-coloured glasses when it was essential for him to go out of the room. Good, nourishing, easily-digested diet was given and Easton's syrup, one drachm in an ounce of water an hour after meals, twice a day, also daily hypodermic injections of strychnine.

Local Treatment.—Sub-conjunctival injections of mercury cyanide, 1 in 2,000, 20 minims, after cocainising the eyes were given on every fourth day, a good deal of local reaction followed the injection and on account of some pain the patient writhed in the bed. Four such injections were given and no improvement resulted. The patient refused to take these injections on account of the very severe pain which he experienced. Then injections of sodium chloride of physiological strength were given instead in the temples daily. After 6 injections his peripheral vision became good, the dark spot in his central vision became dim and the bright circle disappeared. After 4 more injections his vision became clear. He was made to read test type and the vision was found to be 6/12 with both eyes. Local treatment was discontinued at this stage. He was told to wear dark glasses and continue the tonic treatment. After a month he was again seen and then his vision was 6/9; after this he was never seen by me again.

A CASE OF INTESTINAL OBSTRUCTION FOLLOWING A PENETRATING WOUND IN THE ABDOMEN.

By P. N. BASU, M.B., M.R.C.P.E., D.T.M. & H., D.P.H.,
CAPTAIN, I.M.S.,

and

T. BHASKARA MENON, M.B., M.R.C.P.,

Department of Pathology, Medical College, Madras.

C., aged 50 was admitted into the wards of the Second Surgeon, General Hospital, Madras, on

19th June, 1928, with a penetrating wound in the right iliac region, alleged to have been caused by a stab with a knife. A loop of intestine which was projecting through had a tear in it of the size of an 8 anna piece.

(Diagrammatic).

Showing the loop drawn out through two tears in the mesentery.

The wound was enlarged under anaesthesia, the peritoneum drained by two drainage tubes put in one on either side of the umbilicus; a Paul's tube was put in through the opening in the projecting loop and this was stitched into the edges of the wound. The patient's condition was not improved and he died on 20th June, 1928.

The autopsy showed that the coil of ileum about 1 foot above the ileo-caecal junction which was projecting out, had made its way through two tears in the mesentery in succession so that its lumen was completely obstructed. This had caused distension of the whole of the small intestine above this loop right up to the duodenum and the patient had apparently died of intestinal obstruction. There was very little evidence of peritonitis but the peritoneal cavity contained about 2 ozs. of partly clotted blood.

It is curious to note how this ruptured coil had made its way through two tears in the mesentery in succession, since it is reasonable to assume that all the wounds were made by one penetrating stab. One possibility is that the coil of intestine had been pushed in by the knife in its way down through two successive folds of the mesentery and had not dislodged itself with the withdrawal of the knife. Another possibility is that the loop of gut was lying behind all the time and had been pulled out through the two folds of the mesentery by the knife in its egress.

It is extremely unlikely that the ruptured loop had made its way by its own peristalsis through two tears in the mesentery in succession.

The case is also of interest since it brings in the possibility of acute obstruction arising immediately after a penetrating stab wound.

Our thanks are due to Major D'Souza, I.M.S., for permission to report this case.

ELECTRO-COAGULATION (DIATHERMY) IN MALIGNANT GROWTH OF FACE.

By P. P. LALVANI, I.C.P.S. (Bom.),
Civil Hospital, Karachi.

SETH Kimatrai, Hindu, aged 55 years, residence at Ghogharo, District Larkana, Sind.

The patient stated that he developed a small mole, the size of a pea, on the nose about 6 years ago. There was no pain nor did the growth give him trouble in any other way.

During the last 6 months it appreciably increased in size and assumed a diameter of about 2½ inch. He felt that his face was disfigured and for cosmetic reasons he asked a doctor to cut it. This was 3 months prior to his coming to me.

The surgical operation did not help him; cutting made it worse. The wound would not heal and instead more nodules appeared. There was considerable pain which did not allow him to sleep at night.

Fig. 1.

Fig. 1 shows the condition before I did the electro-coagulation. It shows an ulcerated nodular growth involving the nose, and extending on either side to the canthi. There was considerable infiltration in the tissues around. The lymph glands could be felt slightly in the sub-maxillary region.

The case was seen by Lieut.-Col. I. Davenport Jones, M.D., I.M.S., Civil Surgeon, who opined that it was a malignant growth. The nature of the

malignancy could not be determined, as the patient would not allow anything to be cut out for the sake of pathological examination.

On 11th March, I electro-coagulated the entire growth, and also ¼-inch of the surrounding tissues, with the diathermic knife. This was done under novocaine infiltration anaesthesia. As usual there was considerable swelling in the surrounding tissues that very evening. After 4 days the swelling entirely disappeared. Severe pain, which the patient had before electro-coagulation, also completely disappeared in 4 days. The slough took about 2 weeks to detach, leaving a clean healthy ulcer with the nasal bone exposed. The ulcer took about 4 weeks to heal up and the bare nasal bone was covered with granulations.

Fig. 2.

Fig. 2 shows the condition 6 weeks after the electro-coagulation. There is a scar over the area previously occupied by the growth. In the centre there is a little bit of raw surface which would have taken about 3 to 4 days to heal. As the patient had to attend to some important business he went away and I have since heard that the raw surface has completely healed up.

This case was considered as unsuitable for surgical operation, because operation done on him previously had been followed by extension of the growth and also on account of the danger of entropion of the left upper eye-lid as the result of contraction of scar tissue. Diathermic electro-coagulation was, therefore, resorted to in this case with good results.

NOVEMBER.

WILLIAM HARVEY.

THE greater the man the greater are his potentialities for good or for evil, and in many instances for both good and evil. The influence of many great men has been during their life time almost entirely good, yet much harm has been done in their names through the unreasoning hero-worship of posterity. For fifteen hundred years, commencing from the second century of the Christian era, the teachings of Galen had the most remarkable influence on the practice of medicine. This influence, which extended from Asia Minor and Egypt, throughout Europe and even as far east as India, was for the most part a benign influence, but in the 15th and 16th centuries there was probably no one factor which held up the advance of medical science more than the blind adherence of the leading physicians and teachers of those times to the Galenical principles. The modern tendency is perhaps not to honour the past sufficiently but to us nothing seems more stupid than this unintelligent following of ancient dogma. Were it possible for Galen to come to life again, although he would be at first bewildered, we feel sure that he would be the last man to refuse to accept the evidence of his eyes, aided by comparatively modern inventions such as the microscope and the x-ray tube, even if the demonstrated facts were contrary to his own preconceived ideas. In his own time he was progressive; he did not, for instance, accept the established theory that arteries contained only air, but he looked to see and found that they contained blood.

Fortunately, medical science has now almost freed itself from this yoke of tradition.

At the present day, when nothing delights the scientist more than being able to upset the theories of his predecessors, it is difficult to realise the awe in which the older teachings were held; some realisation of the mental state of the times can be obtained by reading William Harvey's introduction to his epoch-making book, *De Motu Cordis*, published for the first time just three hundred years ago. The preface was addressed to the President and Members of the College of Physicians in London; it was written in Latin; the following is a quotation from a contemporary translation. "Since this only book does affirm the blood to pass forth and return through unwonted tracts, contrary to the received way, through so many ages of years insisted upon, and evidenced by innumerable, and those most famous and learned men, I was greatly afraid to suffer this little book, other-

ways perfect some years ago, either to come abroad, or go beyond Sea, lest it might seem an action too full of arrogance, if I had not first propounded it to you, confirm'd by ocular testimony, answer'd your doubts and objections, and gotten the President's verdict in my favour; " William Harvey had announced his "discovery," and he had taught to the students of the time and had discussed with his colleagues at St. Bartholomew's Hospital and elsewhere his theory regarding the circulation of the blood for more than nine years before he wrote this. How very different from the modern method, sending a telegram on the afternoon of the day the discovery is made!

Harvey had the true spirit of the discoverer. He did not accidentally stumble upon the truth, but after many years of careful work he gradually evolved his theory and then proved it to his own satisfaction and to that of his colleagues. With the acuteness to recognise inconsistencies which had escaped his predecessors, the ability to apply the numerous observations which he had made during his life as a practising physician, and the patience to carry out innumerable dissections on dead animals at all embryonic stages of development and experiment on living ones, he had the courage and personality to force his opinions on his contemporaries.

To appreciate fully the value of Harvey's work it is necessary to know something of the state of knowledge on the subject at the time. Aristotle had taught, and his immediate successors had elaborated his theory, that the blood was formed from food in the liver, was carried to the heart and thence distributed to all parts of the body by means of the veins. The arteries carried a vital air or spirit which they had obtained from the lungs and which they likewise distributed throughout the body. Galen, later, showed that the arteries contained blood which, he claimed, was mixed with the vital air. For the next fourteen hundred years there was practically no advance in the knowledge of the subject and at the beginning of the 16th century, although it was realised that the blood was not stagnant, it was thought that its movements were slow and irregular, both in speed and direction; it was supposed that one kind of blood flowed from the liver to the right ventricle and thence through the veins to all parts of the body and to the lungs by the pulmonary artery, and that another kind of blood mixed with vital air which it obtained from the lungs by means of the arteria venosa (pulmonary vein), was distributed throughout the body by means of the arteries; and it was believed that the blood from the right ventricle passed through small pores in the septum of the heart into the left ventricle. In those days they had no conception of the motive power of the heart and they considered that the movements of the blood were due to the mixture of blood and air, producing a sort of boiling effect. During the 16th century certain further advances were made, and there is no doubt that

Servetus, who maintained the imperviousness of the septum and described the lesser circulation, i.e., through the lungs, Columbus, who elaborated this theory, and Andreas Cæsalpinus, who observed the swelling below a ligatured vein and from this inferred the return flow of the blood in the veins, laid the foundations of Harvey's great work.

It was in the face of this prejudice against interference with established authority and out of this confusion, in which there were many grains of truth but an enormous admixture of fiction, that Harvey built his almost faultless conception of the most fundamental problem in physiology. In describing the circulation of the blood exactly as we know it to-day he left one small gap; without the microscope, which had not been invented in his day, his only aid to sight being a small hand lens, he was unable to see the capillary circulation which was described by Malpighi some few years after Harvey's death.

DEATHS UNDER ANÆSTHETICS.

We print below an editorial note from the *Dental Surgeon* of 21st July, 1928. It seems to us that the investigators might achieve very valuable results if the medical profession in general will co-operate. The list of questions to which practitioners are asked to reply is also given.

"One of the painful duties that falls to the lot of the editor of a dental paper is the one which is occasionally cast upon him of chronicling the death of a patient under an anæsthetic, or following its administration. It is not suggested that such events are of frequent occurrence, and, bearing in mind the thousands of anæsthetics which must be given daily for dental operations, the cases which have a fatal termination are few and far between. Nevertheless, it behoves everyone in any way connected with the profession to do what is in his power to diminish the number of such deaths, and it has occurred to us that a dental journal has special opportunities of collecting and disseminating information on the subject. Much difference of opinion still seems to exist as to which are the best anæsthetics for dental purposes. Probably there is no one anæsthetic that is the best in all circumstances; and the question why a particular anæsthetic which has proved itself safe and trustworthy in a multitude of cases should occasionally lead to a fatal result is certainly a matter which calls for the closest investigation. From time to time, inquests have to be held in different parts of the country on persons who have died during, or shortly after, the administration of an anæsthetic for dental purposes. In most cases the information reported in the public press is meagre, and not very illuminating. This is no doubt due to the fact that the lay reporters are not sufficiently conversant with the subject to be able to select

for publication those parts of the evidence which would convey most information to the scientifically-trained mind. It is our hope, by means of a carefully prepared questionnaire, to elicit the essential details from the professional men connected with any such case. This questionnaire will be circulated to the dentist, the anæsthetist, and any other professional man who may be thought able to throw light on the occurrence. It is hoped by this means to collect a mass of details as to the anæsthetics usually employed, and their comparative safety for dental operations; also as to the condition of health of the patient, and particulars of any special preparatory treatment that he may have undergone. The replies will be collated, and, after classification, published in whatever form appears best. It should be explained at once that the replies received will be treated as confidential, and nothing of them will be published beyond the points of medical and physiological interest. It is not intended to publish any names, either of the patients nor of the professional men concerned in the case. The help of our readers and of the medical and dental professions generally is earnestly asked for in this endeavour to improve their, and our, knowledge of the subject."

Questionnaire.

1. (a) Patient's age. (b) Sex.
(c) Married or single.
2. Personal and family history.
3. General health before operation.
4. Was anæsthetist patient's regular doctor?
5. Nature of operation.
6. Date and time of operation.
7. Where was operation performed?
Dentist's consulting-room. Patient's home. Nursing home. Hospital.
8. Was operation one of urgency?
9. Anæsthetic. (a) Nature of.
(b) Reasons for choice.
(c) Preliminary treatment, meals, atropine, etc.
(d) How administered? Closed methods. Open method. Intratracheal, etc.
10. (a) Was preliminary examination of patient made?
(b) If so, was anything abnormal found.
11. Duration of anæsthetic.—
(a) Induction period.
(b) Actual operation.
(c) Subsequent period.
12. (a) Onset of untoward symptoms and signs.
(b) Nature; course, and when first noted.
(c) Nature of treatment employed.
13. At what stage did death occur?
14. (a) Actual cause of death.
(b) Contributory causes.
15. Post-mortem findings.
16. Any further remarks bearing on case.

SPECIAL ARTICLES.

THE PENTAVALENT ANTIMONY COMPOUNDS IN TROPICAL MEDICINE.

By PROFESSOR DR. HANS SCHMIDT,
Elberfeld.

THE pentavalent antimony compounds* were first used in the treatment of infantile kala-azar in Mediterranean countries and subsequently in other tropical diseases; their true importance was, however, only recognised when they were applied to the treatment of Indian kala-azar. Careful and systematic therapeutic research in India first demonstrated that the form in which antimony is present in the p.a.c. is not only much less toxic but also has a much more powerful action on kala-azar than that present in tartar emetic.

In view of the interest in the p.a.c. prevailing in India it is not inappropriate to consider the history of these compounds from their cradle from a chemical and chemo-therapeutic aspect.

It is well known that the use of antimony in tropical medicine originated in the discovery by Plimmer and Thomson of the trypanocidal action of tartar emetic in mice.

The re-awakening of antimony treatment followed closely on the new arsenic treatment (Ehrlich): it was found that the trivalent compounds (salvarsan) and the pentavalent compounds (atoxyl, Spirocid, etc.) were extraordinarily useful in the ætiological treatment of infective diseases. This had not been possible with the inorganic salts or other simple compounds of trivalent or pentavalent arsenic.

Antimony is different in that its tartaric acid salt (tartar emetic) displayed a powerful specific action in a number of infective tropical diseases.

As in the animal experiments the margin between the toxic and the curative dose is narrow, so it was soon found that the prolonged injections necessary in combating sleeping sickness produced all the subsidiary effects and risks which are now well known to range from cough, vomiting and rheumatic pains to sudden death. In kala-azar, bilharziasis, venereal granuloma and other infective tropical diseases in which antimony was in rapid succession found to be an indispensable specific remedy, the secondary effects soon gave rise to grave anxiety.

Antimony compounds had to be found which were suitable for use by modern injection methods, and which were at the same time effective and less toxic than tartar emetic, the official antimony preparation which had been used therapeutically since the middle Ages.†

* Abbreviated subsequently to p.a.c.

† In the 16th and 17th centuries antimony preparations including tartar emetic were very commonly administered internally and externally in other conditions (syphilis, pulmonary diseases, etc.). On account of the risks associated with its use there was much discussion at the time as to whether antimony treatment was permissible.

The model of arsenic suggested that better preparations might be obtained by combining antimony with organic molecules.

The preparation of *organic antimony compounds*‡ was first made possible in 1911 by the method of diazo-synthesis which I discovered in the scientific laboratory of Messrs. Von Heyden's Chemical Works: by the action of antimony oxide on diazo compounds an organic stibinic acid is formed and nitrogen liberated, e.g., sodium p. acetylaminophenyl-stibinic acid following the equation

It was thus possible to prepare the antimony analogue corresponding to arsacetin (stibacetin, stibenyl) as well as the antimony analogue of salvarsan: dioxydiamidostibiobenzol. In the latter, a trivalent organic antimony compound, the link between the antimony and the carbon is too labile.

The former, on the other hand, the pentavalent organic antimony compounds, the aromatic stibinic acids or their salts, were found to be stable compounds with interesting properties. The antimony reactions are obscured; thus they do not give the characteristic antimony reaction, red precipitation of antimony sulphide. The complex colloidal properties of antimonious acid, its power of forming higher molecular complexes, are modified in diverse ways by substitution in the benzol nucleus. When the difficulties of preparation and purification of stable salts had been surmounted, the compounds could be used for animal experiments.

Uhlenhuth and his fellow-workers tested the preparations in experimental infections with those diseases to which antimony treatment was at that time applied: trypanosome and spirillum diseases. Sodium p. aminophenyl-stibinate was one of the first preparations and was tried in 1912 in the spirillosis of fowls; chemically it proved, however, too variable and was correspondingly uncertain in its action. The sodium salts of p. acetylaminophenyl-stibinic acid and other derivatives of p. aminophenyl-stibinic acid were, however, found to have a beneficial effect on fowl spirillosis, rabbit syphilis and mouse trypanosomiasis and to be at the same time less toxic than tartar emetic. They had thus in animal experiments a more favourable chemo-therapeutic index than tartar emetic. Well over 150 antimony compounds were prepared after this auspicious beginning and systematically tested by Uhlenhuth, Kuhn, etc., in animal experiments.

The details are mainly described in papers by Uhlenhuth and by Kuhn and in a summarised publication by Uhlenhuth, Kuhn and Schmidt. It appeared that by substitutions in the benzol nucleus, the chemical properties, the toxicity and the therapeutic properties could be varied within

‡ Tartar emetic is only a loose combination of trivalent antimony oxide with tartaric acid, not a true organic antimony compound.

wide limits. Thus compounds are reached which are highly toxic but have no trypanocidal action, as for example sodium p. chlorphenylstibinate, and on the other hand compounds in which the toxic and trypanocidal or curative doses lie far apart. The latter include a number of other derivatives of p. aminophenyl-stibinic acid.

After some trials in syphilis which were not very effective, the organic pentavalent antimony compounds were first used therapeutically in infantile kala-azar in Italy. Shortly after the discovery by Cristina and Caronia of the tartar emetic treatment of this disease which had hitherto been incurable, Caronia (1915-16) used a number of pentavalent antimony compounds which had been tested on animals by Uhlenhuth. Caronia was searching for a less toxic antimony compound and particularly one which could be given intramuscularly to children even in infancy which was impossible with tartar emetic because of necrosis. Caronia chose sodium p. acetylaminophenyl-stibinate (stibacetin, later called stibenyl); he found that dissolved in water it could be injected intramuscularly without producing necrosis like tartar emetic, subcutaneously the preparation was absorbed too slowly. It was given intravenously in physiological saline to cachectic children. Secondary toxic effects were slighter than after tartar emetic, the therapeutic action slower, but the end result the same.

It is a consequence of political conditions that the echo of these observations has been delayed for a number of years. In Italy (Spagnolio, Foti and Javarone), in Spain (del Diestro and Barrio, Garza, Pittaluga, Catala, Torrademe, Lozano, Sadi de Buen, Puente, Moragas y Garcia, Ortega, Martinez) and in France (Klippel, et Monier-Vinard, Renault, Monier-Vinard et Gendron, Levy, Giraud et Massot.) stibenyl has been used and reported on in whole series of papers. The sporadic occurrence of kala-azar in these countries renders a comparison of uniform observations on large numbers of patients difficult. In essentials, however, extensive tests in Spain confirm Caronia's views.

The general secondary effects of tartar emetic injections are considerably milder with stibenyl. Intramuscular injections are in general well-borne, in a few cases slight abscesses were reported. A case of anaphylactic symptoms which occurred in Spain led to the suggestion that care should be exercised in giving the first dose after an interval in treatment. In addition to reports of rapid and complete cure there are also some of resistant cases in which combined treatment with tartar emetic is recommended.

In India, where in 1915 Rogers and Muir had introduced the treatment of kala-azar with tartar emetic, also attention was soon directed to stibenyl. While Manson-Bahr reported the cure in Europe of a lascar suffering from kala-azar, Napier and others only obtained quite inadequate results in India and with the first batch severe

toxic symptoms. How far the latter may have been due to defective stibenyl from other sources we will not discuss here. With reference to therapeutic effect the supposition that Indian kala-azar as such or under Indian climatic conditions reacts more severely to stibenyl than in European kala-azar districts cannot be lightly dismissed.

In spite of the failures with stibenyl the possibilities of the p.a.c. were recognised in India. Napier tested a further series of antimony compounds which had resulted from Uhlenhuth, Kuhn and Schmidt's work and reported his experience of sodium m. chlor-p-acetylaminophenyl-stibinate (471, Stibosan), in 11 patients with kala-azar.

This preparation was well borne by the patients, and Napier particularly emphasises the absence of pulmonary complications which were not infrequent after tartar emetic; the most striking difference from tartar emetic which Napier observed was however that the curative process was accelerated. The various symptoms—pyrexia, enlargement of the spleen—subsided more rapidly and the final cure was achieved in about three weeks with 10 to 12 injections as compared with 30 injections in 2 months necessary in the tartar emetic treatment.

With these observations a definite advance had been made. Following on Napier's results "471" was introduced into the stock of drugs under the name stibosan. Napier's experience soon received clinical confirmation in India (Greig and Kundu, Das, Hodgson, Rogers).

Napier himself reported further results in the following years, last in 1927 on a series of 104 patients treated. Extensive tests have been carried out to ascertain the number of injections necessary to avoid a relapse.

In the meantime, Brahmachari following Heyden's patent specifications had prepared and tested in the treatment of kala-azar p. aminophenyl-stibinic acid and several derivatives. He found sodium p. aminophenyl-stibinate, which he called stibamine, effective but the low stability of this compound described by Uhlenhuth and myself made its use impracticable. Brahmachari, however, succeeded in preparing a more stable product from the interaction of urea and p. aminophenyl-stibinic acid.* *Urea-stibamine*, which was extensively used in kala-azar as a rapidly acting remedy of low toxicity (Brahmachari, etc.).

Napier has also reported on two other derivatives of p. aminophenyl-stibinic acid; aminostiburea and stibamine glucoside. It appears from the

* Brahmachari at first assumed that this was a urea salt but later considered it to be an ammonium salt of p. carbamide-phenyl-stibinic acid. This has however been disputed.

summarised reports that these four p.a.c. reach the same level with regard to therapeutic qualities, so that the summary* of the advantages of the p.a.c. given by Napier in 1925 probably applies to all four:—

“The total amount of antimony which is necessary to effect a cure can thus be administered in a much smaller number of doses. About 12 doses of pentavalent compounds—against the 30 doses of sodium antimony tartrate—can be looked upon as the average number necessary for a non-resistant case.

“Resistant cases, which show little improvement with the tartrates, rapidly improve when given relatively large doses of antimony in the form of non-toxic pentavalent compounds.

“Certain disagreeable symptoms, such as coughing and severe joint pains, which are frequently associated with sodium antimony tartrate treatment, do not occur when the pentavalent compounds are injected.”

In the other kala-azar districts the results were similar to those obtained in India. Struthers reported the results obtained in China with stibosan and stibamine glucoside and likewise recognised the advantages of the pentavalent antimony compounds with their comparatively rapid action and low toxicity. Struthers administered smaller individual doses (0.2 gm.: 3 grains) of stibosan to Chinese patients than Napier to Indian patients (0.3 gm. $4\frac{1}{2}$ grains) and the treatment consequently took somewhat longer.

The superiority of p.a.c. has been confirmed from the *Russian kala-azar districts*: Artamonoff used stibosan and stibenyl, Smorodintsev and Korchitz obtained very rapid cures with stibenyl.

In the *Mediterranean districts* (see above) stibosan has been used as well as stibenyl, but the same high percentage and rapidity of cures as in India does not appear to have been observed in these districts in recent years.

General experience in India with the p.a.c. subsequently showed that further progress seemed possible and was desirable. The main

**Ind. Med. Gaz.*, November, 1925. Only after the present article had been concluded, the book by Napier on Kala-azar, Calcutta, 1927 was brought to the notice of the author. In this book Napier discusses in a detailed manner the advantages of p.a.c. and mentions among others:—

“The death-rate amongst kala-azar patients under treatment has been very markedly reduced since the introduction of the pentavalent compounds. One of the most frequent causes of death during the course of treatment, namely, pneumonia, has been almost entirely eliminated.”

As to the finer differences of the p.a.c. amongst each other in regard to their keeping qualities, the sterilizing dose, the mean number of injections prior to the cessation of fever, anaphylaxis, etc., special attention may be drawn to the statement made in the book by Napier.

reasons from the detailed reports of the Indian publications may be summarised as follows:—

First the number of recoveries which without treatment was 5 to 10 per cent. rose with tartar emetic treatment to about 80 per cent. and with the p.a.c. further increased to 90 per cent., so that a certain proportion of patients always died during treatment.

Anaphylactic-like symptoms were observed after the p.a.c. ranging from a tingling sensation and mild urticarial rash to severe symptoms (Napier, Struthers†), when stibosan is used; these symptoms are exceedingly rare. In some of the p.a.c., vomiting is not a rare secondary effect.

Chopra compared the pharmacological effect on cats of the p.a.c. with tartar emetic mainly with a view to elucidating the acute symptoms resembling “nitritoid crises” and is of the opinion that:

“The circulatory changes in the pulmonary, systemic and venous systems and the changes in the circulation of the spleen, liver, etc., account for all the milder toxic symptoms such as faintness, feeling of fullness in the region of spleen and liver, etc. The severe toxic symptoms such as dyspnoea, cyanosis, marked respiratory disturbances resembling nitritoid crisis are associated with extreme changes in the pulmonary pressure as well as contraction of the bronchi.” We shall return to Chopra’s observations later.

Napier found that “post-treatment jaundice, a common sequel to treatment by many of the pentavalent compounds” occurred much more frequently than the anaphylactic-like symptoms, which points to damage of the liver from the treatment.

All these circumstances induced Napier to continue the search for a more perfect p.a.c.; he found such a one in preparation 693 (diethylamine p. aminophenyl-stibinate of Uhlenhuth, Kuhn and Schmidt) and reported in 1927 the excellent results obtained in 61 patients with kala-azar.

In order to consider this advance in greater detail we propose to discuss some important aspects of the work which has in the meantime also been extended by various other investigators. The most obvious clinical difference between the p.a.c. and tartar emetic is the more rapid cure obtained. Is the difference a qualitative one or does it merely follow from the fact that it is possible with the less toxic pentavalent compounds to use larger single doses and so administer the total therapeutic dose more rapidly?

† Napier as well as Struthers recommends that when these appear treatment should be continued with another antimony preparation. Napier considers it advisable to continue with very small doses.

The Indian publications give the following as the average doses in kala-azar:

	Full Single Dose.	= Sb.	Total Course.	= Sb.	Total number of injections.
Antimony Tartrate (37 % Sb ⁱⁱⁱ) ..	0.1 gm.	0.037 gm.	3 gms.	1.1 gms	30 or more
Stibosan (31 % Sb ^v) ..	0.3 gm.	0.093 gm.	3-3.5 gms.	0.93-1.08 gms.	10-12
693 (40 % Sb ^v) ..	0.3 gm.	0.12 gm.	2.1-2.7 gms.	0.84-1.08 gms.	8-10

These figures seem to support the latter interpretation.

It is important to remember however that according to Brahmachari 30 to 40 per cent. of urea-stibamine (Sb^v) is excreted during the first twenty-four hours after intravenous injection and only 6 per cent. of antimony tartrate (Sbⁱⁱⁱ) during the same period.*

It may be assumed that this also holds good for other p.a.c. whereby the quantities of antimony circulating in the blood after injections at 2 to 3 days interval would be considerably modified.

Some very interesting observations have been made in India which are reviewed below:—

The first of these observations is taken from Chopra's work in which the effects on the circulation, different organs, etc., are compared.

Chopra observed in experiments on cats "a well marked increase in the spleen and liver from the pentavalent antimony compounds, "rhythmic movements of the spleen are increased"†. Chopra considers it likely that "the influx of a large amount of blood charged with antimony into these organs probably helps in the destruction of the organisms lying therein. The tartrates produce these changes to a lesser degree and possibly this accounts for their lower curative effect"‡.

A further interesting difference is the precipitation of serum by the p.a.c. recently discovered by Chopra. When a solution of the p.a.c. is dropped into the serum of a kala-azar patient flocculation occurs; this has already been used as a serological test in the diagnosis of kala-azar. Tartar emetic does not give this reaction. Napier points out that this flocculation varies in degree, the most effective of the p.a.c. (693) producing the densest flocculation. Fabris was able to carry out the serum test favourably with Stibosan in infantile kala-azar.

* Mallardi in his clinical experiences in regard to the elimination of tartar emetic in infantile kala-azar found that in patients in good general condition the drug is eliminated in 2 to 3 days. In those in bad general condition after repeated doses it might take 5 to 8 days to obtain complete excretion. This indicates longer intervals in its administration in the later stages in debilitated patients.

The conditions of elimination of the pentavalent antimony compounds have still to be further investigated.

† The antimony injections can thus in some cases according to Chopra have a provocative action: "The engorgement and increased rhythmic movements produce rupture of the endothelial cells and liberation of the Leishman-Donovan bodies in the general circulation. The organisms, therefore, appear in the blood of these patients, where they could not be detected before." *Ind. Journ. Med. Res.*, Vol. 15, No. 3.

‡ *Ind. Journ. Med. Res.*, Vol. 15, No. 1. Hodgson mentions that an increase in the size of the liver frequently occurs as a result of the use of p.a.c. compounds.

Chopra further found on trying the new "antimony test" during the treatment with urea-

stibamine that after about the twelfth injection the test is uncertain, which roughly corresponds to the number of injections which practical experience has shown are required to ensure a cure without relapses.

In the two examples quoted there is a distinct difference between the p.a.c. and trivalent tartar emetic while the p.a.c. only show a slight difference among themselves. Both support the view that in addition to the larger doses fundamental qualitative differences play a part in producing the better therapeutic effects of the p.a.c.

With regard to the parasiticide action trivalent antimony has *in vitro* a stronger effect in killing organisms and in inhibiting their development than pentavalent antimony (Friedbergér and Joachimoglu determined this with inorganic antimony preparations).

Attempts at curing *experimental mouse trypanosomiasis* also demonstrated the fundamental differences between the p.a.c. and the trivalent antimony compounds (Uhlenhuth, Kuhn and Schmidt).

Tartar emetic very rapidly damages trypanosomes circulating in the blood stream of the mouse; after 2 to 3 hours they have disappeared from the blood picture; the other trivalent antimony compounds have the same action as antimosan. *The effective p.a.c. on the other hand such as stibosan only produce this effect in 1 to 2 days.* Thus the p.a.c. show a latent period between the injection and the trypanocidal action analogous to that of the arsenic compounds investigated by Voegtlin and Smith. Whether this latent period is due to a chemical reduction to a trivalent compound § which has a direct action as probably occurs in the aromatic arsenic compounds further investigations must show.

The p.a.c. are found to act more slowly in mouse trypanosomiasis than tartar emetic, i.e., the reverse of their action in kala-azar in which the trivalent tartar emetic is the slower. If, however, the ultimate curative effect rather than the action on the trypanosomes circulating in the blood of the mouse be considered the p.a.c. are found to be superior to tartar emetic in the mouse experiments also.

Tartar emetic in the almost lethal dose of 0.4 mg. = 0.14 mg. Sbⁱⁱⁱ will temporarily free mice infected with dourine or *T. brucei* from trypanosomes but relapses occur. A single injection of 2 mg. stibosan = 0.62 mg. Sb^v is frequently sufficient to cure the mice without

§ This reduction proceeds much more readily, as I found by measurement, in the organic arsenic acids and the organic stibinic acids than in the pentavalent inorganic compounds.

relapses; a number of other p.a.c. have a similar action.

This is, however, not a fundamental difference, for with antimosan, as already mentioned, a trivalent antimony compound with reduced toxicity, it is also possible to cure such mice without the occurrence of relapses by means of a single injection of 2 mg. = 0.25 Sbⁱⁱⁱ.

Antimosan is a complex salt of antimony oxide and a non-toxic derivative of pyro-catechin. It contains trivalent antimony but in contrast to tartar emetic the antimony is very firmly bound in a complex molecule so that it is not precipitated from an aqueous solution either by acids or alkalis. When the above excellent results had been obtained by Uhlenhuth, Kuhn and Schmidt in experimental cures it seemed justifiable to assume that it would be possible to obtain a particularly effective kala-azar remedy from the trivalent antimony compounds. It was indeed found that antimosan which is given in single doses of 0.4 gm. = 0.05 gm. Sbⁱⁱⁱ has the advantage over tartar emetic that it is better tolerated locally in intramuscular administration and generally, while it has the advantage of acting more rapidly in kala-azar only to a small extent and is in this respect much less effective than the p.a.c.* (Napier, Muhlen, Struthers).

Though experimental trypanosomiasis cures have been very valuable for selecting suitable antimony compounds from the numerous ineffective ones, Uhlenhuth, Kuhn and Schmidt have drawn attention to this divergence between trypanocidal† and kala-azar action which like other observations points to the possibility of a specific therapeutic action.

As a result of these indications it was necessary to take into consideration in the search for a more perfect p.a.c. for treating kala-azar, not only the therapeutic effect in mouse dourine, but also the experience obtained with kala-azar. His experience led Napier to take particular interest in p. aminophenyl-stibinic acid.

The p.a.c. which have so far been prepared can all be regarded as derivatives of p. aminophenyl-stibinic acid. We can divide them into three groups:—

1. Salts of p. aminophenyl-stibinic acid:

Sodium p. aminophenyl-stibinate (stibamine).

2. Derivatives obtained by substitutions in the amino group of p. aminophenyl-stibinic acid:

Stibenyl (Sodium acetyl p-aminophenyl-stibinate), Urea-stibamine, stibamine glucoside, aminostiburea. (The three latter preparations, as far as can be gathered from the literature, also belong to this group.)

*The superiority of the p.a.c. as compared with antimosan has so far only been proved in kala-azar. In other diseases such as bilharziasis it has not yet been decided whether a trivalent or a pentavalent antimony compound is the better.

†R. Schnitzler was indeed able to demonstrate the superiority of stibosan in experimental nagana when tartar emetic-resistant parasites were used; when mice were inoculated with this they could be cured with stibosan, while antimosan and also stibenyl remained without effect.

3. Derivatives obtained by substitutions in the benzol nucleus of p. aminophenyl-stibinic acid or p. acetylaminophenyl-stibinic acid:

Stibosan (sodium m-chlor-p-acetylaminophenyl-stibinate).

The reasons why the preparations in group 1 have not hitherto been used therapeutically is because the only known salt of p. aminophenyl-stibinic acid, the sodium salt, will not keep. Since a number of derivatives of this stibinic acid are useful in the treatment of kala-azar it was interesting to test the basal substance p. aminophenyl-stibinic acid afresh when the stable diethylamine salt had been prepared (639).‡ Napier's results in kala-azar with preparation 693 are as follows:—

Of 61 patients 58 were cured, of the remaining 3 one only received incomplete treatment and two others were absolutely resistant to antimony. *There was no death in the whole series!* Napier recommends 2.7 gms. to be given in 10 injections. He particularly emphasises that "post-treatment jaundice, such a common sequel to treatment by many of the other p.a.c." was not observed, an extremely useful indication of the non-toxic nature of the new remedy. Anaphylactic symptoms have also never been observed.

Napier's results showed that with the diethylamine salt it was possible to introduce p. aminophenyl-stibinic acid into the treatment of kala-azar in a practical form obviously superior to the derivatives hitherto available.

Before the wholesale preparation of the compound could be considered it was however desirable to eliminate the secondary effects of nausea which had been observed with therapeutic doses and to obtain a more stable aqueous solution.

I was able to carry out these investigations in the laboratory of the I. G. Farbenindustrie at Elberfeld to which the preparation of the antimony compounds had in the meantime been transferred from the Heyden chemical works. In collaboration with Rohl of the chemotherapeutic institute, and Eichholtz, of the pharmacological institute of these works, remarkable results were obtained.

The following preliminary remarks may serve as a general explanation. Two causes have so far been found for the differences in biological action of the various organic antimony compounds (the parasitotropic as well as the organotropic action of Ehrlich) and these were, first the degree of oxidation of the antimony residue (tri- and penta-valent), next the substitutions in the benzol nucleus. The latter have a very marked effect. The following extremes for example are taken from Uhlenhuth, Kuhn and Schmidt's tables:

Sodium p. acetylaminophenyl-stibinate (has trypanocidal action).	Lethal dose for mouse: 12 mgm.
Sodium p. chlorphenyl-stibinate (has no trypanocidal action).	Lethal dose for mouse: 1 mgm.

‡For therapeutic effect in mouse dourine cf. Uhlenhuth, Kuhn and Schmidt.

With the organic stibinic acids another factor also plays a part: *The special significance of the complex chemical and colloid-chemical state of the antimony acid radicle for the whole molecule.*

During my studies of these substances I devoted particular attention to the variability of the stibinic acids and have published in detail the methods used for investigating them and the results obtained. The benzol substitutions in the aromatic stibinic acids have the special effect of determining the condition of the antimony acid radicle in the above sense*. In this connection the formation of salts and the preliminary treatment from the colloid-chemical point of view is also of importance†.

Thus it appeared that in the diethylamine salt of p. aminophenyl-stibinic acid these points might be of particular importance.

By varying the method of preparation step by step and with simultaneous constant control by innumerable animal experiments it was possible to obtain a modification of the diethylamine salt of p-aminophenyl-stibinic acid with definite chemical properties, very stable, of complex chemical structure and characterised by marked diminution of toxic properties.

Thus according to the findings in the chemotherapeutic and pharmacological laboratories here the doses tolerated by mice weighing 20 gm. were as follows:—

Tart. Antimon. (36·6% Sb)	0·4 mg. =	0·15 mg. Sb. ⁱⁱⁱ
Antimosan (12·5% Sb.)	.. 6 mg. =	0·75 mg. Sb. ⁱⁱⁱ
Stibosan (31% Sb.)	.. 15 mg. =	4·65 mg. Sb. ^v
693 (40% Sb.)	.. 7 mg. =	2·8 mg. Sb. ^v
693b = Neostibosan (42% Sb.)	40 mg. =	16·8 mg. Sb. ^v

Dr. Napier has also used the new modification 693b in the treatment of kala-azar: with his kind permission we are able to state that he has obtained similar excellent results with 693b in spite of its much lower toxicity to those obtained with the preparations of 693 previously tested. As was to be expected, the reduction in the toxicity has resulted in the elimination of nausea after therapeutic doses. We look forward with great interest to further information from Napier on the results of treatment obtained.

A 25 per cent. solution of this compound in distilled water is blood-isotonic, is easily prepared in this dilution and according to Napier, when given intramuscularly causes practically no pain or local reaction.

* Differences in precipitation and flocculation by chemicals follow from this, which bear a striking resemblance to the differences shown by the various p.a.c. in the "serum test."

† In this connection it may be mentioned that Brahmachari (*Ind. Journ. Med. Res.*, Vol. 13, No. 1) and Niyogy (*Quarterly Journ. Ind. Chem. Soc.*, Vol. 4) have recently described the preparation of sodium-chlor-p. acetyl-amino-phenyl-stibinate, which is supposed to be identical with stibosan (471). It does not, however, correspond in either case since these authors precipitate their preparation from an aqueous solution with alcohol while a solution of stibosan, however concentrated, remains clear on the addition of alcohol.

The preparation of p.a.c. in stable form and of constant composition requires special experience and apparatus.

The preparation 693b is being introduced into the treatment of kala-azar under the name of "Neostibosan."

The history of the therapeutic use of the p.a.c. is mainly the history of the progress made in the treatment of kala-azar in India during the last seven years.

In the other tropical diseases which are treated with tartar emetic the p.a.c. have as yet not been so extensively tested but a large number of results have already been reported.

According to a number of authors a course of injections of stibenyl or stibosan will cure *oriental sore* (Plessier, Torrademe, Snijders, Talaat, etc.), even in cases in which tartar emetic has failed (Oven). Some authors recommend instead of or in addition to intravenous and intramuscular administration, the application of an ointment to the ulcer‡ (10 per cent. Stibosan ointment, Lindenberg) or injection into the ulcers (Plessier, etc.).

In Brazilian leishmaniasis of the mucous membrane (espundia) the curative effect of the p.a.c. did not according to Lindenberg reach that of the trivalent compounds (tartar emetic and antimosan). Wilson and Shrewsbury cured a severe chronic case (11 years!) of espundia with 17 injections of stibosan = 4.6 gm. after a few preliminary injections of tartar emetic.

Trypanosomiasis.

V. d. Branden found in the Belgian Congo that stibosan was not superior to the trivalent compounds in chronic cases.

Manson-Bahr cured one case of sleeping sickness with stibenyl which had not improved with tartar emetic.

Kleine found that stibosan was more effective than the trivalent compounds, especially when combined with Bayer "205" (Germanin).

Veneral Granuloma.

In his campaign against this disease carried out on a large scale in New Guinea, Thierfelder has used in addition to tartar emetic, antimosan and Bayer 211, stibenyl and stibosan. Of the two pentavalent compounds stibenyl followed tartar emetic in therapeutic effect, while stibosan acted more rapidly and more strongly than stibenyl and apparently was also more effective than tartar emetic. Both preparations were better tolerated than tartar emetic, the *marked tonic action of both the p.a.c. was striking*. The patients became so to speak "fat and round," while tartar emetic especially with repeated courses of treatment produced a diminution in body strength.

Manson-Bahr and Anderson found the p.a.c. superior to tartar emetic in effect and better tolerated.

‡ Tartar emetic is also applied by some direct to the ulceration, but this is a painful method of treatment and can only be carried out after the ulcers have been anaesthetised. For this purpose the non-irritating p.a.c., e.g., 10 per cent. stibosan ointment, are much more suitable.

Bilharziasis.

Manson-Bahr was unable to produce any effect in one case with stibenyl. Ziemann and Schirokauer on the other hand report excellent results in a number of Egyptian students treated in Germany. From Egypt itself the mother country of bilharziasis, where the trivalent antimony compounds are extensively used in combating the disease and the toxicity of tartar emetic gives rise to grave anxiety, no decisive conclusions have been reached on the p.a.c.

In *leprosy* Froilano de Melo found stibenyl effective as an adjuvant to chaulmoogra treatment and in one case Archibald obtained a similar result with stibenyl alone in *tubercular leprosy*.

Leber (Java) cured 2 cases of *tropical pemphigus contagiosus* with stibenyl injections.

Reviewing the latter results the reports at present available indicate the superiority of the p.a.c. only in oriental sore and venereal granuloma but this has not been as definitely proved as with kala-azar.

From the experimental and clinical observations it is not impossible that in some tropical diseases we shall not be able to dispense with the trivalent antimony compounds with their more powerful immediate effect, though it will be possible to avoid many of the drawbacks of tartar emetic which, as already mentioned, is an unsuitable preparation for use by injection; trivalent compounds such as antimosan are available which are suitable for injection and more readily tolerated.

The results with kala-azar demonstrate very clearly, however, that antimony treatment with the p.a.c. has become indispensable since it can be made more rapid, safer and more certain by the use of larger doses and probably by a different mode of action, so that it seems desirable to use the p.a.c. wherever they achieve the same or better results than the trivalent antimony compounds. Further tests are in progress in various places through the courtesy of tropical research workers and these include tests of neostibosan, the improvement recently found in India for the treatment of kala-azar.

THE SCIENTIFIC AND ECONOMIC IMPORTANCE OF RESEARCH ON INDIAN MEDICINAL PLANTS.

By SUDHAMOY GHOSH, D.Sc., F.R.S.E.,

Professor of Chemistry, School of Tropical Medicine and Hygiene, Calcutta.

IN a recent very interesting paper on Indian Indigenous Drugs (The Held for Research in Indian Indigenous Drugs—by R. N. Chopra, M.A., M.D., Lieut.-Col., I.M.S., *The Patna Journal of Medicine*, Vol. III, No. 3, July, 1928), Col. Chopra has discussed the chemical, pharmacological and clinical aspects of the subject and has also pointed out a few of the economic and scientific aspects of the question. In this paper I will try to discuss these latter aspects in more detail in order to bring out other points likely to be of interest to the physicians of the indigenous systems and also to other people interested in the subject.

Statistics.

Starting with the economic side of the question, let us consult only the statistics for a short period of 5 years, say, from 1919 to 1924.

The total value of Drugs and Medicines (excluding chemicals and narcotics).

	1919-20	1920-21	1921-22	1922-23	1923-24	Average per year
Exported from India ..	Rs. 45,46,980	48,32,390	35,13,048	22,89,352	28,97,624	Rs. 36,15,878
Exported from Bengal ..	Rs. 11,79,360	13,60,130	8,05,995	5,39,660	11,52,914	Rs. 10,97,603
Imported to India ..	Rs. 1,82,49,640	2,11,28,270	1,58,37,225	1,66,08,551	1,81,32,945	Rs. 1,79,91,326
Imported to Bengal ..	Rs. 58,53,690	77,35,950	55,21,575	54,61,091	60,00,246	Rs. 61,14,510

India's Potential Resources.

A perusal of this table will show the large amount of drugs and medicines (excluding chemicals and narcotics) exported from India and a very much larger amount (about six times) imported for our use. There can be little doubt that India has great potential resources. It only requires the attention of the people to develop these on economic lines, and it is not too much to hope that India may supply the whole world with drugs growing in tropical and sub-tropical climates.

Drugs of European and American Pharmacopœias growing in India.

The chemist and the pharmacologist can help in different ways. Many of the drugs used in Europe and America, for which some sort of standard has been laid down, grow in various parts of India. A systematic research or chemical and biological assay of all these drugs can be gradually taken up by the chemist and the pharmacologist and their value relative to those growing in other parts of the world can be ascertained. It will be necessary not only to assay those growing wild in different parts of India, but also to find out the seasonal variation of the more important ones and the soils in which they grow best.

Increased Export and Cultivation: Some Examples.

The work will naturally lead to an increased export and also to more scientific cultivation in order to increase the value of the drugs. Russian *Artemisia* growing wild had a santonin content of less than 1 per cent., but its cultivation increased the content to nearly 3.6 per cent., and Russia gradually became the best source of santonin. *Artemisia* grows wild in some parts of the Himalayas, in Baluchistan and in the Hindu-Kush mountains. India can supply the whole world with santonin if only a little attention is given to its cultivation. *Digitalis* leaves or preparations used to be imported in large amounts from outside India. Recent researches in India showed that the imported drug deteriorated to a great extent owing to transit, storage or climatic conditions and that it was necessary to get fresh leaves from Indian sources to secure an active preparation. *Digitalis* leaves of excellent quality are now being grown in different

parts of India, and the Indian drug is gradually coming into wider use. Again, *Ephedra vulgaris* grows wild in many parts of Northern India, and recent researches on Indian ephedra have created a great demand for it outside India. America alone ordered 34 tons (918 maunds) of ephedra during 1928. The alkaloid (taking the minimum yield of 0.5 per cent. of ephedrine) from 34 tons would fetch a value (at current price) of nearly four lakhs of rupees. And if further researches lead to its wider use in medicine, India will be a rich source of the drug. Numerous instances like the above can be found which would lead not only to increased export but also to increased cultivation.

Industrial Enterprise.

Again, the utilisation of some of these drugs in local factories would prove more economical than the export of the crude material. Thus the manufacture of caffeine from tea-dust, or of strychnine from *Nux vomica* seeds are examples of substance whose manufacture in India have proved quite economical in spite of the high cost of solvents bought from abroad. These factories would in turn lead to other industries for the manufacture of solvents or chemicals as soon as demands for these increase.

Drugs not recognised by B.P. or U.S.P.

There are again other drugs which are widely used by the physicians of the indigenous systems, but which have so far found no place in the European or American pharmacopœias. Systematic study and research will certainly help to create a demand for some of these drugs outside India and indirectly help their increased production and the evolution of industrial enterprises. The simple case of Indian Kurchi (*Holarrhena antidysenterica*) may be cited as an example. The recent researches on the subject in India have aroused great interest in the drug and already people in India and abroad are enquiring about the alkaloids, and drugs merchants are receiving orders for the crude drug outside India. The case of Kut root (*Saussurea lappa*) is another instance in point. Recent researches have shown that its alcoholic extract has a remarkable effect in controlling the paroxysms of bronchial asthma and is particularly effective in the vago-tonic type of asthma which is the

prevalent form in India. Manufacturers have now taken it up and it is bound to find a demand outside India.

Economy by the Use of Crude Drugs.

Coming again to the scientific aspect of the subject, let us discuss some of the questions raised. Physicians of the indigenous systems and also some of the general public have often been heard to remark that there is considerable economy in the use of crude drug powders, decoctions or fresh juices for a poor country like India and that it is unnecessary to isolate the active principles and study them on modern scientific lines. We have never disputed that this is an economical method, and we are even aware that examples are not rare in modern European and American medicines where the drug is used as a whole without attempting the isolation of the active ingredient. But there is this difference, that whereas Europe or America would not accept any drug unless tested by modern chemical, biological, pharmacological or clinical methods, we are asked to accept it on grounds of tradition or reference in an old text.

Modern Scientific Attitude.

We should never try to forget the attitude of the modern scientific mind, be it European, American or Asiatic. It has been aptly pointed out by Col. Chopra, that until these drugs are investigated on modern scientific lines, their use by the profession must necessarily be restricted, while other countries not bound by our local traditions will not use them at all, until the case is proved as to their utility. I would go a little further and say that even the physician of the indigenous system, with his modern scientific bent, should hesitate to use the drug, before he is satisfied that he can get the genuine substance of undoubted activity; for this there are several reasons:—

Variations of Active Principles.

Firstly, it has been proved in the case of many drugs that there may be enormous variations of their active principles with the change of season, the diversity of place, the nature of the soil, and even with the slightest variation of the species. I may simply cite the case of ephedra, a drug which we have ourselves studied. The active principle, ephedrine, has been found to vary a good deal with the seasons, and a variation in the species has resulted in the complete absence of the alkaloid. It is impossible for an ordinary drug supplier, the class of person on whom the physician has to depend (especially when practising in a town) to distinguish such variations of species, and it is even a very difficult problem for an expert botanist to do the same unless he is supplied with the various parts of the plant. A physician may thus be administering a drug without knowing whether it contains the active ingredient responsible for the cure. It is

only by the researches of the chemist and the pharmacologist aided by the botanist that such catastrophies may be avoided. There is not only the risk of the patient's losing all faith in the physician, but also of landing the system into disrepute. There is no harm in using the drug as a whole for economy, but one should know for certain that the active ingredient is present, even if not in the exact strength desirable for efficiently producing the very best effect.

Drugs that require Sifting.

Secondly, it is well known that there are various drugs having very little therapeutic value, which are used only because they are mentioned in old literature and because nobody has taken any trouble to confirm the truth or otherwise of these statements. A scientific basis is, therefore, essential and research is necessary to confirm their curative value or to reject them as useless. If the researches do point out the value of some of these drugs, they will then be accepted by the scientific world outside India.

Modern Conditions.

Thirdly, we should be wide awake to our modern conditions of life. The physicians of old, born and trained in a less artificial country life, had better opportunities of knowing the genuine herbs from their childhood. They knew the proper soil for their growth, the proper time for their collection, and several other factors to which the older works on the subject refer. The modern physicians, mostly trained in towns, never get these opportunities of knowing the plants first-hand and have to depend on unreliable and illiterate drug collectors, and they are even unable to satisfy themselves as regards their exact identity, not to speak of the proper season, soil or culture.

Are Fresh Drugs better than Active Principles?

It has been remarked by physicians of the indigenous systems that fresh juices or drug powders or other decoctions are better than the so-called active principles isolated by chemists, and also that modern methods of isolation destroy some of these active principles. A detailed discussion of the modern methods would lead me beyond the scope of this paper. I am quite aware of the drawbacks of the chemical methods, but as was only recently expressed by an eminent English professor of medical chemistry, one of the foremost research workers of the world, we are unable to accept the view that most of the active ingredients are destroyed by the modern chemical methods, assuming, of course, that due care and consideration have been bestowed during the investigation of a drug.

Combined Action of a Drug.

There is no doubt that there may be cases of drugs where the individual substances isolated do not explain the action produced by the drug as a whole and the result of a combined action must be assumed, but this can always be

safeguarded by simultaneous clinical trials of the whole drug. And after all, this consideration is by no means sufficient to deter a real well-wisher of the systems from supporting the pursuit of the scientific study of drugs.

Why are the Older Systems lagging behind?

It is not an easy problem to popularise a system for a large country like India. Drugs of the so-called allopathic system have steadily displaced the older systems prevalent in India, as I believe, not due to any political considerations, but because people have found them to be more speedy in their action and because they are based on scientific principles. Nobody can deny that there are hosts of really good drugs in the indigenous systems, but they have to be raised from empiricism to science. A systematic scientific study, a combined effort of the botanist, the chemist, the pharmacologist and the clinician is necessary to point out the really good points in these drugs; then, and then only, can we expect them to be accepted by scientifically minded people, be it in India or outside of it.

Scientific and Economic Value of Active Principles.

The isolation and detailed scientific study of the active principles from vegetable and animal sources draw our attention in two ways. First of all, these methods have made enormous contributions to our store of medical and scientific knowledge. Experiments on the pure compounds have revealed the exact pharmacological action of each of them and the study has led to scientific studies of a most varied nature on the chemical side. Secondly, they have contributed a good deal towards the development of various industries on synthetic and other lines.

Institutes in Europe for the Study of Medicinal and Economic Plants.

A study of the activities of Europe on the subject will be of interest to us here. In countries like Switzerland or Germany, one comes across either a pharmaceutical institute or department in almost every university. A large number of students are trained in chemistry, botany, pharmacognosy, pharmacy, toxicology, and many other allied subjects. Research is carried on in medicinal or economic plants, side by side with research on synthetic lines and the work leads to economic developments in various ways, not to speak of the scientific achievements of which they can rightly boast. The chemical departments of the various universities likewise contribute a good deal towards research on these lines.

Need for More Centres.

It would be difficult to find any medicinal plant growing in Europe which has not been investigated by scientists and it is a pity that this branch of research is neglected in India, a veritable emporium of medicinal plants. There is no dearth now of research chemists of the highest

order all over India and the only thing is to draw the attention of these workers to a subject of such economic and scientific importance. Some of the research students in each university might be entrusted with this work and important advances could be expected from such a combined effort.

Research Laboratory is Not Extravagant.

The initial cost of starting a research laboratory for chemical and pharmacological studies in a province, and even its recurring expenditure, may appear to be great, but the various benefits derived therefrom will amply justify its existence as an economic project. The example of business-minded people like the Germans or the English spending lavishly on research should certainly help to convince us about the economy in the long run.

Co-operation of Physicians of the Indigenous systems.

Lastly, the co-operation of the physicians of the indigenous systems (Ayurvedic or Tibbi) is essential in a work of this nature. They may, first of all, help us in the difficult problem of selection of good drugs which is often a source of great disappointment and discouragement to a new investigator. Again the work of the investigator is simplified a good deal if he knows the preliminary treatment of the drug, the exact mode of its administration, the kind of action to expect, and a few other points of a similar nature which the experience of the physician can alone teach him. The present method of finding these out from old literature entails a good deal of time and labour which could be considerably lightened by the physician practising in that system.

Appreciation of Scientific Spirit.

Finally, a proper appreciation of the scientific spirit, instead of the present distrust arising out of a groundless fear of our encroaching upon the domain of secret remedies, is essential for the above co-operation and the proper development of the systems on a surer, scientific basis.

We must remember in the words of Dean Stanley, that "Nothing is so narrowing, contracting and hardening as always to be moving in the same groove with no thought beyond what we immediately see and hear close around us."

Current Topics.

League of Nations. Health Organisation. Malaria Commission.

Meeting of the Malaria Commission at Geneva, June 25th-29th, 1928. Medical Press-Report.

FOLLOWING upon the publication of the Second General Report of the Malaria Commission and a Report on a visit to the United States of America undertaken by members of the Malaria Commission, certain criticisms

were made both in America and in the Far East regarding the conclusions reached in these two reports. It was decided therefore to invite a number of leading malariologists outside the Malaria Commission to submit in writing their criticisms upon the reports and further to attend the next meeting of the Malaria Commission. This meeting was held in June 1928 at Geneva and was attended by thirty-four malariologists, including members of the Commission. Amongst those attending for the first time, there were in addition to members of the United States Public Health Service and the International Division of the Rockefeller Foundation, representatives of the Colonial Office, London, the London School of Hygiene and Tropical Medicine, the Superior School of Malaria, Rome, the Royal Colonial Institute, Amsterdam, and the Department of Hygiene of the Hebrew University, Jerusalem. Engineering in its relation to malaria was represented by the Deputy Director of Public Works, Nigeria and the Chief Civil Engineer, Rome.

The Session lasted six days during which the conclusions of the Malaria Commission were discussed and proposals made regarding questions calling for international study. In the first instance, four general principles of anti-malaria work, as laid down in the Second General Report of the Malaria Commission, were considered by the full Commission. These principles, which were adopted after certain minor alterations in the wording, were as follows:—

1. In Europe, having regard to the present state of knowledge, correct anti-malarial practice is an endeavour to reduce the incidence and severity of the disease. Measures designed to accomplish more than that (particularly measures aiming at "eradication") are not a wise proposition and can be justified only under very exceptional circumstances.

2. It is not always necessary to deal with malaria by a method arising directly out of the knowledge that the disease is transmitted by mosquitoes.

3. In every country and very largely in every area, there must be preliminary examination to ascertain what method is best suited to the local conditions.

4. At present, it cannot be said that for malaria control there is a method for choice superior to all others.

The Commission set up three Sub-Commissions to facilitate the task of the Conference.

The First Sub-Commission dealt with the methods to be employed in anti-malarial work as indicated in the Second General report of the Malaria Commission.

The Second Sub-Commission considered certain epidemiological aspects of malaria and recommended to the plenary session a number of subjects for international studies and collaboration.

The Third Sub-Commission discussed the use of quinine in malaria.

After very full discussion, the following resolutions were submitted by the First Sub-Commission to the plenary Commission.

1. "Each Government should establish a central permanent organisation, either independent or attached to an institute, composed of several selected workers who would devote their whole time to malaria research and would act as scientific advisers."

2. "The Sub-Commission is not in favour of utilising all available methods of control in the same locality at the same time. It considered it preferable to employ only the method or methods which, with the means available, can be brought above the standard called minimum effective degree of perfection."

3. "Subject to certain defined limitations, determined by a knowledge of local conditions, there should be considerable freedom of choice as regards the particular methods of malaria control to be adopted. The Sub-Commission deprecates the use of measures in one region solely on the ground that they have been successful in another where, perhaps, circumstances and conditions are quite different."

4. "Whatever other means may be employed in malarial localities, the Sub-Commission considers that it is essential in the first place to treat the sick."

5. "The good results of early diagnosis and efficient treatment are more apparent in the reduction of the severity of the disease than in the reduction of its incidence."

6. "The execution of the measures must reach a sufficiently high degree of efficiency ('minimum effective degree of perfection') before its effect on incidence becomes appreciable."

7. "The improvement of the conditions of the inhabitants which results from the development of widespread 'bonification' is one of the determining factors in the regression of malaria. The work done is only efficacious in so far as it leads to intensive cultivation of the ground."

It is certain, however, that the use of anti-larval measures whilst more extensive works are being carried out, is of great value inasmuch as it reduces the anopheline density and serves to bridge the dangerous period which accompanies and follows such undertakings."

The treatment of the sick was accepted by all members as the invariable initial step in any anti-malaria campaign. No unanimity existed, however, as to how far this could be regarded as a preventive measure. There appears to be no doubt that the effect of the distribution of quinine is to lessen the severity of the disease, but no definite evidence of a resulting reduction in the number of cases was forthcoming.

Passing to the preventive aspect of anti-malaria work, the Commission laid stress on the fact that in every district malaria presented a local problem, the solution of which could only be found by a detailed study of the conditions obtaining in the locality. This investigation can only be satisfactorily undertaken by a highly trained group of research workers who devote their whole time to the investigation of malaria and whose services would be available in an advisory capacity for any locality in their district. As a corollary to this, the Commission deprecated the use of methods solely on the ground that these had been of value elsewhere and it consequently further urged the inadvisability of adopting all available methods of control until one or more of these methods had actually reached, in the locality in question, a standard of efficacy which the Commission termed "the minimum degree of efficacy."

The need for searching scientific investigation in every locality and the careful and deliberate selection of one or more methods based on the results of these researches is, in the opinion of the Commission, of universal application. In this connection, the fact is to be noted that a research staff should deal with malaria only and not with this disease simply as one of a number of public health problems. The Commission, moreover, emphasised the fact that in order to avoid discouragement by disillusion, it was essential to remember that each method possessed only a relative value, and this again depended on a certain degree of efficiency being reached. The considered opinion of the Commission was summed up in the final resolution, which reads as follows:—

"The Commission considers that the first duty of administrations which have to organise anti-malarial measures is to provide for the treatment of the malarious sick with the additional object of reducing sources of infection."

Simultaneously, or subsequently, according to the circumstances and conditions of the various regions, a study of the causes of endemicity should be undertaken with the object of choosing and carrying out the most efficacious, the cheapest and best adapted method or methods in the solution of the local problem. Provision should also be made either for radical measures (large 'bonification,' drainage) or for other temporary measures (anti-larval work).

The Commission is of the opinion that in all cases the use of mechanical protection and measures against the adult insects are desirable."

The Sub-Commission which dealt with certain aspects of malaria, discussed the following points:

(1) Utilisation of historical data for the epidemiology of malaria; criteria of reliability of these data; spontaneous decline of malaria in various countries of Europe.

(2) Criteria for the declaration of "malarious" zones.

(3) Habits of anopheles and their influence on the transmission of malaria; Anophelism without malaria.

(4) Influence of the mode of construction of the human dwelling on malaria prevalence.

With regard to the first of these points, the Sub-Commission shared the view expressed by the Commission and considered that, in general, historical records of mortality statistics "did not provide a good method of ascertaining the distribution and character of malaria, and that the results of their use, as an indicator of success in anti-malarial measures, might be very misleading."

With reference to the declaration of malaria zones, the Sub-Commission was in agreement with the opinion of the Malaria Commission that this declaration should depend on reports received from district Government Medical Officers notifying the occurrence, simultaneously or at brief intervals, of two or more first attacks of malaria, due consideration being also given to the presence of malaria-carrying mosquitoes and of breeding-places.

Finally, under the last two headings, a number of possible lines of research were suggested by individual members as follows:—

I. *Studies Relating to the Biology of Anopheles.*

(1) Pathogenicity of the various plasmodia to anopheles; can an intense infection produce sterilisation of the mosquitoes and modify the migration of these insects?

(2) Domestic malaria and proofs of the permanent domesticity of anopheline carriers of malaria.

(a) Domesticity of the various species of anopheles.

(b) Changes in adaptation of anopheles of a given species according to the varying conditions of their "habitat."

(c) Means of estimating the degree of domesticity of a given species of anopheles.

(d) Importance of "peridomestic" collections of water and their relationship to the "habitat" of adult anopheles.

(3) Study of certain facts influencing the biology of anopheles and their relationship to the efficacy of anti-larval measures:

(a) Degree of permanence of collections of water used as breeding-places.

(b) Mechanical limitation of the migration of anophelines:

(i) Length of flight.

(ii) Altitude.

(iii) Wind and other meteorological factors.

(iv) Forests, etc.

(c) Biological obstacles to the migrations of mosquitoes.

(i) Inhabited houses.

(ii) Stables, animal sheds, etc.

(4) Study of the various factors which cause "anophelism without malaria," i.e., which prevent the local anophelines from acting as malaria vectors.

This enquiry should be carried out particularly in districts where the phenomenon occurs and which border upon areas where malaria is endemic. Efforts should be made to ascertain whether any of the factors claimed to be the cause of the phenomenon are operative in the country under observation and the investigation would be especially concerned with the following subjects:

(a) Differences in the anopheline density of the malarious and non-malarious regions.

(b) Morphological and biological differences of the anopheline population of these regions; especially with regard to selection of food (animal or human blood), shelter (animal or human habitations), and breeding-places (hydro-telluric conditions).

(c) Differences in relation to receptivity, of both anopheline faunas, with regard to malarial infection.

(d) Differences in relation to the human host and its surroundings;

(i) Numerical relationship of anophelines in contact with man and animals in stables, especially such animals as may be shown to be attractive to anopheles by means of the precipitin test.

(ii) Conditions of housing, especially with regard to the shelter offered to anopheles.

Note.—It is understood (1) that these factors are not necessarily the same in the various regions; (2) that it is essential for the present not to take it for granted that an explanation obtaining in one region holds good in another, however feasible it may be; (3) that it is only after the determination of such factors in many localities that it will be possible to determine the fundamental cause of the phenomenon.

II. *Studies Relating to Malaria in Man.*

(1) Possibility of persistence of the capacity for evolution of gametes derived from an individual treated with quinine. This knowledge is necessary for an accurate estimation of the value of quininisation in infections by the various species of plasmodia.

(2) Climatic and seasonal influences on schizogonic development of the various plasmodia.

(3) Study of hæmoglobin in the course of malarial infection and during treatment.

(4) Determination of a method of distinguishing:

(a) Primary infections.

(b) Re-infections.

(c) Relapses.

III. *Studies Dealing with Anti-Malarial Measures.*

(1) Factors in the so-called "spontaneous regression" of malaria:

(a) Value of the data on malaria contained in vital statistics.

(b) Experimental study of the factors involved in "complete bonifications" in the diminution of endemic malaria.

(c) Influence of ricefields.

(d) Influence of the cultivation of other irrigated crops.

(2) Study of the various methods of destroying anopheles in dwellings without injuring the contents of the rooms.

(3) The determination, in each country and region, of the domestic animal which attracts anopheles most and the correlation between this fact and malaria prevalence.

(4) Is the development of zygotes inhibited by the absorption of animal blood by the infected anopheles during this development?

Emphasis was also laid on the desirability of undertaking an international study of house construction in relation to anophelism and malaria, the study to include the construction of stables and the relationship between stables and human dwellings.

The Sub-Commission on Quinine considered the following questions:

I. The dosage of quinine and the duration of treatment. The grounds upon which these figures are based. Standard treatment and its effects.

II. Experiments with other cinchona alkaloids.

III. Use of drugs other than quinine, with special reference to plasmochin.

Under the first heading, the first Commission fully discussed the distribution of quinine as a social problem. With reference to dosage, the Sub-Commission expressed the opinion that due regard should be paid to the form of the parasite, the nature of the disease and the character of the epidemic.

It is essential to continue treatment after the attack has been cured, but treatment should not be continued for more than four to six weeks, and large doses are unnecessary. The Sub-Committee thought that a daily dose of 1 gram of quinine for an adult should be sufficient for consecutive treatment, and that the latter half of this treatment should be interrupted for three or four days each week during which no quinine should be given.

With reference to the second point the Sub-Commission considers that:

Experiments should be continued with various samples of kinetum extracted from different varieties of bark, more or less rich in quinine, and with the various secondary alkaloids. The scope of these investigations should be enlarged so as to include a trial of these drugs for intensive treatment.

With reference to the third heading, the Sub-Commission urged the necessity of a study of the value of plasmochin and quininstovarsol in the treatment of malaria—the enquiry being carried out in hospitals or in circumstances permitting of direct daily medical supervision.

The following are to be asked if they would be willing to undertake this study:—

Professor Ascoli	.. Italy
Professor Nocht	.. Germany.
Colonel Christophers	.. India.
Professor De Langen	.. Netherlands East Indies.
Anti-Malaria Service of	Madagascar.
Dr. Barber	.. U.S.A.
Professor Pittaluga	.. Spain.
United Fruit Company	.. Central America.
Professor Ciuca	.. Roumania.

The Sub-Commission further recommended that investigations be carried out in different countries to ascertain the practical importance of the intensive treatment by quinine of patients suffering from malaria, as a general prophylactic measure against this disease.

In the final meeting of the full Commission, after some discussion, the reports of the Sub-Commissions as outlined above, were adopted in their entirety together with the following programme of future work.

I. Housing in Relation to Malaria.

Documentation on this subject is to be collected by the Secretariat particularly with reference to tropical and southern countries. Messrs. Evans and Bonamico are to draw up on the basis of this documentation a plan for further systematic study.

Dr. Hackett made a proposal which can be classed as a chapter in the study of the above subject, namely, the investigation of the degree of contact between anopheles and man in areas of different malarious intensity:

(a) Ratio of anopheles in stables to those in bedrooms;

(b) Proportion of anopheles that bite human beings (precipitin test).

The following four groups are to be asked to undertake this experimental and epidemiological study:

Professor Brumpt and Professor Carlos Chagas.
Stazione Specimentale in Rome and Dr. De Buen.
Colonel Christophers and Dr. Kligler.
Dr. Mafey and Dr. Sfarci.

II. Systematic and Biological Study in Europe and in America of *A. maculipennis* and of *A. quadrimaculatus* in their Relation to Malaria Transmission and Prevention.

This study was entrusted in the first place to a group of laboratories in the United States of America to be designated by the United States Public Health Service and the International Health Division of the Rockefeller Foundation, on the one hand, and to the Institute of Tropical Medicine, Amsterdam, and Colonel James's laboratory in England, on the other hand.

When sufficient progress has been made, the collaboration of further laboratories is to be invited on the basis of the first provisional report. In the meantime, the Commission suggests that those members who would be willing to engage in the experimental studies of this subject might forward their observations to the Secretariat for communication to the first group of workers.

III. A plan was drawn up for the study of the practical importance of intensive quinine treatment of malarious sick, considered as a preventive measure in a malaria campaign.

This plan included:

(a) A critical study of the data available up to the present.

(b) Epidemiological and statistical study of the frequency of pre-epidemic relapse in individuals who have undergone an intensive quinine treatment.

These two studies are to be undertaken by the Secretariat who will obtain such advice and invite such expert collaboration as may be found to be necessary.

(c) Experimental study of the effects of treatment on:

(1) The time of appearance, the persistence, the rhythm of reappearance and the number of gametocytes.

(2) The possible loss of evolutionary capacity of the gametes found in treated persons.

This experimental study can obviously only be undertaken by laboratories in intimate and constant contact with hospitals able to supply sufficient clinical material. The following three groups of workers are to be asked to undertake this work:

(1) Professor Nocht, for the Hamburg Institute of Tropical Hygiene.

Professor Ascoli, Professor Ottolenghi for the Clinics and Hospitals in Italy.

(2) Colonel Christophers, for the Institutes of British India.

Dr. Kingsbury, for the Institutes of the Federated Malay States.

(3) Professor Pittaluga, for the Hospitals and Clinics in Spain.

Dr. Sergent, for the Institutes in Algeria.

The other suggestions contained in this report as to proposed studies are to be classified and brought to the attention of members of the Commission and other malarialogists. Should such studies be undertaken, the Commission would be glad to be informed from time to time of the progress made.

Portal Cirrhosis Associated with Chronic Inorganic Arsenical Poisoning.

Report of two cases.

By PAUL A. O'LEARY, M.D.,

ALBERT M. SNELL, M.D.,

and

EDWIN G. BANNICK, M.D.

(*Jour. Amer. Med. Assoc.*, June 9, 1928, p. 1856.)

THE damaging effects of organic arsenical compounds on the liver have been known for some time but hepatic lesions, following the exhibition of inorganic arsenic, are of much less frequent occurrence. The two cases reported by the authors are therefore of some interest.

Case 1.—A farmer, aged 52, first observed in November 1926, had been complaining of abdominal distention for six weeks. The familial and marital histories did not have any bearing on the condition, and the patient was not addicted to the use of alcohol. He had gone through the usual infectious diseases of childhood, and influenza and pneumonia in 1918. In 1921 generalized dermatitis appeared, which was characterized by the formation of wheals, vesicles and blebs. The itching and burning caused extreme discomfort. Dermatitis herpetiformis had been diagnosed elsewhere but the disease had not been relieved. He had taken arsenic, which had been prescribed in one form or another for about four years; during one year he recalled taking solution of potassium arsenite in doses of 10 minims (0.6 c.c.) three times daily. For some time before he had noticed pigmentation of the skin and "wartlike growths" on the palms and soles. In October 1926, he was seized with cramp-like pain in the lower part of the abdomen and general malaise; within forty-eight hours the abdomen began to increase rapidly in size; with the abdominal distention definite shortness of breath on exertion developed, but the pain subsided.

The patient was mildly dyspnoic and emaciated. The skin of the trunk showed extensive speckled pigmentation of the arsenical type and there was marked arsenical keratosis of the palms and soles. The characteristic

pigmentation of dermatitis herpetiformis was obscured by the arsenical pigmentation. Many excoriated plaques, papules, wheals and groups of vesicles and bullæ were noted on the trunk and thighs. The pupils were regular and equal and the fundus oculi normal in appearance; the teeth were in poor condition and the tonsils were small and atrophic. The thyroid gland was not palpably enlarged and there were no enlarged lymph nodes except a small one in the left axilla. The heart seemed to be displaced upward but was otherwise normal; the lungs were clear except for slight dulness at both bases. The abdomen was greatly distended with fluid: no organs or masses could be made out. A few enlarged veins were observed over the lower part of the abdomen. There were no hemorrhoids of any consequence. The deep reflexes were normal and the genitals, extremities and rectum were normal. Urine analysis, blood counts, a blood Wassermann test and chemical studies of the blood were not productive of anything abnormal. The stools did not contain parasites or ova. The roentgenogram of the chest was negative except for thickened interlobar pleura on the lower right side.

A tentative diagnosis of dermatitis herpetiformis and portal cirrhosis due to chronic arsenical poisoning was made. Because of the possibility of abdominal carcinomatosis, however, it was decided to perform a biopsy on the lymph node from the left axilla, to be followed by abdominal exploration if the node did not prove to be malignant. The node was reported inflammatory by the pathologist. When the abdomen was opened a large quantity of clear yellowish fluid escaped; careful examination of the abdominal viscera was negative except for definite cirrhotic changes in the liver, which were described as being of the hobnail type. A Talma-Morrison operation was then performed, a piece of omentum being sutured into the space between the peritoneum and the posterior sheath of the right rectus muscle. The patient made an excellent recovery but returned for a second time in January, 1927, because of mild abdominal distention. The dermatitis herpetiformis had improved greatly. Ascites was only moderate, and in general the patient was quite comfortable. He was readmitted to the hospital, January 3, 1927, for a trial of treatment with diuretics. Re-examination and repetition of the laboratory studies did not reveal any new abnormality. Tests of hepatic function with bromsulphalein were negative and the serum bilirubin was normal in amount. Since the patient was anxious to return to his work, treatment was instituted at once, ammonium chloride being given in a dosage of 6 gm. daily and three doses of merbaphen (0.5, 0.75 and 1 c.c., respectively) being given intravenously on the first, third and fifth days. There was a satisfactory diuretic response, the patient losing 10 pounds (4.5 Kg.) in weight and the ascites disappearing promptly. Even with the abdominal cavity "dry," no enlargement of the liver or spleen could be made out. The bromsulphalein test when reported showed slight dye retention, graded 1.

After dismissal the patient had variable success in controlling the ascites for several months, but gradually this condition became less troublesome. Except for the persistence of the dermatitis herpetiformis, he apparently had made excellent progress.

Case 2.—A farmer, aged 41, was admitted to the Mayo Clinic, April 30, 1927, complaining of weakness, extreme fulness and distress in the abdomen, and diffuse pigmentation of the body. The family history was unimportant, and the previous history was essentially negative. He had been a moderate user of tobacco and had used very little alcohol, none in the previous four or five years and only rarely before that time. The patient had been employed in a copper smelter from 1913 to 1921. He stated voluntarily that the vegetation in the community was sparse because of the irritating fumes produced in the smelting process. During the last few years of his work in the smelter he had noticed that his eyes watered and that there was some swelling of the lids, especially noticeable in the morning. In 1918 he had suffered from burning pains in the soles of the feet and similar discomfort in the calves of the legs, which appeared at intervals and finally caused him to give up his work

and start farming. He remained on the farm from 1921 to the time of his admission. In 1922, because of slight persistent pain in the feet and slight weakness, he was advised to take solution of potassium arsenite, which he did for about three months, in doses of 5 minims (0.3 c.c.) four times daily. This made his eyes water and he discontinued it. He continued with farm work without especial complaints, except that he did not seem to be as strong as he thought he should be. In April 1926, he again began the use of solution of potassium arsenite four times daily, and continued this for one year. Shortly after he began the use of this solution for the second time, he noticed slight pigmentation about the body but did not pay any particular attention to it. This pigmentation gradually became more and more prominent, and associated with it he noticed what he called "calluses" on the palms and soles. Two months before admission he began to notice definite anorexia and gradually swelling of the abdomen. As, a result, he stopped the solution of potassium arsenite but the swelling of the abdomen continued and soon he noticed swelling of the ankles also. About two weeks before admission a large amount of clear fluid was withdrawn by abdominal paracentesis. When the fluid reaccumulated, he presented himself for examination.

The patient was somewhat underweight with marked ascites and moderate oedema of the lower part of the legs. There was diffuse, mottled brownish pigmentation of the "rain-drop" type over the entire body; it was more marked over the trunk and especially around the axillæ, the neck, the anterior aspect of the chest and the genitalia.

There was a mild degree of pigmentation in the mucous membrane of the mouth, a not unusual condition in arsenical pigmentation. There was marked arsenical keratosis of the palms and soles extending over the dorsum of the hand in some areas. The heart was normal in size, and no abnormalities of cardiac action were detected. The lungs seemed entirely normal. The blood pressure was 110 systolic and 70 diastolic. The abdomen was markedly distended with fluid. A few collateral venous channels were visible. The ascites prevented the possible palpation of organs or masses. Complete neurologic examination was entirely negative except for some tenderness in the calves, which, when considered with the history of ingestion of arsenic, suggested the possibility of arsenical neuritis. Urine analysis and a blood Wassermann test were negative. Hemoglobin was 70 per cent. (Dare); erythrocytes numbered 3,940,000 and leukocytes 8,600. The blood urea and creatinine values were normal. A phenolsulphonphthalein test showed 50 per cent. return of the dye in two hours; an electro-cardiogram did not show any changes of significance. A test of hepatic function performed with bromsulphalein showed absence of dye retention; the serum bilirubin was 0.5 mg. for each hundred cubic centimetres. The same tests repeated three weeks later showed dye retention, graded 1, but no change in the serum bilirubin content. The fasting blood-sugar and dextrose tolerance tests were within normal limits. Urine specimens examined nearly every day were positive for arsenic, there being on an average about 10 mg. of arsenic for each thousand cubic centimetres of urine.

The treatment instituted consisted of a low-salt, low-fluid type of diet, ammonium nitrate by mouth in doses of 6 gm. daily, and injections of merbaphen intravenously at intervals. The satisfactory diuretic response and gradual loss of weight coincided with complete disappearance of oedema and ascites. In a small piece of skin removed from the axillary fold the Osborne stain revealed granules which have been considered to be arsenic sulphide. Mallory's iron stain showed also deposits of hemosiderin about the sweat glands.

The diagnosis was arsenical dermatitis, cirrhosis of the liver with ascites (probably due to arsenic) and probably a mild degree of hæmachromatosis. Since the urine still contained a considerable amount of arsenic, a course of sodium thiosulphate was indicated as a possible means of increasing the elimination of arsenic and thus protecting the liver, especially, against further

injury. This drug was given intravenously in doses of 1 gm. on each of ten successive days. During the first half of this period the amount of arsenic in the urine was definitely increased and then the excretion gradually fell to the previous constant level. The patient was dismissed, June 9, feeling much stronger, free from œdema, and without demonstrable free fluid in the abdomen.

In two cases of chronic arsenical poisoning, after the cutaneous changes were well established, ascites and other signs of portal cirrhosis appeared. It is suggested that such cases represent a clinical entity; they may be described as arsenical cirrhosis. The changes known to occur in the liver in arsenical poisoning, the appearance of the liver at operation in one of the cases described and the occurrence of similar cases in epidemic arsenical poisoning may be cited in support of this view. A favourable response to treatment was noted in both cases.

Dangers of Hasty Generalisation.

(An abstract from an article "On the Value of the Statistical Method in Practical Medicine.")

By PERCY STOCKS, M.D., D.P.H. (Camb.)

(*Lancet*, June 16, 1928, p. 1243.)

I do not need to quote examples to show how often in the past, over long periods of years, tens of thousands of patients have been subjected to some form of treatment in the erroneous belief that it had been proved to be beneficial, whereas an application of statistical methods at an early stage might have shown that it was useless. It is by this kind of thing that the progress of medicine has been so often retarded and much expensive effort wasted; some medical practitioners attribute the cure of a malady to a particular treatment because they have seen it associated with that event in a few cases; others attribute it to another treatment for the same reason, whereas both are mistaken in having hastened to generalise whilst overlooking the normal expectation of coincidences, which could easily be measured by the theory of probability. Most diseases have been attributed to chills and syphilis on this account.

The Work and Responsibilities of the Pathologist.

(An extract from a lecture delivered by Sir Bernard Spilsbury to the Research Defence Society.)

(*Brit. Med. Journ.*, June 23, 1928, p. 1079.)

At the outset Sir Bernard Spilsbury defined a pathologist as a specialist in the study of the scientific aspects of disease, including the essential cause, the changes, visible and microscopical, produced, and the reactions provoked in the patient. The growth of scientific knowledge and of the laboratory method of investigation during the last fifty years had greatly increased the pathologist's labours and had brought about the division of the work between the pathologist (in the narrower sense of the term), the bacteriologist and the chemist.

Sir Bernard Spilsbury then gave a few illustrations of the achievements of pathology in the study of the causes and processes of disease. The first was what he called the "romance" of anthrax. This disease had been recognized from very early times; the murrain of cattle recorded in Exodus was supposed to have been anthrax. In the middle of the last century the observation was made that minute bodies were observed microscopically in the blood of animals suffering from this disease, and it was stated that the blood which contained these bodies would produce the disease when injected into the healthy animal. The matter was still in dispute when Koch, in 1876, then a country practitioner in Germany, devised a method of growing the organism outside the body in broths and jellies, showed that these cultures had distinctive characters, and was able to

reproduce the disease in healthy animals by injection. Koch's proof of the cause of anthrax was utilized by Pasteur, who had already begun his investigations on infectious disease, and he developed a method of protecting animals against infection. He experimented with cultures of the anthrax bacillus until he so reduced the virulence that on injection of the attenuated cultures into the healthy animals, those animals developed protective powers which enabled them to resist subsequent injection of virulent organisms. The result of the widespread adoption of protective inoculation was that the mortality in cattle and sheep from this cause had greatly diminished; in France it had been reduced to one-twentieth of what it was before inoculation methods were adopted.

Another illustration was hydrophobia, where Pasteur found that the virus was always present in the spinal cord of rabbits used in experiments, and that healthy dogs could readily be infected by injections made therefrom. He also found that the virus lost its strength with keeping, until after a time it failed to reproduce the disease on inoculation. Taking advantage of this fact, he injected into patients who had been bitten by rabid dogs preparations from the spinal cord of the experimental rabbits, using first very attenuated virus and repeating the injections with matter of increasing virulence, thus protecting the patient before the original disease had time to develop. The results of this treatment carried out in the Pasteur institutes in various parts of the world had been to reduce the fatalities to less than 1 per cent. of the patients treated.

In some infections the protective power was resident in the blood, and patients were treated by the injection of the serum of an animal which had been immunized against that particular infection. The immunization had been obtained by giving the animal a series of injections containing the organism or its specific toxin in carefully graduated doses, so that it developed substances which counteracted the effect of the poison and presently gained complete protection. One of the most important applications of serum treatment was to diphtheria; it had been clearly proved that the mortality was greatly reduced by injection of the specific serum, especially if the patient was treated at an early age.

Part of the pathologist's routine work was to diagnose infectious disease by the discovery of the organisms, but in some cases microscopical examination of the suspected material failed, and recourse had to be made to animal experiments. In early and obscure cases of tuberculosis, for example, to search for the organism by microscopical means was like searching for the needle in the haystack. In such cases injection of suspected material was made in the guinea-pig, which after a time was killed, and if the tubercle bacillus had been at work the characteristic changes were found. Another difficulty with which the pathologist had to contend was that some bacteria which produced specific disease had their innocent "doubles," and again it was animal experiment which enabled the problem to be solved.

A good deal of misconception existed with regard to animal inoculation. In the vast majority of cases the animal suffered no worse effect at the time of introduction of the material than the soon forgotten prick of the hypodermic needle. In some cases the development of the disease led to speedy death; in others, as in tuberculosis, the animal would presently show slight signs of disease sufficient to indicate that it should be destroyed and its dead body examined. It was only in a very small proportion of cases that serious suffering in the sense of pain attended inoculation experiments, and even then it was usually short-lived owing to the rapid progress of the disease.

Sir Bernard Spilsbury then mentioned some chemical problems which were presented to the pathologist, how, for example, by animal experiment, tetra-chlor-ethane was incriminated as the liver-damaging element in aeroplane "dope" during the war; also how experimental methods, again on animals, afforded the information required as to the hygienic measures to be adopted in factories against poisoning by T.N.T. Again, the experimental work by Dr. J. S. Haldane in connection

with carbon monoxide gas indicated the mechanism by which this form of poisoning acted, and his experiments on mice demonstrated once and for all the proper method of treating those who were suffering from its effects.

Practically the whole of bacteriological knowledge was based upon experimental work—inevitably so in the present state of affairs, for there were no means of testing the suspected organism except by the reproduction of the disease in living animals. The same was true of the diagnosis of disease. Every pathologist who worked alone, in a small hospital, found himself compelled to have a Home Office licence for vivisection if he was to do his duty to the patients in the diagnosis of obscure disease. For that reason, in recent years, the number of licences granted to pathologists all over the country had greatly increased. But chemical problems also required animal experimentation in such matters, for example, as the testing of new drugs. The pathologist was a medical practitioner, who, like his clinical colleague, had to apply his skill and knowledge to the best advantage on behalf of the patients. He must avoid error as far as possible, and must employ exact methods, including, at present, animal experiment. The scientific advances of the last fifty years, very largely based on experiment, had gone far to revolutionize the treatment of disease, so that there were some diseases, formerly rampant, with which the modern practitioner was scarcely acquainted. If only our forebears of last century could see the work which had been done in modern science and medicine, how they would exclaim at the enormous amount of suffering which, had they possessed the knowledge in their day, would have been prevented!

Diagnosis of Early Tuberculosis.

(*Medical Press*, June 27, 1928, p. 517.)

THERE is no diagnosis of major importance which is beset with so many difficulties as is the recognition of pulmonary tuberculosis in its earliest stages. Moreover, the physician is necessarily hampered by the fact that, his patient—whether or not he asks the direct question—has as a rule knowledge enough of the possible significance of his symptoms to share the doctor's anxieties, and to demand, not merely treatment, but a definite and unequivocal diagnosis. Very different it is, as a rule, in the case of cancer. At the stage when the patient's own suspicions have been aroused it is usually no very hard matter for his doctor to form a definite opinion on the case. At the stage when the doctor finds it well-nigh impossible to make a definite diagnosis for or against malignant disease, the patient is, as a rule, unconscious how serious an interpretation his symptoms may have. Where the diagnosis of tuberculosis is genuinely in doubt, and where it is of importance that if the disease exists the patient should make a radical change in his mode of life, it is the wisest course, we believe, to take the patient into our confidence. Where, on the other hand, there are strong reasons for not even raising the suspicion, and where, as in the case of a boy or girl not yet employed in a profession, a month's careful rest is not a very disturbing prescription, it is often necessary to give the definite assurance that no signs of disease are detectable in the lungs: a half-truth, but a necessary one. In this common difficulty it is surprising that doctors do not more often resort to guinea-pig inoculation. From four to six weeks is all that it is necessary to wait, and the inoculation provides at once the best chance of a positive bacteriological diagnosis, and the nearest possible approach to a negative one. When symptoms have cleared quickly it is of great importance to the patient to learn that his attack was really tuberculous; while when catarrhal symptoms persist without any tendency towards general symptoms, a negative inoculation is powerful support to the gradually dawning conviction that the affection of the chest is really non-tuberculous.

A Contribution to the Study of the Erythrocyte Sedimentation Reaction.

By COLONEL DAVID TOWNSEND, M.D.,

and

HELEN B. ROGERS, B.L.

(*Journ. Lab. and Clinical Med.*, June 1928, p. 819.)

THE authors tested the value of the erythrocyte sedimentation reaction in several thousand cases of whom the majority were tuberculous. Three different methods were used and the authors record the following conclusions:—

- (1) The erythrocyte sedimentation reaction is not specific for tuberculosis.
- (2) A parallelism exists between the severity of the disease and the increase in the sedimentation rate.
- (3) With improvement in the condition of the patient, the speed of sedimentation decreases; the opposite being true with increasing severity of the disease.
- (4) The phenomenon sometimes disappears shortly before death.
- (5) The sedimentation rate is not an index of the extent of the tuberculous involvement.

The Pupil Reactions.

By C. L. GIMBLETT, M.D., M.R.C.P., F.R.C.S.,

The Practitioner, June 1928, p. 354.

NOTES on the significance of variation in the size and of inequality of the pupils are quoted below:—

The Size of the Pupils.—The size of the pupils varies with age and the condition of the central nervous system as well as with accommodation and intensity of illumination. It is also affected by drugs.

(a) *Age.*—In infancy the pupils are contracted, in early adult life often widely dilated, while in old age they become, as a rule, small once more.

(b) *Central nervous system.*—Dilatation of the pupil occurs in emotions, such as anger or fear, and follows the excitation of sensory nerves. Constantly seen in the presence of pain, as in biliary or renal colic, it may be used as a test of its genuine severity. Anæsthesia provides a series of changes in the size of the pupils. During the first "excitement" stage they are dilated, in the second "surgical" stage contraction is present, while in the third stage—and in all states of "exhaustion" such as alcoholic coma and immediately preceding death—the pupils become widely dilated. During sleep, contrary to expectation, the pupils are constricted, the eyes are rolled upwards, and the visual axes convergent, hence the constriction is considered part of a synergic act.

(c) *Drugs.*—The actions of the alkaloids of atropine and cocaine to produce dilatation, and of those of pilocarpine to cause constriction, will be referred to when considering inequality of the pupils. The alkaloids of opium produce marked pupillo-constriction when given in clinical doses for the relief of pain—not by any local action on the pupil, for no constriction follows their instillation into the conjunctival sac, but by an effect upon the central nervous system (probably the basal ganglia).

Inequality of the Pupils.—The causes of inequality of the pupils, both in size and reaction, may be peripheral in the eyes themselves, or in the sensory and motor nervous paths or their central connections.

I. Locally in the Eye-ball.

(a) *Trauma*—not syphilis—is the commonest cause of inequality of the pupils. As the result of a blow—which need not have been severe—muscle fibres of the iris become torn. The pupil is permanently altered in size and sluggish in reaction, while its position is slightly eccentric and its margin irregular.

(1) The dilator pupillæ tears at the periphery of the iris—its thinnest part—with the formation of a "black crescent" in this situation (iridodialysis). A view of the fundus can be obtained through this gap

as well as through the pupil. The segment of iris affected becomes inactive, and its margin irregularly flattened, the normal circular outline being lost.

(2) The constrictor pupillæ usually tears at the pupil margin; if severely, the pupil becomes widely dilated and entirely inactive to light, both directly and consensually, while it does not contract to accommodation. Such a pupil is *more* inactive than that of a blind eye.

Many lesser degrees of trauma exist in which only a few fibres are torn. Such a pupil—a little dilated, reacting sluggishly to light and contracting somewhat ineffectively to accommodation—is, far more often than is supposed, considered as due to syphilis.

(b) *Drugs*.—Clinical doses of the alkaloids of atropine, eserine, cocaine and perhaps adrenaline, are common causes of inequality of the pupils. Instillation is usually clinical, but may occasionally be accidental or even fraudulent. The presence of the drug alters visual acuity by affecting the ciliary muscle, which somewhat alarms a patient unaware of the cause of his sudden inability to use one eye. Accidental sources are liniment prescribed for lumbago, or eye ointment ordered for some other member of the family. The right eye is usually affected in such patients. The effect of atropine lasts ten days, and in an elderly person may result in a rise of intraocular tension, so that instruction as to the care of the hands should be given to patients using liniments. The nerve-endings in the muscles are the points of action of these drugs; atropine paralyzes and eserine stimulates those of the third nerve in the constrictor, while cocaine and adrenaline stimulate those of the sympathetic in the dilator pupillæ—adrenaline only affecting the pupil in pancreatic insufficiency (Levi's test). When the pancreas is normal its internal secretion—present in the bloodstream—is thought to neutralize adrenaline immediately upon absorption.

(c) *Inflammation*.—(1) Inequality of the pupils may be due to the presence of iris adhesions—synechiae—characteristic of iritis, which are of frequent occurrence and often much more marked in one eye than in the other. A "quiet iritis" may occur and synechiae form without the patient being able to give any history of a definite "attack." A drop of cocaine—by dilating the pupil—demonstrates the points at which the iris is adherent to the underlying lens.

(2) Within the eye-ball (apart from synechiae) inequality of the pupils may result from glaucoma—increased intraocular tension—in which the pupil becomes dilated (midriasis), eccentric and inactive to light, and the visual acuity finally reduced to no perception of light. This condition is in many chronic cases unocular, and unaccompanied by pain or conjunctival redness. The shallow anterior chamber, hard eye-ball and reduced visual acuity should make the diagnosis clear.

(d) *Neoplasm*.—Growths of the iris or ciliary body give rise to inactivity of the pupil by partially obstructing its movements. These growths are often quite invisible upon external examination, but inactivity of one section of the iris (apart from iridodialysis or the presence of an intraocular foreign body)—especially if there is irregularity in the depth of the anterior chamber—should make one suspicious. Intraocular neoplasms usually give no symptoms of any kind until a comparatively late stage.

Trypan-blue and Certain Dithio-Aniline Derivatives : Their Efficacy in the Treatment of Piroplasmosis and Other Affections in the Central Provinces.

By MAJOR R. F. STIRLING, F.R.C.V.S., F.R.G.S., D.V.S.M., F.Z.S., I.V.S.

Memoirs of the Department of Agriculture in India.
March, 1928, p. 129.

PIROPLASMOSIS, or tick fever, is a disease of considerable importance in the Central Provinces. In unselected villages, the incidence of the infection in the animals examined was as high as 80 per cent. This

widespread infection of cattle is a point of considerable economic importance. The regular dipping of cattle in arsenical baths in order to rid them of ticks is a method which has met with considerable success in other countries, but is not suitable for use in India. Considerable success has been achieved by administering trypan-blue intravenously. A 2 per cent. solution in water is used, the dose for cattle being 40 c.cms. and for dogs 5 to 6 c.cms.

The Memoir deals with the clinical effects of this treatment. Exact figures are not quoted; an excerpt from the report is given below.

(a) "Its general value as a tonic is undoubtedly a great one. Many unthrifty animals put on condition after one or two injections of trypan-blue and its use is getting very popular with cattle owners. In milking cows, injections result in a better yield of milk and the quality and quantity of the butter is increased considerably. I have found it very useful in cases of chronic skin affections in dogs."

(b) "Its value as a general tonic is unparalleled. There have been many instances in which animals have shown wonderful improvement in condition after one or two injections."

(c) "In acute cases an injection of trypan-blue almost immediately brings down the temperature and clears the blood of piroplasms. Even if the blood is still free after seven days a second dose should be given. The present dosage is sufficient. In chronic cases, at least three doses are necessary at intervals of a week, or earlier if the mucous membranes show no blue staining. As a general tonic, it is much more useful than iron, arsenic, etc. Milch animals, which give an inferior quality of milk in spite of good food and tonics, yield a large quantity and a better quality of milk after injection. In two recent cases, a cow and a she-buffalo which had dried up almost entirely owing to unknown causes, animals started to give milk after the first injection. I am of opinion that for all debility cases trypan-blue should be adopted as a routine treatment whether parasites are found in the blood or not."

(d) "In acute cases of piroplasmosis early treatment with trypan-blue has been found efficacious in over 95 per cent. of cases. I have treated many cases of indolent ulcer, which defied all ordinary treatment, by means of trypan-blue injections combined with external dressings of an ordinary kind. Other chronic diseases of a constitutional nature such as recurrent colic and tympanitis showed rapid resolution when the dye was used in conjunction with ordinary medicaments which by themselves had failed to effect resolution."

Quantitative Determination of Quinine in the Blood.

By M. M. PANTSCHENKOW AND A. A. KIRSTNER
Moscow University.

Arch. f. Schiffs-u-Trop. Hygiene, 1928.

Bd. 32, No. 3. p. 137.

(Translated by O. Urchs, M.D.)

THE determination of quinine in the urine was hitherto carried out by means of Giemsa's method (Giemsa and Schaumann, 1907, *Beih. z. Arch. f. Schiffs-u. Trop. Hyg.* No. 3). This method shows quinine in a dilution of 1:200,000, but the same cannot be employed in a medium containing albumen and is, therefore, not suitable for determining the quinine content of the blood.

After as large doses as five grammes Giemsa and Schaumann found only traces of it in the blood.

The above authors took advantage of the fact, that quinine becomes fluorescent if exposed to ultra-violet rays.

Their method is in short: 10 c.cms. of blood together with a certain amount of sodium bicarbonate are concentrated by evaporation on the water-bath. After 1½ hours this process is usually finished. The dried and carefully pulverised blood is shaken with 100 c.c. of ether and thereafter left alone for 24 hours. The ether is removed after 24 hours, replaced by another

100 c.cms. and this process is repeated a third time.

All the three ether portions are collected in one glass vessel and filtered. The filtrate is very carefully concentrated through evaporation on the water-bath (danger of explosion!).

To the remaining portion 2 c.cms. of diluted sulphuric acid is added and the mixture is warmed slightly. After that it is put in a glass tube and under ultra-violet rays compared with a standard solution of quinine bisulphate. The room should be entirely darkened. As the quinine solution starts to fluoresce after about five minutes one has to wait accordingly.

The glass tube, which is used for the experiment, has to be tested first under ultra-violet rays, in order to avoid a glass which gives fluorescence in itself.

With this method the authors claim to be able to determine quinine even in a dilution of 1:200,000.

The results so far have shown, that erythrocytes contain more quinine than the serum.

Extract of Yeast.

By ULF VON EULER,

Pharmakol. Inst. Stockholm. Biochem. Zeitschr.

1928. Bd. 194, No. 1/3.

(Translated by O. Urchs, M.D.)

If yeast is extracted with 25 per cent. alcohol, which contains 1 per cent. hydrochloric acid, one obtains an extract which produces typical insulin-action after adding to fresh muscle pulp plus glucose plus phosphates (as buffer). After hypodermic injection of 0.05 gm. in a rabbit, the preparation does not produce any significant decrease of the blood-sugar. This failure of the result upon the blood-sugar is explained through the small proportion of active substance. In the experiments with muscle pulp the preparation is efficient only in much higher concentrations, compared with original insulin.

Reticulo-Endothelial System and Endocrinal Glands.

By LEITES AND RIABOW,

Laboratory for Pathol. Physiology, Charkow. Ztschr. f. d. ges. experim. Medizin, 1928, 59, No. 5/6.

(Translated by O. Urchs, M.D.)

AFTER the removal of the thyroid and ovarian glands the storage capacity of the reticulo-endothelial system (RES) can be increased through the administration of insulin or pituitrin. Adrenalin decreases the storage capacity; pancreas, parathyroid and testicles seem to be without influence upon the storage capacity of the RES, because the function of the RES is by no means affected by the removal of these glands. If spleen and ovarian glands are removed, the blocking of the RES takes place very quickly.

A Comparative Study of the Action of Cinchonidine and Cinchonine on the Heart.

By R. N. CHOPRA, M.A., M.D. (Cantab.),

LIEUTENANT-COLONEL, I.M.S.,

B. B. DIKSHIT, M.B., B.S. (Bombay), D.P.H. (Cal.),

AND

J. C. DAVID, M.B., B.S. (Madras).

Indian Journ. Med. Res. July, 1928. Vol. XVI. p. 125.

SINCE the introduction of cinchona bark into therapeutics considerable experimental work has been done on two of its alkaloids, namely, quinine and quinidine, but little attention has been paid to cinchonidine and cinchonine. These latter alkaloids have been passed over with the remark that they have the same action

as quinine. Fredricq and Terroine working with cinchona alkaloids on the isolated turtle's heart found that all of them diminished the frequency and amplitude of the heart beat, producing a diastolic arrest, and that laevo-bases were more powerful than their dextro-rotatory isomers. De Arric (1912) found that the turtle's heart was slowed by all doses and the amplitude was decreased by the higher concentrations but increased by the lower ones. McGilchrist (1914) made an extensive experimental study of the cinchona derivatives and strongly advocated the use of cinchonine in benign tertian malarial infections. He made a comparative study of the toxicity of the four chief alkaloids of cinchona bark on guinea-pigs and found that cinchonine was the most toxic and cinchonidine the least. The protozoicidal action of cinchonine, however, was so marked that in spite of its higher toxicity its use against malaria was advocated. Post-mortem examination of guinea-pigs showed that both after cinchonidine and cinchonine the heart was stopped in systole. Biberfeld (1916) found that in mammals and man the cinchona alkaloids quickened the pulse and produced a rise of blood pressure. Cushney described cinchonidine and cinchonine as possessing the same action as quinine and said that the former is more liable to produce symptoms of poisoning. Acton (1922) in his researches on the cinchona alkaloids, pointed out that quinidine and cinchonine were dextro-rotatory while quinine and cinchonidine were laevo-rotatory; he therefore suggested that the nomenclature was defective. After an experimental study on the toxicity of these alkaloids he came to the conclusion that cinchonidine was less toxic than cinchonine. He quotes Cushney as saying that cinchonidine is more liable to produce symptoms of poisoning, and remarks that Cushney evidently means cinchonine when he writes cinchonidine. Clerc and Pezzi (1923) observe that all the cinchona alkaloids paralyse the bulbar centre of the vagus. They further state that the acceleration of the heart caused by small doses of these drugs is due to excitation of accelerators and not to paralysis of the pneumo-gastric, which requires larger doses. Sollmann (1926) in his text-book on pharmacology, describes the action of cinchonidine and cinchonine as resembling that of quinine but says that the two former are endowed with less of the desirable effects and more of the undesirable side-effects. He further observes that cinchonine is much more depressant to the heart and more toxic than cinchonidine.

It will be seen therefore, that a good deal of discrepancy exists between the findings of various observers. Some have credited less toxicity to cinchonine, while others signal it out as the most toxic. In this paper we propose to investigate the action of these two alkaloids on the heart.

Summary and Conclusions.

(1) Intravenous injections of cinchonidine in animals produce a marked depression of the amplitude of auricular and ventricular contractions accompanied by a fall of blood pressure. The irritability of the myocardium is markedly decreased, the latent period and the refractory period are both lengthened.

(2) Cinchonine produces an apparent stimulation of the auricle and a depression of the ventricle. The former effect is shown to be produced by depression of the inhibitory nervous mechanism and the latter by direct action on the heart muscle. The irritability of the myocardium is decreased but not to the same extent as with cinchonidine. The latent period is not increased in frog's heart muscle and the refractory period is not appreciably affected.

(3) Both cinchonine and cinchonidine temporarily restore the normal rhythm of the heart after it is experimentally made irregular with aconitine. This is partly due to the depression of the vagal mechanism and partly to direct depression of the heart muscle.

(4) Our experiments show that the laevo-rotatory alkaloid cinchonidine has a more powerful depressant action on the heart muscle than the dextro-rotatory cinchonine.

Reviews.

THE GENESIS OF EPIDEMICS AND THE NATURAL HISTORY OF DISEASE.—By Lieut.-Col. C. A. Gill, M.R.C.S. (Eng.), L.R.C.P. (Lond.), D.P.H., D.T.M. & H. (Eng.), I.M.S. London: Baillière, Tindall and Cox, 1928. Pp. xxvi plus 550, with 18 charts, 10 maps and 1 diagram. Price, 21s. net.

In a province like the Punjab, where general and localised outbreaks of malaria, plague, cholera, relapsing fever, influenza or other epidemic diseases have occurred with such frequency in the past, the opportunities for the study of the genesis of epidemics are very great. An exposition of this subject by an officer who has spent so many years in the Public Health Department of this province, and who has made a special study of epidemiology in all its varied aspects is something to be welcomed. Those of us who have known that this book was in the process of compilation have looked forward with great interest to its publication and have not been disappointed in the result.

Epidemiology has been studied by many methods—the historical, the parasitological, the statistical, the experimental and practical—and as in any scientific subject which has many aspects, the tendency has been to consider the special method used as the most important one and the others of minor value. In this way any true picture of the facts is liable to be obscured. In the book under review an attempt has been made to consider the subject from all points of view, and Colonel Gill with his extensive field, statistical and laboratory experience of epidemic diseases, more especially malaria, is eminently suited to perform this task.

The theory of the genesis of epidemics, which forms the subject of this book, was first advanced by the author in 1914, in connection with epidemic malaria, and since that time he has had ample opportunity of continuing his investigations and of testing the applicability of the hypothesis to epidemics of other diseases.

The hypothesis states that "the genesis of all epidemics is a loss of equilibrium between infection and immunity and that the essential factor in this loss is of a quantitative nature rather than a qualitative one." The causes of this disturbance of equilibrium may vary in different diseases, but the essential mechanism is the same.

This 'quantum' theory postulated that four factors—the reservoir of infection, a parasite factor, an immunity factor and a transmission factor—are concerned in the mechanism of all epidemics, and that the factor of predominant importance in determining the character of communal disease is the last. It is with regard to the influence of meteorological conditions on these factors that a large part of the work is concerned. With the discovery of micro-organisms as the causes of infection, the 'airy influences' of Sydenham and the 'miasmatic theory' of older workers, were considered to be minor or negligible factors in disease, but Colonel Gill has shown, not merely by theoretical considerations but by actual experimental evidence in the case of malaria at least, that the 'climatic factor' is one which plays a marked part in the natural history of disease.

The hypothesis has been greatly strengthened by the fact that it has stood the test of practical application in the case of epidemic malaria, in that it has formed the basis on which it has been possible to forecast with a very considerable degree of accuracy the occurrence of localised epidemics of this disease in the Punjab. This is a very severe test for any hypothesis which is not founded on a sound basis.

The book is divided into five parts of which the first or introductory one gives definitions of the terms used, and, after reviewing the ancient and modern theories regarding the causation of epidemics, ends with a brief exposition of the 'quantum' theory.

The second part is concerned with the natural history of three great epidemic diseases—malaria, influenza and plague. These three diseases have been chosen because they afford examples of different methods of disease transmission—malaria is carried indirectly by insects,

influenza is spread directly, while plague in its bubonic form is carried indirectly and in its pneumonic form directly.

Colonel Gill's previous work on malaria should need no introduction to those engaged in the study of this disease. In the present volume he has included the relevant portions of his work on the genesis of malarial epidemics and on meteorology in relation to the spread of this disease. In addition he has recorded the details of such new and original work, in confirmation and extension of the observations on which he originally founded his 'quantum' theory. By means of his malarial forecasts, it has been possible for the first time to study an epidemic of malaria from the pre-epidemic period right through its height and on to the post-epidemic period. In this way very valuable information has been obtained with regard to the behaviour of the four factors mentioned above. In the past, too much work on malaria has been done of a qualitative rather than a quantitative nature, but here we have work in which precise measured data play a predominant part. It is such quantitative work which is needed to further the study of epidemiology and make it a more exact science.

In the chapters dealing with influenza, the influence and relationship of the factors postulated in the 'quantum' theory have been considered in detail, more especially in connection with the epidemics which have occurred in the British Isles and in India. Here, again, has been collected much evidence that such epidemics are the result of a disturbance of the equilibrium between infection and immunity. As in the case of malaria, meteorological conditions appear to play an important rôle.

In the case of epidemic plague, the four factors of the 'quantum' theory have been considered in relation to the experiments and observations of many workers on this subject, and it has been shown how the varied findings of these researches can be fitted into their appropriate places in the theory. Again as in the other diseases considered, climatic conditions appear to have an important relationship to the spread of this disease, in both its bubonic and its pneumonic forms.

Part III deals with the general properties of epidemics and shows how the 'quantum' theory affords a rational explanation of the genesis of epidemics, as far as the facts relating to these are available at the moment.

The author does not maintain that the accuracy of the hypothesis has been established for all diseases, although the evidence in the diseases mentioned is very strong, but that it is a rational explanation of the nature and significance of all epidemical phenomena, founded on a reasoned and reasonable basis. Although many of the conclusions may need confirmation by observation and experiment, it can at least draw attention to these unsolved problems and indicate lines along which investigations may profitably be directed.

The fourth part of the book is concerned with the bionomics of disease and here are considered evolution in relation to disease and the effects of climate on health and disease.

The last part of the book gives some final reflections on the problems which have been discussed.

One finishes the book with the feeling that the author is one of those who is not content to accept the *ex cathedra* statements and surmises of authority, when it is possible to deal with facts, which attitude should be one of the fundamentals on which all true research is built.

This is a book which should be in the library of every student of public health and of every malariologist. It is not a book to be skimmed lightly but to be carefully read from cover to cover. Even if the reader does not—and he probably will not—agree with all the views enunciated, he will find in it a store of very valuable information and technical detail, much food for thought and many original ideas for further research on the epidemiology of disease.

The book is well produced and printed. The misprints are few in number, the main and almost only one, is "*Anopheles hyrcanus*" for "*Anopheles hyrcanus*."

J. A. S.

Nov., 1928.]

MODERN METHODS OF TREATMENT.—By Logan Clendinning, M.D. Second Edition. St. Louis: The C. V. Mosby Co., 1928. Pp. 815, with 95 illustrations. Price, \$10 net.

THE object of this book may best be defined by quoting from the author's preface to the first edition. "A book on treatment should give a method of procedure so clearly and minutely that a person who has never heard of it could do it from the description." This is the view-point that the author and his collaborators (for the volume is not entirely the work of Dr. Clendinning), have kept steadfastly before them and the result is eminently satisfactory.

The first 184 pages are devoted to rest and drugs in the treatment of disease and in these days of polypharmacy it is indeed refreshing to discover a physician who does not suffer from mental nystagmus as a result of the never-ending succession of complex synthetic preparations that flash across the field of view and who appreciates to the full the virtues (and short-comings) of the tried and trusted remedies—the arsenicals, mercury, quinine and digitalis. The author, however, is no reactionary and recent therapeutic advances of proved merit, as for example the use of ephedrine, of novasurol, and of mercurochrome-220 receive appropriate mention.

The author definitely states that the book does not deal with the treatment of tropical diseases and hence no attempt has been made to incorporate the latest advances in the field of tropical medicine. The practice of introducing each of the principal drugs with a brief historical note adds materially to the interest of this section of the book.

Chapters III and IV are devoted to a consideration of biologic therapy and of organotherapy respectively, and the author adopts a very reasonable attitude towards both subjects. It certainly requires more than the average amount of courage to prepare a table such as that shown at p. 187 in which no fewer than nine biological products, enjoying either singly or collectively considerable vogue in different circles are included in a column headed "value negative." The section on dietetics and infant feeding is very comprehensive, taking up nearly 100 pages, and, as might have been anticipated in a work of American origin, it includes a very up-to-date account of the dietetic treatment of pernicious anemia evolved by Murphy and Minot. The subject of hydrotherapy is particularly well handled and this is one of the few books which in our experience gives adequate information on such common and necessary procedure as the wet pack, the compress and the enema.

Dr. Clendinning is a psycho-therapist with a rational outlook: he recognises the fact that it is on occasion necessary to treat the patient as well as his disease, but he carefully avoids being drawn into the Freudian controversy and his exposition of the whole subject is gratefully free from the sexual note which characterises the refrain of the more enthusiastic devotees of the cult of psycho-analysis. Part II of the volume is devoted to the application of therapeutics to particular diseases and the various subject comprehended in this section are treated on more or less conventional lines.

If we have one major criticism to offer, it is that there is at places a suggestion of a want of balance. For example, the treatment of infectious diseases of non-tropical origin is dismissed in the comparatively brief space of 31 pages while diseases of metabolism claim 54 pages of which no fewer than 37 are devoted to diabetes: 11 pages are taken up solely with diabetic diet lists and more or less complicated formulas are given for optimal dietary calculation and for estimating the ketogenic—anti-ketogenic balance. The section on dietetics in Part I, although eminently readable, appeared to the reviewer to be a little top-heavy for the rest of the volume. Of actual errors there are remarkably few but we do not like to see the familiar name of Wenyon masquerading as Menyon (page 58). No omissions of note were detected but some reference to the work of Mollgaard and his school on pulmonary tuberculosis might usefully have been included.

Dr. Clendinning's book can be warmly commended to the general practitioner for whose benefit it is obviously

designed: it tells not only what to do, but of even greater importance, how to do it. The photographs, skiagrams and other illustrations are good, and there is an adequate index together with brief references to the more important literature of the different sections. Printing and general get-up are in accordance with the best traditions of the well-known publishing house responsible for its production.

J. M. H.

THE DEVELOPMENT OF THE HUMAN EYE.—By Ida C. Mann, M.B., B.S. (Lond.), F.R.C.S. (Eng.), Assistant Surgeon, Royal London Ophthalmic (Moorefields) Hospital, with a foreword by Sir J. Herbert Parsons. London: Cambridge University Press. Published for the British Journal of Ophthalmology, 1928. Pp. 306. Price, 36s.

MISS MANN'S book is one of the most important contributions to British ophthalmology of recent years and will take its place amongst the classical productions of the English school in this specialty. From the time of her earliest publications, it was evident that Miss Mann's work would rank with that of continental authors who had made a prolonged study of the subject. In the comparatively short time since then her observations have advanced our knowledge of the subject to a very considerable extent and rank as authoritative expressions of recent investigations in this field. The volume noted above places at the disposal of English readers not only material which was not heretofore available in English, but a compilation of Miss Mann's own work arranged and presented in a way which makes it comparatively easy for anyone to follow the march of events in the upbuilding of the human eye from its very beginning.

Chapters I and II deal with the formation of the primary optic vesicle and describe in general its development together with its associated mesoderm. Starting from a stage of embryonic life before ocular structures are recognisable, the development of the eye is rapidly traced to its condition at birth. In this survey some interesting points are brought out such as the inherent power of the optic vesicle to invaginate, and the converse with regard to the lens plate formation and its invagination. The latter is not an inherent power in any localised area of surface ectoderm, but occurs as a reaction on the part of the undifferentiated surface ectoderm to some stimulus from the invaginating vesicle. It has been shown in frog embryos that a primary optic vesicle transplanted to a site where it is not in contact with surface ectoderm will invaginate and if transplanted beneath the surface ectoderm in another part of the body, the ectoderm in contact will attempt to form a lens. The probable reason given for the formation of the foetal fissure is interesting. If invagination of the cup occurred symmetrically without the formation of a cleft, there would be no direct continuity between the inner retinal layer and the optic stalk so that nerve fibres developing in the inner side of the cup would have no direct path to the brain. The mechanism of the production of congenital abnormalities in general is briefly dealt with shorn of ambiguous phrases, and such conditions as anophthalmos and microphthalmos with cysts of cup and fissure explained. Elsewhere throughout the book different congenital defects are dealt with. These explanations will clear up many faulty impressions in this connection especially in regard to opacities of the lens and the colobomata of choroid and iris.

Chapter III deals with the detailed development of the lens and the information contained therein is indispensable to anyone who wishes fully to appreciate the advantages of the slit lamp.

Chapter IV on the neural ectoderm is a fascinating study in embryonic histology. It is divided into four sections. (a) Retina proper, (b) ciliary epithelium (pars plana and pars plicata), (c) iris, and (d) optic nerve. The astonishing development of the inner layer of the cup is described—the outer unicellular layer remaining simple right on into adult life except that it becomes pigmented. The layers at first separated by the cavity of the primary vesicle eventually come together,

but their relationship even in the adult is not very close; hence the ease of detachment of the retina (the inner layer). The progress of the growing margin of the cup into the plicated ciliary region with its pigment free but simple unicellular inner layer is traced, and the continuation forward and inward of the two layers as the posterior part of the iris (the deep layer of which eventually becomes pigmented) is dealt with in detail describing the interesting origin of the sphincter and dilator muscles from the neural ectoderm. It may be noted that the choriocapillaris only develops from mesoderm in contact with the pigment epithelium.

Chapter V forms instructive reading for those interested in the operative treatment of cataract, and the ætiology of primary glaucoma. The vitreous body proper is described developmentally in two stages. The primary vitreous consists of ectoderm fibrils originally uniting the lens vesicle and the inner neural ectodermic layer of the cup which has become invaded by and continuous with the mesodermal elements associated with the vasa hyaloida propria and the tunica vasculosa lentis posterior. With the atrophy of the vascular elements and the growth of the cup ectodermal fibres developing from the neural epiblast lining the cup proceed to fill the space till eventually the structure thus composed forms the main mass of what in the adult is the vitreous body. It is largely composed of ectodermal fibrils having continuity with the internal limiting surface of the retina and pars plana and has no bounding layer as such except that which constitutes the membrana limitans interna of the retina. The zonule is regarded as the tertiary vitreous. It is purely ectodermal in origin arising from the cells of the inner layer of the cup in the region anterior to the ora serrata. This chapter makes clear our ideas on such things as the retro-lental space, the vestigial remains of the hyaloid artery and the tunica vasculosa lentis as seen by the slit lamp, Cloquet's canal, Egger's line, the so-called hyaloid membrane; and explains why the vitreous detaches up to the ora serrata. To quote from the text "Thus we see that the adult vitreous is practically entirely derived from the neural ectoderm of the inner layer of the optic cup, only that portion lying immediately behind the lens and in the neighbourhood of the canal of Cloquet having in it any element derived from the surface ectoderm (lens) or mesoderm."

Chapter VI deals with the associated mesoderm and the advent of the foetal blood system including the development and retrogression of the foetal intra-ocular system, which has to do with the early nourishment of the primary vitreous and lens. The important part which the associated mesoderm plays in connection with the iris is fully described and many points in connection with the normal iris structure are rendered clearer thereby. The formation of the cornea, anterior chamber, ciliary muscles with the parts adjoining the angle and the sclera are detailed and an explanation for certain abnormalities such as buphthalmos and posterior staphyloma explained. The latter is associated with the lagging behind in the development of the sclera in its posterior portion and may be correlated with the greater stretching of this region in progressive myopia. It is of interest that the chromatophores of the choroid do not appear till about the 5th month.

Chapter VII deals with the orbit and its contents, and Chapter VIII briefly sets forth the phylogenetic development and morphology of the human eye. The book concludes with Chapter IX which is a synoptic comparison of ocular with general development in parallel column form. This is followed by an extensive bibliography and an index.

The book is profusely illustrated with original drawings by the author which are beautifully reproduced in keeping with the style of the whole work. There is a foreword by Sir John Herbert Parsons in which he points out that Miss Mann has been able to place on a sounder foundation, many debatable points by having studied them for the first time on human material. He states that "the author has placed all who are interested in the subject under an obligation by providing them with so exhaustive and well-authenticated a treatise."

R. E. W.

A TEXT-BOOK OF GENERAL BACTERIOLOGY.—By Edwin O. Jordan, Ph.D. Ninth Edition. London and Philadelphia: W. B. Saunders Company, Ltd., 1928. Pp. 778, fully illustrated. Price, 28s. net.

THIS is a standard book on bacteriology. That it is an extremely popular one is obvious from the fact that it has gone through nine editions since 1908 and that each edition has had to be reprinted at least once.

"General Bacteriology" is a misleading title as the book is essentially one on medical bacteriology; there are admittedly chapters on industrial bacteriology and the bacterial diseases of plants, but they are short chapters and would not, one imagines be of much value to students of these branches of the science.

The author is an American and appears to depend almost entirely on the American medical press for his information; fortunately, America is by no means backward in this subject so that the book does not suffer to any serious extent, but, nevertheless, it does suffer.

In the chapter on *Bacillus lepræ* (sic) two pages are devoted to the subject of cultivation of the organism and another to animal experiment; the work of Clegg, Duval and others is described and there is actually an illustration of a pure culture of *Bacillus lepræ*, but in these three pages there is no note of scepticism and no reference to the fact that many well-known and very conscientious workers have completely failed to confirm the observations of these workers, and that in the opinion of many bacteriologists the bacillus of leprosy has never been grown on artificial medium, nor has the disease been transmitted to animals.

The author states that the chapter on parasitic protozoa has been entirely re-written. As the reviewer has not a copy of the last edition of this book he cannot confirm this statement, but the chapter has certainly not been brought up-to-date.

The book is published in America; the printing, paper and binding are, therefore, excellent and in the very best style of this well-known firm of publishers.

L. E. N.

SYSTEMATIC INFECTIONS: THEIR DIAGNOSIS AND TREATMENT.—By A. K. Gordon, M.B., B.C., B.A. (Cantab.). London: Baillière, Tindall and Cox, 1928. Pp. x plus 176. Price, 10s. 6d. net.

THIS book is written with the object of showing the general practitioner how he can make use of the pathologist, more especially the bacteriologist.

There is no attempt to teach the practitioner to be an amateur bacteriologist; for technique—other than that of taking the specimens—he is referred to bacteriological hand-books. But he is shown how to interpret the laboratory findings.

The book appears to be well written and the subject is dealt with in a clear manner; nevertheless, we cannot help feeling that the contents *thereof* could be found in most modern text-books on medicine and that there it would be seen in truer perspective. The table in the appendix is, in the opinion of the reviewer—a bacteriologist—thoroughly immoral.

• One does not quite see what long-felt want (so dear to reviewers!) is supplied by this book, unless perhaps a suitable present from a pathologist to the medical practitioner in the neighbourhood.

The get-up of the book is satisfactory, but unattractive, and not in the very best style of this well-known firm of publishers.

L. E. N.

SOME PRINCIPLES OF DIAGNOSIS, PROGNOSIS AND TREATMENT.—By Robert Hutchison, M.D., F.R.C.P. Bristol: John Wright and Sons, Ltd., 1928. Pp. 54. Price, 2s. 6d. net.

ANYTHING from the pen of Dr. Robert Hutchison is always worth reading and this small volume is no exception. It contains nothing that we did not know before (as the author himself admits in his preface), but it does reveal how very infrequently we apply our much-vaunted commonsense, in every day medical practice. The rapid growth of the wholesale drug industry has tended to cause a decline in the art of elegant

prescribing. So it is also with our diagnostic faculty: the clinical sense is in danger of undergoing considerable atrophy in these days of excessive reverence to the presiding deities of the microscope, the incubator and the X-ray tube.

It is realised that we are probably in a distinct minority in disliking the expression "follow-up" departments on p. 22—that it defines exactly what the author means we admit, that the phrase is of trans-Atlantic origin weighs nothing with us, but we would rather not have seen it.

A most excellent little book.

J. M. H.

STERILITY IN WOMEN: DIAGNOSIS AND TREATMENT.—By Sidney Forsdike, M.D., B.Sc. (Lond.), F.R.C.S. (Eng. & Edin.). London: H. K. Lewis & Co., Ltd., 1928. Pp. viii plus 133, with 25 illustrations, including 17 plates. Price, 9s. net.

"Sterility in Women" by Forsdike is a very useful short book of 120 pages. Sterility is defined as a condition in which fertilisation does not take place, and not as the inability to produce a living child. The diagnosis of sterility in woman and man is fully dealt with in Chapter III, and the causes in woman are well done in Chapter IV. Not every gynaecologist, however, will agree that "retroversion without dyspareunia is rarely a cause of sterility." The author makes the interesting point that the tubes of a retroverted uterus may be apparently blocked at 300 m.m. and patent at 120 m.m. after replacement. Functional sterility is well discussed in two chapters, but we should like to point out that the statement "vaginismus is a true neurosis and is not dependent upon any local lesions of the vulva" is, in our opinion, incorrect and is incompatible with one that follows it almost immediately, i.e., "..... but where an organic lesion is present and remediable, the condition may be cured."

There is an excellent practical account of inflation of the tubes. Provis's modification of Currier's apparatus is recommended with a special forceps of the author for clamping the cervix around the uterine tube. The author prefers not to use an anæsthetic. Bonney's more simple apparatus is not even mentioned. The author not only supports Rubin's claim of 10 per cent. of pregnancies after inflation but claims 15 per cent.: he does not state, however, whether these followed after one inflation or after repeated inflation.

Investigation by lipiodol is well described and fairly discussed: his experience is that it has an even greater therapeutic effect than inflation. Several excellent hystero-grams are reproduced showing the various conditions that are met with.

Chapters XI and XII are devoted to treatment and contain much that is well considered, deliberate and judicious. Emphasis is rightly laid on the necessity of proving the husband to be beyond reproach before submitting the wife to treatment which may turn out to be useless and unnecessary. We cannot agree with the statement, made in connection with Gilliam's operation, that "the round ligaments are frequently so attenuated and frail that the operation cannot be done"; this is a condition we have never seen. Salpingostomy is given only a cautious and qualified approval in suitable cases; this is sound teaching.

The last chapter deals with therapeutics. Endocrine therapy (except with thyroid extract) is referred to in terms which must be very disappointing to the unreasoning enthusiasts of a few years ago.

There is a good bibliography at the end of each chapter. The book is excellently printed and can be confidently recommended alike to the general practitioner and to the specialist.

S. A. McS.

RADIUM IN GYNÆCOLOGY.—By J. G. Clark, M.D., C. C. Norris, M.D. and G. Failla, E.E., M.A., D.Sc. Philadelphia and London: J. B. Lippincott Company, 1927. Pp. 351, with 49 illustrations and 1 plate. Available from Messrs. Butterworth & Co. (India), Ltd., Calcutta. Price, Rs. 26-4 or (35s.).

This is one of the most readable and practical books on the subject which we have had the pleasure of

reading. After a short chapter on the history of the discovery of radium, and the development of treatment thereby, Mr. Failla gives us a very interesting discourse on the physics of radium and its relation to the constitution of matter, including problems dealing with the distribution of the element, filtration and certain biophysical considerations.

The third chapter deals with the pathology and action of radium, including its effect on various tissues, innocent and malignant neoplasms.

The remaining chapters deal with the symptoms, diagnosis and treatment of the various gynaecological conditions in which radium has been found of use.

In the final chapter on sterility and dysmenorrhœa a reference is made to the treatment of hypo-function of the ovaries by small doses of X-rays (according to Hirsch 15 per cent. of the castration dose to each ovary). The results in carefully selected cases are stated to be improvement in ovarian function as shown by the regulation of menstruation and the induction of pregnancy with birth of healthy children.

The book is profusely illustrated and the drawings illustrating the technique of intra-cervical and intra-uterine application of radium are particularly clear and helpful.

J. A. S.

A MANUAL OF PHYSICS, THEORETICAL AND PRACTICAL, FOR MEDICAL STUDENTS.—By Hugh C. H. Candy, B.A., B.Sc. (Lond.), F.I.C. Third and Enlarged Edition. London: Cassell and Company, Ltd., 1928. Pp. 488, with a colour frontispiece and 289 figures in the text. Price, 7s. 6d. net.

It is a handy volume covering all the branches of physics and meant for medical students. Part I is devoted to general physics, Part II to heat, Part III to sound, Part IV to light, Part V to electricity and magnetism, and Part VI to practical physics. Eleven tables of useful data have been appended. The standard of this book does not exactly correspond to that of any examination in this province (Bengal), but it will be found very useful by the students preparing for the Primary Licentiate Examination of the State Medical Faculty of Bengal, the syllabus of which it fully covers. But the standard falls far short of that of the Pr. Sc. M.B. of the Calcutta University.

The treatment is elementary from the standpoint of modern views, and as far as possible non-mathematical; the little knowledge of trigonometry that is required can be obtained from the first chapter of the book itself. The language is throughout lucid, the diagrams good and the examples at the end of each chapter have been well selected.

Several topics of advanced character which are not usually included in books of this size and standard have been introduced for example, kinetic theory, spherical aberration, double refraction, polarisation, saccharimetry, diffraction, Tyndall effect, etc. These are useful for medical students no doubt but the treatment of many of these subjects is so meagre that it will not be helpful to one who does not possess any previous knowledge of them.

The following are some of the defects that are evident in the book. Schematic diagrams are given for the aneroid barometer and Sixe's thermometer, but their pictures should have been added. No figure is given of finding the heat of combustion although the method explained; nor are there any diagrams given of Nicol's prism, the saccharimeter or d'Arsonval galvanometer. It is noticed also that the terms isotonic, hypertonic and hypotonic solutions have not been explained in connection with osmotic pressure and osmosis. The application of the method of integral calculus in finding the potential at the point due to a charged body is inconsistent with the rest of the book and could easily have been avoided, and a simpler proof given.

T. C. K.

STUDENTS' HANDBOOK OF OPERATIVE DENTISTRY.—By R. Ahmed, D.D.S. Calcutta: The Indian Dental Journal, 1928. Pp. II plus 418. Price, Rs. 20.

DR. AHMED has been very ambitious in attempting to put before his students notes on Dental Anatomy, Dental Histology, Dental Therapeutics, Operative Dental Surgery and Dental Electro-Therapeutics in one volume of 400 pages.

His task has been a very arduous one and he has not met with as much success as his efforts deserve.

According to the bibliography at the end of his book, he has consulted in all about 80 works. Dr. Ahmed would have been more successful, if he had consulted only the most recent work in each subject.

Yet there are a number of discrepancies and at the same time some subjects seem to have been dealt with more fully than one would expect in a book of this nature.

For example, while seventy pages are given to the description of the anatomy of the teeth, cavity preparation is dismissed in less than four pages.

There are many points to which one might take exception. It will suffice to quote one—from page 299 dealing with the technique of extraction of the upper central incisor.

"The operator should stand behind the patient, his left arm should be placed upon the head of the patient and with the palm of his hand the lips should be retracted and some of his fingers should support his jaws."

A stance behind the patient would not appear to be the best position for the operator in extracting any upper teeth, the orthodox position on the patient's right front being preferred, whilst the retraction of the lips by the palm of the hand seems almost impossible.

The book itself is well produced and well printed on good paper, but the price at Rs. 20 makes it rather costly from a student's point of view.

J. E. G.

AN INTRODUCTION TO THE TECHNIQUE OF SECTION-CUTTING, FROM THE NOTES OF THE LATE MR. PETER JAMIESON.—By Frances M. Ballantyne, M.A. Edinburgh: E. & S. Livingstone, 1928. Pp. xii plus 80, with 11 illustrations. Price, Rs. 2-4. Obtainable from Messrs. Butterworth & Co. (India), Ltd.

THIS is an excellent little book on technique compiled from the notes of the late Mr. Peter Jamieson of the Department of Zoology in the University of Glasgow.

In it are described briefly and clearly methods of preparing tissues, and of cutting sections by the paraffin and celloidin methods. Many points are described in connection with the various procedures and beginners, even in the tropics where special difficulties not mentioned in it are encountered, will find it a valuable guide.

G. S.

DEAFNESS AND ITS ALLEVIATION.—By Vincent Nesfield, F.R.C.S. (Eng.). London: H. K. Lewis & Co., Ltd., 1928. Pp. v plus 85, with 19 illustrations. Price, 7s. 6d. net.

THE operation that Mr. Vincent Nesfield now describes for the alleviation of chronic deafness does not give us the thrill of a novelty. It was advocated by Aristide Malherbe as many as 29 or 30 years ago, and then quickly was lost sight of until its present resuscitation. Briefly the operation is one in which a new communication is made from the outside through the mastoid cortex posterior to the tympanum to the antrum. It would appear that the special indication for the operation is Eustachian obstruction, but Mr. Nesfield has also performed it with success in cases of oto-sclerosis.

Mr. Nesfield has operated on over 300 cases. Of this vast number, the results of only 11 cases are given and one is left in complete ignorance of what happened to the remaining 289 patients. The results of these 11 cases are not in the least bit convincing as Mr. Nesfield has not given any definite clinical picture of the cases

before or after treatment, so that one does not know what the functional tests of hearing were before and after. He states that his best and almost miraculous results have been in 2 cases where deafness was of only 2 years standing.

Such statements as "Three months later, i.e., after operation, she could hear a tuning fork on the mastoid bone for ten seconds" and in another case "A year later she was able to hear her name when spoken to in the dark at 2 yards and went to a lip reading class and improved her apparent hearing very considerably" are given as proofs of the remarkable results of the operation. Mr. Nesfield's book might have served a very useful purpose, either to prove or disprove the utility of this operation, had he based his observations on more scientific lines, but as it is, we are unconvinced and remain completely in the dark.

N. J. J.

HANDBOOK OF DISEASES OF THE NOSE, THROAT AND EAR, FOR STUDENTS AND PRACTITIONERS.

—By W. S. Syme, M.D., F.R.F.P. & S.G., F.R.S.E. Edinburgh: E. & S. Livingstone, 1927. Pp. 400, with 26 text illustrations and 21 coloured and X-ray plates. Obtainable from Butterworth & Co. (India), Ltd., Calcutta. Price, Rs. 9-6.

IN this small handbook of the Diseases of the Nose, Throat and Ear a very wide field has been covered, indeed so wide is the field and so small the book that of necessity the author has touched very briefly on most topics. The book, owing therefore to the very superficial treatment of the subject, is hardly one where information on difficult points is to be obtained. The aim of the book, however, is "to stimulate the interest of students in the specialty" and from this point of view, the book is an excellent introduction of the subject to a student just commencing his classes in the Diseases of the Nose, Throat and Ear Departments.

N. J. J.

DISEASES OF THE THROAT, NOSE AND EAR.—By Dan McKenzie, M.D., F.R.C.S.E. Second Edition. London: Wm. Heinemann (Medical Books), Ltd., 1927. Pp. 677, with 3 coloured plates and 254 figures in the text. Price, 45s. net. Agents: Thacker, Spink & Co., Calcutta.

SEVEN years have elapsed since the appearance of the first edition of this admirable work. The present edition is larger by nearly one-third and in it is given a clear and concise account of the diseases of the nose, throat and ear upon all points that come within the scope of this branch of surgery. The book, however, expresses the author's point of view and opinions, some of which may be challenged, and it does not attempt to be a book of reference which, for its size, it might well be. Nevertheless, it is the expression of a long experience and sound judgment, and for this reason it is to be commended. The book has been written mainly from the practical point of view and there are many excellent accounts dealing with the operative surgery of these parts.

Malignant disease and its treatment, surgical diathermy and endoscopy are all fully dealt with, and the book has been brought thoroughly up-to-date. One would not hesitate in recommending it as a first class text-book.

N. J. J.

PRACTICAL GUIDE TO DISEASES OF THE THROAT, NOSE AND EAR, FOR SENIOR STUDENTS AND JUNIOR PRACTITIONERS.—By William Lamb, M.D., C.M., M.R.C.P. (Lond.). Fifth Edition. Revised by F. W. Sydenham, M.D., C.M., F.R.C.S. (Edin.), D.P.H. (Vict.). London: Baillière, Tindall and Cox, 1927. Pp. xvi plus 450, with 31 plates and 78 figures in the text. Price, 12s. 6d. net.

THE fifth edition of Lamb's Practical Guide to the Diseases of the Throat, Nose and Ear, is an excellent little book on the subject. The aim of the author is to present to the student and practitioner a guide to

enable them to recognise the common abnormalities and to treat minor ailments. One may say without hesitation that the book does all that it has set out to do. The work has been written and revised by two gentlemen who had been in general practice for many years before setting out to specialise, and it, therefore, should be of special value to the general practitioner whose point of view is stressed. The book has been brought thoroughly up-to-date and is certainly to be recommended.

N. J. J.

ELEMENTARY BACTERIOLOGY.—By E. Joseph and E. O. Greaves. Philadelphia and London: W. B. Saunders Company, 1928. Pp. 506. Illustrated. Price, 15s. net.

This is another publication, and quite a good one, dealing with elementary bacteriology. It is, however, somewhat too comprehensive for under-graduates in medicine, and not full enough to serve as a work of reference.

Having sections dealing with the bacteriology of water-sewage, milk, milk products and other foods it may be a suitable text-book for students of bacteriology in courses of public health, but for under-graduates there are other and more satisfactory publications on the market.

G. S.

EXPOSURES OF LONG BONES AND OTHER SURGICAL METHODS.—By Arnold K. Henry, M.B., B.Ch., F.R.C.S.I. Bristol: John Wright and Sons, Ltd., 1927. Pp. xi plus 80, with 51 figures in the text. Price, 10s. 6d. net.

THE best methods for the exposure of long bones for dealing with ununited or malunited fractures or for removal of sequestra of any size in the shaft of a bone receive but scanty notice in text-books. When the earlier chapters of this book appeared in the *British Journal of Surgery* many surgeons who had been profoundly dissatisfied with the wholesale cutting of muscles and the cramped exposure afforded by the external lateral approach to the femur must have been grateful to Professor Henry for the neat and almost bloodless approach he described, applicable to any condition of the bone and especially to the cases of chronic osteomyelitis, so common in this country, with very large sequestra of the shaft surrounded by masses of sclerosed bone and having several sinuses in unpleasant proximity to the line of the femoral artery. Equally welcome was the method of exposing the whole shaft of the humerus without risk to the radial nerve and of the radius with the deep branch of the radial safely displaced with the supinator muscle. The lines of approach are lines of safety, simplicity, and speed with the minimum of anatomical disturbance and we welcome the re-publication of these papers in book form.

The remaining chapters deal with original methods worked out by the author in regions almost unexplored, the ligature of the first part of the left sub-clavian artery from behind, which suggested an ingenious modification of the ordinary aneurysm needle, the removal of the left cervico-dorsal sympathetic ganglion from behind, the ligature of the vertebral artery in its second stage, and some ingenious modifications of the transphenoidal approach to the pituitary are pioneer works whose value is certain to be appreciated and utilised by others, if not by the author himself.

W. L. H.

BAILLIÈRE'S SYNTHETIC ANATOMY.—By J. E. Cheesman. Part IX Pterygo-Maxillary Region. Enlarged from Part IX. London: Baillière, Tindall and Cox. Text 6, Plate 12. Price, 2s. 6d. net.

We welcome the successful production of those plates of the pterygo-maxillary region. The external maxillary, the lingual and the internal maxillary arteries with their branches in successive stages of the dissection have been more prominently displayed in these enlarged plates. An intricate part like the pterygo-maxillary region requires

a magnification for clear conception and the author has done well in publishing these enlarged plates of the region as a separate part. The remaining parts containing plates of the thorax, abdomen, inferior extremity and the perineum are in preparation. The index has been well arranged as in the previously published parts for easy reference. Students of anatomy will find these plates very useful and interesting in the leisure hours. It is suggested that the publishers should ascertain whether these plates will adhere together in a tropical climate if kept long. For in some of the old publications, adhesion between adjacent plates has been observed at the coloured areas.

N. P.

THE BASIS OF SENSATION.—By E. D. Adrian, M.D., F.R.C.P., F.R.S. London: Messrs. Christophers, 1928. Pp. 122, with 31 illustrations. Available from Messrs. Butterworth and Co. (India), Ltd., Calcutta. Price, Rs. 5-10.

As the author points out the title is an ambitious one and the student of metaphysics or psychology may be disappointed in finding a product of the physiological laboratory. The author is a distinguished physiologist, and the book is, in fact, an account of his brilliant researches during the last few years into the nature of the nervous impulse and its relations with internal stimuli, and with the central nervous system.

This work has been rendered possible by the use of a valve amplifier, similar to that used in wireless telegraphy. This has "made it possible to detect the smallest electric changes with relatively insensitive recording instruments."

By this means it was found possible to detect and record the action currents in sensory nerves, thus opening up an entirely new field for investigation.

In this way it has been shown that a stimulus to an end organ must reach a certain critical intensity in order to evoke sensory recognition. For instance, the impulses produced by a pain stimulus are of the usual type, and have the usual range of frequency, but the discharge must have a certain mass (duration and intensity), to evoke the pain reaction.

The sequence of events between the stimulus and the mind are finally shown in diagrammatic form. The stimulus is shown as appearing suddenly and remaining at a constant value. The excitatory process in the receptor declines gradually, and as it declines the intervals between the impulses in the sensory fibres become longer and longer. These impulses are integrated by some central process and the rise and decline of the resulting sensation follows that of the excitatory process in the receptor. The quality of the sensation pain, touch, temperature, etc., seems to depend on the path taken by the impulses.

The author recognises that he has not entirely filled the gap between stimulus and sensation; but, he has at any rate added one more step to the causeway, and paved the way for others, as well as showing how advances in one science can be made by utilizing discoveries in other sciences.

J. A. S.

THE RADIOGRAPHY OF THE CHEST. VOL. II.—By W. Overend, M.A., M.D. London: William Heinemann (Medical Books), Ltd., 1928. Pp. 196. Price, 21s. net.

THE author of this work—Dr. Walker Overend—died in 1926 when the volume was ready for publication and it has been seen through the press by his son, Dr. T. P. Overend.

The present volume is the logical successor to the first volume, which dealt almost entirely with pulmonary tuberculosis. It completes the work by giving an account of other lesions of the lungs, pleura, thymus and diaphragm, from a radiological point of view.

The general arrangement of the subject-matter is similar to that in the first volume. Normal appearances are first discussed and the various non-tuberculous conditions are taken up *seriatim*.

As in the original volume the author's conclusions are checked and brought into line with the data of physical examination. The author's dictum in the preface to the first volume that "the correct interpretation of pulmonary opacities may become a very difficult problem, and necessitate the exercise of expert clinical skill as well as a wide-radiological experience" is the coping-stone of the whole work.

These two volumes are in fact an indictment of the too-prevalent idea that diseases can be diagnosed by laboratory methods only to the exclusion of the old clinical examinations. It is well known in this connection that many cases diagnosed in the early days of X-rays as hilum or perihilar tuberculosis, have never shown any clinical signs of the disease and are well to-day after the lapse of years. The volumes under review deprecate this attitude and insist on the correlation of clinical and laboratory investigations. From this it follows that the individual with a knowledge of both sides of the question will be more valuable than the specialist.

This volume differs from the former in that the skiagrams are collected at the end of the book and one notable defect is the fact that the numbers given in the text do not always correspond with the numbers of the skiagrams.

J. A. S.

TROPICAL MIDWIFERY.—By Lieut.-Col. V. B. Green-Armytage, M.D., F.R.C.P., I.M.S. Calcutta and Simla: Thacker, Spink & Co., 1928. Pp. xvi plus 173. Price, Rs. 3-8.

Lieut.-Col. V. B. Green-Armytage, I.M.S., has so firmly established his reputation amongst the students of the Medical College, Calcutta, as a brilliant teacher that "Tropical Midwifery," which is the second edition of "Labour Room Clinics," is sure to be welcomed by them. It is a handy volume of 173 pages of octavo size. We think the old title is a more suitable one for the work, which is presented as a series of lectures and not as a treatise or handbook planned out on a settled scheme. As might be expected from the author, the teaching is entirely up-to-date and practical.

The penalty for being so convincing a teacher is the necessity for the most meticulous accuracy and it is for this reason that we drew attention to a few points which are open to criticism. "The De Lee low Caesarian Section" is described as being done by "a curved transverse incision" in the lower uterine segment. This is incorrect: De Lee is entirely opposed to the transverse incision (which is recommended by Munro Kerr above the bladder, and by Phaneuf after separating and pushing the bladder down), a smaller point is that the mortality of eclampsia treated by conservative methods in Bengal is estimated to be 15 per cent.; we wish it were only that. Few authorities will share either the author's enthusiasm for Luker's method of treating puerperal sepsis or his utter detestation of dried milk in any shape or form.

Whether one agrees or not with every detail, the lectures are so impressive, so stimulating and so convincing that one can congratulate his students on having so brilliant a teacher and one can strongly recommend the book to them and to the profession generally in India. It is excellently printed and published by Thacker, Spink and Co. at the very low price of Rs. 3-8.

S. A. McS.

SURGICAL "DONT'S" (AND "DO'S").—By C. Hamilton Whiteford, M.R.C.S., L.R.C.P. Second (Enlarged) Edition. London: Harrison & Sons, Ltd. Pp. 68. Price, 4s. net.

In the second edition of this little volume, the author has added five new articles to the original number of ten.

The book is composed of a series of remarks, some of which are elaborated. Most of them are sound common sense and can be described as practical, every-day tips. They should be read, marked, learned and inwardly digested by all young surgeons and some older ones.

H. E. M.

RECENT ADVANCES IN SURGERY.—By W. Heneage Ogilvie, M.A., M.D., M.Ch. (Oxon.), F.R.C.S. (Eng.). London: J. & A. Churchill, 1928. Pp. 481, with 108 illustrations. Price, 15s. net.

This little volume put together by Mr. W. H. Ogilvie with the assistance of five collaborators covers a very great deal of the ground opened up by recent experimental work in surgery. Consequently there is nothing in the book which can be called new, as most of the work which has been discussed and brought into prominence by the author has already appeared in the medical periodicals.

Of particular merit is the chapter on the abdomen, especially where it deals with the surgery of the stomach which has been described in detail. The modern methods of the treatment of cancer have been fully gone into, and the author strongly recommends the use of radium in front of all other non-operative measures.

Plastic surgery is reviewed in a carefully considered chapter in which the writer describes a new Thiersch graft-cutting knife devised by a Dublin surgeon, which he states promises to revolutionise graft-cutting.

In the section on venereal disease we are surprised to note that while syphilis is discussed in full, gonorrhoea is dismissed in one page, and no mention whatever is made of its treatment. The statement that stovarsol 1 gr. daily for 6 days has been advocated as a prophylactic for syphilis is interesting.

We have no hesitation in stating that this book which shows that the author has made an exhaustive study of modern literature, is well compiled, and is a valuable addition to the "Recent Advances" series.

H. E. M.

AIDS TO ORGANIC CHEMISTRY.—By Stanley F. Smith, with an Introduction by Professor R. H. A. Pinner. London: Baillière, Tindall and Cox, 1928. Pp. 114. Price, 3s. net.

It is a small volume containing a collection of notes and formulæ useful as a guide to the grasping of the fundamentals of organic chemistry. The printing and get-up are good. The formulæ and notes will supply the student with a summary of the most useful information suitable for making a rapid review of the subject.

S. G.

A MANUAL OF SURGICAL ANATOMY.—By Charles R. Whittaker, F.R.C.S. (Edin.), F.R.S.E. Fourth Edition. Revised and Enlarged. Edinburgh: E. & S. Livingstone, 1928. Pp. xii plus 471, with 116 illustrations. Price, Rs. 11-4. Obtainable from Messrs. Butterworth & Co. (India), Ltd.

This new edition of Whittaker's surgical anatomy is sub-divided into six sections dealing respectively with the head and neck, the superior extremity, the thorax, the abdomen, the inferior extremity and the spine. In this edition, the number of illustrations has been increased and several radiograms have been incorporated to the advantage of the reader. Much information has been presented in a tabulated form and these tables will be of much help for quick reference. In the tables of the muscles, their origins, insertions, and nerve supplies have been given. In the tables of the blood vessels, their branches have been enumerated. In the tables of the lymph nodes, their situations, drainage areas and terminations have been beautifully arranged. The table of the nerves, besides giving their origin, contains the branches classified according to distribution as sensory, motor or articular. The anatomical facts required for application to surgery, have been concisely and lucidly dealt with. The illustrations both coloured and uncoloured are very instructive and the radiograms have added to the attractiveness of the book. Every student of medicine and every practitioner will find it very useful and interesting reading.

N. P.

MANUAL OF ORGANIC CHEMISTRY FOR MEDICAL STUDENTS.—By S. Ghosh, D.Sc., F.R.S. (Edin.) and Lieut.-Col. T. C. Boyd, F.R.C.S.I., D.P.H., F.I.C., I.M.S. Calcutta: Scientific Publishing Co., 1928. Pp. 263. Price, Rs. 4-8 or 7s. 6d.

THIS is a manual in which is embodied the result of the authors' long experience of teaching as professors of chemistry in the two premier medical institutions in India. It is not a small task to compile within a small compass all the subject-matter pertinent to the needs of a medical student. An ordinary manual of organic chemistry, which is usually thought sufficient as a general course of study for the B.Sc. degree, hardly satisfies the requirements of a medical student. In it, there is a good deal of superfluous matter which only serves to burden his memory with unnecessary details to the detriment of his learning things which are really important from the point of view of medicine. The main object of compiling an organic chemistry for medical students is to emphasise the importance of those organic compounds that are being used in medicine. The authors have acquitted themselves of the task very admirably, showing stage by stage as we glide along chapter after chapter, the formation of various groups of organic compounds.

They could not, however, help making this somewhat of a synoptical nature in order to suit the particular requirement of the student. They are fully alive to the fact that medical students who have got to go through so many subjects besides chemistry will detest a bigger text-book and prefer one of this kind. It is, however, neither too concise at the expense of clarity of expression nor at the sacrifice of the subject-matter as is the case with other existing books of this nature. Many notable improvements have been made upon the latter by deleting obsolete terms like "amylons" for "starch" and giving Werner's formula for urea—to quote a few examples. The chapters have been arranged quite in their proper sequence except the one on halogen derivatives of hydro-carbon, which might have been placed after the chapter on "aldehydes" inasmuch as chloroform is derived from chloral which is an aldehyde. In the chapter on proteins, the classification and definition may be left out altogether for a bigger text-book. A few typographical mistakes have crept in which, no doubt, will be corrected in future editions. The book is very well got up and its price is by no means high. It can strongly be recommended as a text-book of organic chemistry for students appearing in the 1st M.B. examination of an Indian University.

R. B. K.

AIDS TO PUBLIC HEALTH.—By W. G. A. Robertson, M.D., D.Sc., F.R.C.P.E. Second Edition. London: Baillière, Tindall and Cox, 1928. Pp. vi plus 186. Price, 3s. 6d. net.

THIS is the second revised and extended edition of this small book, the aim and object of which as the author says is mainly to help students preparing for examination in public health in order that they may "refresh their memory." The author does not and cannot claim that this small book can serve the purpose of a recognised text-book on public health which has become recently a very important subject. The whole of this subject is treated in 15 chapters in a small book of 186 pages. It is true that whole chapters are devoted to such subjects as "Meteorology," "Vital Statistics," "Sanitary Law and Sanitary Administration," "School Hygiene," "Industrial Hygiene," "Maternity and Child Welfare," yet the information given is so incomplete that a student going up for his examination in the Diploma in Public Health can hardly expect to go through his examination or satisfy his examiners with the scanty knowledge obtained from this little book. For an Indian student going in for the D.P.H. Examination of an Indian University, the information given is still less complete. Mere headlines are given in every chapter without explaining the important details. The book may be of some help in the subject of hygiene to those students who are preparing themselves for a degree or a licence in medicine and surgery—i.e., a general medical qualification, but it would hardly help a D.P.H. student.

R. B. K.

AIDS TO EMBRYOLOGY.—By Richard H. Hunter, M.D., M.Ch. London: Baillière, Tindall and Cox, 1928. Pp. 160, with 30 figures. Price, 3s. 6d. net.

THIS little book of the "Aids" series consists of 12 chapters dealing with: (1) the sex cells; (2) the germ layers; (3) the foetal membranes; (4) differentiation and law of recapitulation; (5) the skin and its accessory glands; (6) the nervous system; (7) the development of the eye and the ear; (8) the alimentary canal and its associated glands; (9) the circulatory system; (10) the coelomic cavities; (11) the urogenital system, and (12) the muscular and skeletal systems. The author has given in a short space the important facts with regard to the development of the human embryo and foetus. While quoting conflicting views with arguments for and against, the author has given his own views which appear more reasonable to him. The abnormalities of development which are commonly met with in the dissecting hall and the wards of the hospital have been suitably placed at the end of a chapter and will be extremely useful to students of medicine. Similarly, the summary of the development of the systems has been given at the end of each chapter and this will be of immense help to students revising their studies before an examination. The pharyngeal arches have been nicely tabulated for easy reference. The book does not pretend to replace big books on embryology, but it is an excellent aid for quick revision of the whole subject before an examination.

The book is strongly recommended to every student of medicine who will find it useful reading. There are a few typographical errors which we hope will be rectified in the next edition.

N. P.

QUARTERLY JOURNAL OF PHARMACY AND ALLIED SCIENCES.—Vol. I. No. 1 Jan.-March. London: Pharmaceutical Press, 1928.

WE have received a copy of the first issue of this journal which is being published by the Pharmaceutical Society of Great Britain, who also publish the Pharmaceutical Journal, the British Pharmaceutical Codex and Pharmaceutical Pocket Book. Besides a number of original articles of interest to the pharmacist, this number of the journal contains a résumé of a large number of papers dealing with the allied sciences of chemistry, pharmacognosy, pharmacy, pharmacology and therapeutics, bacteriology, clinical tests and new remedies. The names of the members of the editorial committee are sufficient to convince any one that the journal will not only be a great boon to the pharmacist, but will also be of considerable interest to the medical profession.

R. N. C.

Annual Report.

ANNUAL STATISTICAL RETURNS AND SHORT NOTES ON VACCINATION IN BENGAL FOR THE YEAR 1926-27. BY DR. C. A. BENTLEY, M.B., D.P.H., D.T.M. & H., DIRECTOR OF PUBLIC HEALTH, BENGAL. CALCUTTA, BENGAL SECRETARIAT BOOK DEPOT. PRICE, Rs. 1-3-0.

DR. BENTLEY's annual reports are always characterised by being more readable and more interesting than most, for although they include the usual dry statistics, he gives illustrative and informative maps and graphs, and forcible comments on the matter at issue from the point of view of an enthusiast in the sphere of public health. And the present report well illustrates this.

The most important change of the year was that the entire provincial vaccination establishment (with the exception of that in Darjeeling) was handed over to the district boards, in accordance with the official policy of expansion of local self-government. The Local Government have agreed to meet the salaries of an Inspector and a Sub-Inspector. When the scheme for a rural

public health organisation is in full operation, however, separate inspectors of vaccination will not be necessary, for inspection of vaccinations will become part of the general duties of the rural health officers and sanitary inspectors.

During the year a total of 3,278,581 vaccinations was carried out, an increase of 8.2 per cent. on the previous year's figures. Primary vaccinations decreased by 0.53 per cent., whilst re-vaccinations increased 20.1 per cent., owing to the general prevalence of small-pox. As the result of epidemic small-pox the number of vaccinations increased considerably in some districts, notably Pabna, Murshidabad, and Birbhum. On the other hand several districts showed a marked falling off; this is attributed in the Burdwan district to the large number of vaccinations during the two previous years when small-pox was unusually prevalent, and also to the diversion of vaccinators to anti-cholera duty; in Chittagong to the same reasons; and in Darjeeling to the absence of epidemic small-pox and a recent thorough-going vaccination campaign on the tea gardens. In Howrah, however, conditions were very unsatisfactory; Howrah is closely adjacent to Calcutta city, where small-pox was markedly epidemic, yet there was a marked falling off in the number of vaccinations performed. (Howrah, in fact, appears to tend to go Bolshevik in public health as well as in political matters.) In the *mofussil* municipalities also there appears to be a steady falling off.

Agencies outside the official one carried out 96,867 vaccinations during the year. The state of vaccination among the labour force of the Darjeeling tea gardens is reported to be satisfactory, but in the Duars conditions are quite unsatisfactory—only 1,580 vaccinations were carried out among this very large labour force during the year.

There was a decrease of 13.3 per cent. in the vaccinations of infants as compared with the previous year's figures. In some districts, such as Malda, Rajshahi and Darjeeling, over 500 per mille of infants are protected; in 7 districts the proportion was between 300 and 400; in 8 others between 200 and 300; in 7 others between 100 and 200; whilst in 2 districts it fell as low as 77 and 33 per mille (Bogra and Bakarganj, respectively). The last two figures in reality mean a population almost entirely unprotected against small-pox. Six-puncture vaccination is proving increasingly unpopular.

The total cost of the department during the year was Rs. 4,52,819, of which sum Rs. 1,64,841 came from provincial revenues, Rs. 1,69,685 from district funds, and Rs. 1,18,293 from municipal funds. The expenditure in Calcutta on vaccination rose considerably, and Government again repeated its annual contribution of Rs. 50,000 to assist in the provision of free vaccination. The average cost per successful vaccination was 2 annas 11 pies.

A very instructive diagram given on page 8 shows (a) the death-rate from small-pox, and (b) the state of vaccination of the public in each district of the Province during the year. A study of the diagram shows that in only two districts—Burdwan and Darjeeling—is more than half the population protected by vaccination. This diagram is one of the most instructive ones in public health we have ever seen, for it visualises the facts. In Calcutta, for instance, it is seen that the mortality from small-pox—1.32 per mille—is beginning to creep up towards the total number protected—48.67 per mille. The difference may seem enormous, but a continuance of a *laissez faire* attitude on the part of the people may tend to make the figures equal.

Deaths from small-pox during the year numbered 31,936 as against 18,618 in the previous year. The quinquennial outbreak, which started in December, 1924, continued throughout 1925 and 1926, and exerted its heaviest toll in the period November 1926 to May 1927. The disease was prevalent in almost all districts. Extra vaccination staff was provided in the districts where the epidemic was severe.

Glycerinated lymph was in use, and the success rate is reported to be 92.8 per cent. for primary vaccinations, and 24.7 for re-vaccinations. Dr. Bentley comments

severely on the slackness of district health officers in inspecting vaccination. In Midnapur, where the epidemic was very severe, the district health officer spent only 47 days on tour; in Birbhum the district health officer inspected only 721 persons; and the health officer of Nadia was only on tour for 3 days and inspected 96 persons. "It is regretted that some of the district health officers have not yet sufficiently realised their heavy responsibilities..... Vigilant and careful inspection is necessary to give an impetus to the staff..... Personal control is demanded to prevent unreliable figures being returned, only to give a false sense of security." The district inspecting staff inspected 24.5 per cent. of primary vaccinations, and 11.3 per cent. of re-vaccination.

The total output of lymph from the Bengal Vaccine Depot at Entally was 2,680,464, doses and, as this was insufficient to meet the demand, extra lymph had to be purchased from Bihar and Orissa. The calf supply is the chief difficulty at Entally, but, with the discovery by Dr. Blaxall of the Government Lymph Establishment, London, that lymph can be kept without losing its potency for long periods if stored at 10°F., it should become possible to build up a reserve in cold storage for use in times of epidemics. The appointment of the English Vaccination Committee by the Ministry of Health in Great Britain in February, 1926, is an event which should do much to improve methods of vaccination in India, when their report is published.

Dr. Bentley's final summary is so important that we take the liberty of presenting it *in extenso*.

Summary.—From the facts stated in the preceding paragraphs, some broad and simple conclusions may be drawn. It is quite clear that the incidence of small-pox has shown a notable increase in Bengal since the year 1921, and there appears to be no evidence that the zenith of the present recrudescence has been reached. I must again draw attention to the grave risks incurred in respect of small-pox as a result of the large proportion of the population which is not vaccinated. Statistics indicate quite clearly the falling percentage of primary vaccinations to births. In view of the apprehended pandemic of small-pox forecasted as likely to occur in or about the year 1930, it becomes incumbent on all local authorities to put forth all their efforts in preparing the population to meet it whenever it comes. This preparation should consist in wholesale vaccination and re-vaccination of the whole population.

The protection which vaccination and re-vaccination affords cannot be disputed by anyone who has had actual experience in dealing with small-pox. The long experience of the country has taught us:—

(a) That, beyond all question, the mortality from small-pox is much less now than in pre-vaccination times.

(b) That the greatest diminution in the small-pox mortality is found in the early years of life, in which there is most vaccination.

(c) That in countries in which there is adequate vaccination and re-vaccination relatively to the population, there is little small-pox.

(d) That in houses invaded by small-pox in the course of an outbreak, not nearly so many of the inmates are attacked as of the unvaccinated in proportion to their numbers.

(e) That the fatality rate among persons attacked by small-pox is much greater, age for age, among the unvaccinated than among the vaccinated.

(f) That the degree of protection conferred by vaccination corresponds to the quality of the vaccine and to the thoroughness with which the operation of vaccination has been performed.

(g) That the protection afforded by vaccination wanes with the lapse of time.

(h) That improved sanitation, however beneficial in itself, cannot account for these facts; and

(i) That though early diagnosis, prompt isolation of small-pox patients in suitable hospitals, effective disinfection, supervision of "contacts" and other such public health methods are invaluable, they are no substitute for vaccination.

Insufficiency and inefficiency of vaccinators, coupled with inadequacy of pay, should be remedied without further delay. No evasion of the statutory rules for the qualifications of public vaccinators should be allowed, and their prescribed duties should be strictly enforced. For this reason, a living wage must be ensured before good work, satisfactory both in quality and in quantity, can be reasonably expected from the vaccinators. The local funds, set free by the Local Government's provision of a complete public health organisation, should be utilised in employing an adequate number of qualified vaccinators of the right stamp, to whom adequate remuneration should be offered. The Health Officers, Assistant Health Officers, Sanitary Inspectors and Vaccination Inspectors should keep a close watch over the vaccination condition of their jurisdiction and exercise a strict supervision over the Health Assistants and public vaccinators' work. Those District Boards and Municipalities which still employ only season vaccinators should abandon this false economy, which costs so much in human lives, and begin at once to keep all the year round, wholtime Health Assistants, who are qualified public vaccinators and whose services will be available in the other lines of public health work also.

In conclusion, I should like to place on record the valuable advice and assistance always rendered me by Dr. M. K. Chakravarti, M.B., the veteran Superintendent of the Bengal Vaccine Depot.

Correspondence.

FUNGUS INFECTIONS OF THE HANDS AND FEET.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—In the *British Medical Journal* of May 19th last, Dr. Rupert Hallam published an article entitled "Fungus infections of the hands and feet."

All of us practising in tropical climates have seen cases of skin infection between the toes, usually the fourth and fifth. Many of these are exceedingly difficult to cure and are apt to recur every hot weather. Cases of *dhobi* itch also do not often begin in the cold weather. Since reading Dr. Hallam's article, I have seen three intractable cases of this interdigital infection. On investigation, two of these were found to be suffering from *Tinea cruris*, although the fact was not mentioned by the patient. Both these cleared up under treatment directed to the parasite.—Yours, etc.,

C. NEWTON-DAVY,
Staff Surgeon.

BANGALORE.

18th August, 1928.

RODENT ULCER.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—In the October 1927 issue of your journal, my article on "A rodent ulcer cured by injections of Selenium" was published. The patient has come back as his rodent ulcer has broken down again. I have repeated ten injections of selenium this time but the improvement, if any, is very slight. I am now giving him X-ray treatment and if it fails, I shall perform the usual surgical operation.—Yours, etc.,

R. P. GHOSH,

CAPTAIN, M.B.,

Teacher, Medical School, Darbhanga.

LAHERIASARAI,

16th September, 1928.

Service Notes.

APPOINTMENTS.

LIEUT.-COLONEL N. M. Wilson, O.B.E., I.M.S., Civil Surgeon, Simla West, is appointed to hold charge of the duties of the Civil Surgeon, Simla East, in addition to his own, during the absence on leave of Major H. K. Rowntree, M.C., I.M.S.

Government notification regarding posting of Lieut.-Colonel W. Lapsley, I.M.S., as Civil Surgeon, Meerut, is hereby cancelled.

Major H. E. Murray, M.B., I.M.S., First Resident Surgeon, Presidency General Hospital, Calcutta, acted as Surgeon Superintendent of the Hospital, *vice* Major Kirwan, from the 26th April to the 31st May 1928.

Major H. E. Murray, M.B., I.M.S., First Resident Surgeon, Presidency General Hospital, Calcutta, is appointed to act, until further orders, as Surgeon Superintendent of the Hospital, in addition to his duties, *vice* Major Kirwan, with effect from the 1st June, 1928. This cancels notification No. 100T.-Medl., dated the 30th April 1928.

On return from leave, Major E. H. V. Hodge, M.B., I.M.S., was on general duty at the Medical College Hospitals for the period from the 22nd to the 29th April 1928.

Major T. L. Bomford, M.B., I.M.S., Civil Surgeon, Darjeeling, acted as Surgeon to His Excellency the Governor of Bengal, in addition to his own duties, from 21st May to 29th June 1928, *vice* Major H. Hingston, I.M.S., granted leave.

Captain T. H. Thomas, I.M.S., Second Resident Surgeon, Presidency General Hospital, Calcutta, acted as First Resident Surgeon of that institution in addition to his own duties, *vice* Major H. E. Murray, I.M.S., from the 26th April to the 31st May 1928.

LEAVE.

Lieut.-Colonel J. F. Boyd, I.M.S., Civil Surgeon, has been granted, by the High Commissioner for India, leave on half average pay for three months in extension of the three months' leave.

Major R. F. D. MacGregor, M.C., I.M.S., an Agency Surgeon, is granted leave on average pay for 8 months combined with leave on half average pay for 4 months under the Fundamental Rules, with effect from the 30th August 1928.

Major H. K. Rowntree, M.C., I.M.S., Civil Surgeon, Simla East, is granted leave on average pay for three months and ten days, with effect from the 3rd December 1928.

RETIREMENTS.

Lieut.-Colonel T. Hunter, C.I.E., M.D., I.M.S., dated 18th August 1928.

Lieut.-Colonel J. H. Murray, C.I.E., M.D., I.M.S., dated 24th March 1928.

NOTES.

PERNICIOUS ANÆMIA AND ITS TREATMENT WITH LIVER EXTRACT B.D.H.

THE treatment of pernicious anæmia by adding liver to the diet of the patient was first introduced by Minot and Murphy in 1926, and has since been widely adopted. In those cases in which the patient is able to tolerate the liver diet, very encouraging results follow its administration.

The treatment has drawbacks, however, not the least of which is the fact that many patients cannot tolerate a daily ration of half a pound of liver—the smallest quantity recommended to produce optimum results.

There is also the danger of over-cooking in the attempt to make the liver more palatable, with the possible destruction of much of its therapeutic activity.

The production on a manufacturing scale of a highly-active powdered liver extract, containing in small bulk the therapeutic principle of the original fresh liver, is of the greatest importance. This concentrated, potent extract is known as Liver Extract B.D.H.

Liver Extract B.D.H. is manufactured in the Chemical Works of The British Drug Houses Limited by a process, adapted from the observations of Cohn and others, which has been tested clinically and found efficient by the Medical Research Council.

Clinical Trials.

The clinical trials made in various hospitals upon samples of liver extract distributed by the Medical Research Council were reported upon briefly in the *British Medical Journal* and the *Lancet* of 10th March, 1928. In these trials the extract was gauged by the rate of increase of the young red cells (reticulocytes). In practice it was found that simultaneously with this increase there was a distinct feeling of general improvement in the patient, and this was followed by a progressive increase in the count of red blood corpuscles.

Of the thirty-four cases treated, thirty-two responded to the treatment, but nine of these were ruled out owing to complications such as a possibility of natural remissions and the influence of some previous treatment.

In thirty-three cases the improvement could be attributed with certainty to one cause only—the administration of the liver extract.

The daily dose given was the equivalent of half a pound of fresh liver. The rise in the percentage of reticulocytes reached a maximum in 12 to 15 days, whilst the count of the red blood corpuscles rose from 750,000 at the beginning of the treatment to 5,000,000 after 34 days' treatment.

Larger doses gave a quicker response, but the "half pound" daily dose is recommended as the most satisfactory.

In addition to the work carried out by the Medical Research Council, clinical experiments have been made with whole liver and with liver extract by Fraser and others. These workers reported their results in the *British Medical Journal* of 7th February, summarising their results as follows:—

"Nineteen patients with pernicious anæmia have been treated with whole liver or a liver extract. Nine of them were in the first attack or in a relapse, and seven of these showed a prompt response to treatment, with a temporary rise in the percentage of reticulated red cells in the circulating blood, and a steady increase in the total red cells and the hemoglobin. The reason for the failure of the treatment in the other two patients is not clear.

Ten patients commenced treatment during the remission stage or received other forms of treatment in addition, so that observations on the immediate effects of the treatment were not possible. The condition of these patients at the end of varying periods of treatment (up to six months) affords confirmatory evidence of the value of this treatment."

Further, the clinical evidence furnished by Minot and Murphy in their more recent experiments with a non-protein liver extract prepared by the method of Cohn confirms the evidence that liver extract is just as efficacious as whole liver.

In pointing out the advantages as to simplification of treatment in using the extract, these workers direct attention to the necessity of prescribing an adequate well-balanced diet during the course of the treatment.

Thus liver extract B.D.H., made in accordance with the method tested by the Medical Research Council and administered in conjunction with a full and well-balanced diet, will produce results in pernicious anæmia as beneficial as those obtained with a diet of whole liver.

Method of Administration.

Liver extract B.D.H. is administered orally. It is best given in hot water in the same way as meat extract with condiments to suit the individual palate; in this way it is quite palatable. As far as is known there are no conditions in which liver extract B.D.H. is contra-indicated.

How Liver Extract B.D.H. is issued.

Liver extract B.D.H. is issued in glass tubes each containing one daily dose, the equivalent of half a pound of fresh raw liver, and the tubes are supplied in boxes of three and of six.

A REPORT ON THE INVESTIGATION INTO THE ÆTIOLOGY AND PREVENTION OF NAGA SORE IN ASSAM.

By D. N. ROY, M.B., D.T.M. (Cal.),

Assistant Professor of Medical Entomology in the Calcutta School of Tropical Medicine.

INTRODUCTION.

AN enquiry into the ætiology, cause and prevention of ulcers in the tea gardens of Assam was undertaken at the request of the Indian Tea Association. This lasted for only two months from 25th May to 23rd July of last year.

Reasons for Undertaking a Research on Naga Sore.—These ulcers appear in a sporadic, an

May, June and July and a portion of August. Apart from this question of pecuniary loss, the loss of an average of 41.4 days of labour among 50 coolies in a single garden is a thing which needs serious consideration.

Comparative tables have been given at the end to show the loss of labour which the company suffered during 1923-24, 24-25, 25-26 among 17 gardens under one estate in South Sylhet. The cases have been placed under one heading as ulcers and Naga sores, for, as will be mentioned later on, they are clinically indistinguishable.

I made my observations in South Sylhet in Balliserra Valley tea estates and in Cachar in Tarapore tea estates.

Climate, Rainfall and Humidity.—The rainfall is everywhere abundant during the monsoon months. These heavy rains moderate the summer heat, and make the places warm and damp. The variations between the three have been shown in Appendix A and B.

APPENDIX A.

endemic and at times an epidemic form at a particular season and are responsible for the crippling of a large number of tea garden coolies. In some years the epidemic is so bad that as many as 35 to 40 per cent. of the coolie population in some gardens are affected during the busiest season of the year. The economic loss from this disease has been considered to be enormous. At places, this has been found to be much greater than from all other diseases taken together during the whole year. Thus in one of the gardens in South Sylhet the company had to pay to the labourers a sum of £30 as sick bonuses to those who, through Naga sore alone were temporarily disabled from attending to their work during

Distribution of the Disease in Assam.—As it was not found possible for me to make a survey of the distribution of the disease throughout Assam, Dr. Hugh Smith, Medical Officer, Balliserra Valley, at my request made enquiries from various medical officers practising in the tea gardens at different places in Assam. Dr. Murphy's figures from Luskerpur Valley, and Dr. Gibson's from Madhabpore will be found in Appendix C and D. These show that the disease is widely prevalent in South Sylhet, except in Longai Valley, where Dr. Terrell reports comparative freedom from Naga sore. A visit to Dr. Terrell's practice would certainly have elicited much useful information, but I had to abandon

the idea as the time at my disposal was very short. In Cachar, the disease was found to be as prevalent as in Sylhet.

Reports from Upper Assam showed that the disease, though not evenly distributed, was fairly common there.

chemical manures, poisonous herbs, caterpillar stings, etc.

(iii) Scabies.

The writer selected 386 ulcers that were found on 210 patients in Cachar and in Sylhet as those which seemed to him clinically to be typical cases

APPENDIX B.

Synonyms.—Various names have been given to these ulcers according to where they are seen; thus in India they are known as Cachar sore, Naga sore, Frontier sore, Jungle ulcer or Jungli ghao.

Predisposing Causes.—In Assam the following have been observed to be predisposing factors in the causation of the disease:—

(i) Trauma—injuries, cuts, abrasions, wasp bite, cat bite, leech bite, etc.

(ii) Dermatitis of the skin from bonemeal,

of Naga sore, and their contributory factors when analysed showed:—

Trauma from various causes	..	45.3	per cent.
Leech bites	..	3.6	"
Itching from various causes	..	34.4	"
Papules	..	7.5	"
Water sore (ankylostoma)	..	0.2	"
Abscesses and boils	..	3.1	"
Scabies	..	2.8	"
Old ulcers broken down and probably tuberculous	..	1.0	"
Tuberculous ulcers as diagnosed clinically	..	0.8	"

APPENDIX C.

These factors would naturally vary in different gardens; thus where water sore is common, these ulcers develop at those sites and a large number of such cases are found. There are places which abound in leeches more than others and ulcers follow such bites. Under the heading of abscess and boils I would like to mention that in some gardens the coolies complain of intolerable itching of the legs when they come back from work. They not only scratch the parts, but also pull off the hairs to allay this itching. So many of these ulcers start as small abscesses and boils.

Sex.—Out of 210 cases, 138 were males and 72 females, or 65.7 per cent. males and 34.3 per cent. females. This figure taken as a whole would be misleading if I fail to mention the fact that in certain gardens the female population were more prone to this disease while in others the reverse was the case.

Age Incidence.—Roughly 99.6 per cent. of cases were among adults and 0.4 per cent. among children and infants.

Season of Onset.—The season of onset of this disease varies with the place. In most of the places the disease appears after the first shower in the hot months. It begins in May and attains its maximum in July, when there is usually very heavy rain. It diminishes after the monsoon and in the cold months entirely disappears. Enquiries on this point had been made from various medical officers in Assam and the following were the replies obtained:—

Jafflong Tea Estate (Sylhet)—highest during the monsoon months—June to September.

Luskerpur Valley (Dr. Murphy)—March to October: highest in May, June and July.

Madhabpur Tea Estate (Dr. Gibson)—Rainy season: the height of the disease is in July.

Balliserra Valley (Dr. Hugh Smith)—April to August: worst in June and July.

Assam Frontier, Doom Dooma (Dr. Williams)—Rainy season: worst in September.

Hautley Tea Estate, Golaghat (Dr. Bannerjee)—Early part of the rainy season: highest in August.

The fact is clear that it is connected in some way or other with temperature, humidity and rainfall.

Distribution of the Disease on the Body.—This disease is not equally distributed all over the body. It is remarkably selective in its distribution. The ulcers have been found mainly on the legs and feet from the knees downwards. Occasionally a few cases have been observed on the elbow, forearm, dorsum of hand, back, thigh—both inside and outside, and on the nape of the neck. The distribution of the disease as observed by me has been given below.

Out of a total of 386 ulcers, 382 were found on the lower extremity, 3 on the upper and 1 on the trunk.

On the lower extremity they were distributed as follows:—

Thigh	..	11
Leg	..	232
Ankle	..	54
Foot	..	85

On the upper extremity—

Elbow	..	1
Forearm	..	1

On the trunk—

Hand	..	1
Back	..	1

In connection with the above the exciting factors causing the lesions in various parts are shown below:—

cannot always be relied upon, as they are very often exaggerated or underrated. They cannot in most cases even definitely say the length of the time of their own sufferings. Their idea of the difference between the duration of 5, 10 or 15 days is vague.

At the earliest stage there is nothing but an abrasion or a breach on the surface of the skin. This may heal up or may be the starting point of the characteristic sore. Within a day or two a small ulcer forms which deepens considerably, and becomes covered over with a greyish-yellow, thick, purulent, bad-smelling slough. The

Occupation.—Occupation has been observed to play an important rôle in the epidemiology of the disease. The ulcers are usually found in the following classes of people:—

- (i) Coolie class,
- (ii) people working in the fields who have to work bare-footed,
- (iii) those whose work exposes them to trauma, injuries, cuts, abrasions, etc.,
- (iv) those who are subject to leech bites.

Signs and Symptoms.—It should be taken into consideration that the narration of their own symptoms, as disclosed by tea garden coolies,

margins are always undermined and this tendency is noticed from the very beginning: in fact one can pass the end of the platinum loop for some distance all around the margin. The ulcer spreads very quickly and in the course of five to six days usually attains the typical shape and aspect of these sores. The shape of the ulcer depends on the nature of the trauma: when it is only a prick or a leech bite, it is circular; when it is a cut from a spade it is irregular. Lymphangitis is not a constant sign, though present in about half the number of cases. In a few it is present on the whole leg, while in a majority of them it is local and is confined around the ulcer. There was one case which simulated filarial elephantiasis.

The edges are undermined, the margins are considerably raised, indurated and give it a cup-shaped appearance, when the ulcer is circular. The depth of these ulcers cannot be judged by merely looking at them, as they are full to the brim with the characteristic slough. A thin watery sero-sanguinous discharge is also often seen running down from these sores, which is nothing but hæmolysed blood mixed with the purulent discharge from the ulcer. The

discharge is putrid and has a gangrenous odour. It is difficult to remove the tenacious slough but

at those places from which it is removed a red granulating raw surface is exposed which bleeds freely on the slightest touch.

No appreciable difference of colour on the surrounding skin could be noticed in my cases as the coolies are very dark coloured.

Pain, as a symptom, has attracted the attention of many of the previous observers. If one could rely on the statement of the coolie, probably he would say that every ulcer is painful; but if one cared to watch him for some time at a stretch, one would be convinced that pain is not a striking symptom in a majority of the cases. Pain depends mostly on the stage of the ulcer, and also on the site. When nerve filaments are exposed, the pain is very severe and is of a burning kind as the coolies complain of a sensation of feeling something very hot. When the ulcer is in a spreading condition with marked lymphangitis, this stage is also painful. With the exception of two coolies, I have never heard any others complain of loss of sleep due to pain, nor of being unable to attend the dispensary every morning. Walking and standing are painful, but the pain is very much relieved on lying down. On no occasion has involvement of the neighbouring glands been observed. There is little or no constitutional disturbance. The disease is afebrile throughout its whole course. In only 2 out of 96 cases could I detect fever by feeling the patient's pulse.

Self-limitation is one of the features of these ulcers, which have a tendency to stop spontaneously at the deep fascia, though this is by no means the rule. They may spread beyond the deep fascia, expose the tendons and muscles and sometimes may extend as far as the bone.

The ulcers are often multiple. The ætiological factors in a majority of cases can easily be traced if one has the patience to question a coolie and get at the truth.

Microscopical Examination of Direct Smear.—I had to remain satisfied with merely examining the smear under the microscope as I had not the equipment to make detailed studies. At first smears were taken from the undermined edges of these ulcers, but when cases clinically resembling Naga sore, as described by various observers, showed neither spirochaetes nor fusiform bacilli, I began to take 3 to 4 smears from every case, one from the discharge, one from the deep slough next to the granulation tissue, one from the undermined edge of the ulcer and one after scraping the granulation tissue from the margin of the ulcer. Such examinations were continued from day to day as often as possible. It is noteworthy that the microscopical findings were the same in all the smears taken from each case in Sylhet.

In Cachar, on the other hand, I could not do more than merely examine a few smears from each case as the time at my disposal was too short for making a more thorough examination of each individual case of ulcer at its various stages, as could be done in Sylhet.

The ulcers seen in Sylhet and in Cachar were at all stages of the disease. The earliest case that came under my observation was on its second day and it turned out to be a virulent ulcer. Otherwise, the cases, judged according to the statements of the patients—which in a majority of the cases were not very reliable—and the nature of the conditions present, were from the third to the seventeenth day of the attack. A few of the patients who went back to work apparently cured, left with only a granulating raw surface, but came back during the course of a week or a fortnight with the leg much swollen, and the ulcer again angry-looking. It was further observed that a certain number of cases, clinically resembling typical Naga sore, showed no spirochæte or fusiform bacilli in the smears at the first examination; but for some reason or

other these patients stopped coming to the hospital and in the meantime had taken off their dressings and gone about in the usual way; three or four days after this when they came back to the out-patients' department, either voluntarily as the swelling had considerably increased and walking was more painful, or because they were compelled by the authorities to attend the hospital, examination of smears from these ulcers now revealed a large number of fusiform bacilli.

I would here like to classify the cases into two groups, those in which repeated examinations were done and those in which only one or two examinations, as conditions permitted, were made.

A. Repeated examinations were done—

No. of ulcers.	Findings.	
156.	Fusiform bacilli	59
	Spirochæte and fusiform bacilli	4
	Spirochæte alone	2
	Negative findings	91

B. Examined only once or twice—

No. of ulcers.	Findings.	
230.	Fusiform bacilli	65
	Spirochæte and fusiform bacilli	1
	Negative findings	164

No spirochæte or fusiform bacilli could be found in ulcers on other parts of the body except on the portion from the knee downwards.

Dr. Ramsay told me of a case he had seen which he thought to be a typical Naga sore; the ulcer was situated on the nape of the neck and he found large numbers of fusiform bacilli in the smear.

Duration.—Even with treatment they take as long as six weeks to three months to recover. Osteitis and osteomyelitis take a much longer time. I saw one case where the patient was laid up for 15 months and pieces of necrosed bone had to be extracted on two occasions.

I had not the opportunity to observe how long the ulcer would take to heal if left untreated; or if there was any tendency for these ulcers to spread without treatment.

Prognosis.—Prognosis is usually good except when bone complications set in. In ordinary cases recovery is the rule. The disease itself is not fatal though intercurrent infections like pneumonia, which occur very frequently in tea gardens, may kill the patient.

Complications and Sequelæ.—Complications are not very common. Osteitis and osteomyelitis are sometimes met with. Tuberculosis of bones and joints may be a sequela, as all the patients suffering from bone and joint tuberculosis complained that the disease appeared first in the form of an ordinary Naga sore, which took its usual time to heal, but in the course of a few months the scar tissue broke down. Usually thin, supple scars are left. The author in the course of his investigations never came across any case of deformity which could have been accounted for as an after-effect of these ulcers.

Contagiousness.—The disease is not contagious. Parts which are opposed, and as such naturally come into constant contact with the ulcer, are not affected.

The ulcer has no tendency to spread among members of the family or among those who come into intimate contact with the patients.

Immunity.—Newly recruited coolies are equally affected with those who are born in the gardens. Coolies suffering from these ulcers one year may get the same kind of ulcer next year on some other part of the legs. No immunity is conferred on patients by an attack of Naga sore.

PART II.

DISTRIBUTION OF THE DISEASE IN VILLAGES AND IN TOWNS.

The cases I examined were mostly among tea garden coolies. With a view to finding out the incidence of the disease in villages and in towns quite adjacent to these gardens, I examined the cases I got in two villages and also at Srimangal, a town situated within a distance of two miles from the nearest tea garden, where there were many cases of ulcer.

These villagers are divided into two classes; firstly those who earn their livelihood by working as day labourers in tea gardens and secondly those who plough their own lands.

The soil was found to be the same at both places and the conditions were identical.

In each of the two villages the number of inhabitants was two to three hundred, approximately, while the incidence of the disease was from 2 to 3 per cent. at a rough estimate, and all these cases were confined among those who used to work in the gardens as day labourers.

A disease which roughly speaking resembled "ulcus infantum," as described by Castellani and Chalmers, was commonly met with among children, but these have not been included in the above figures.

At Srimangal, on the other hand, I could get only four cases which appeared to me more like cases of scabies than of Naga sore.

Habits of the People in whom the disease is found.—Coolies for tea gardens are recruited from Bengal, Bihar, Orissa, Madras and Assam. It is needless to mention that coolies have a very crude idea of sanitation. They are ignorant and are to some extent superstitious. They are guided by their own laws of sanitary principles. So long as they are left to fend for themselves, they consider a cut as a cut, and cannot conceive that the consequence of a cut, if neglected, may prove fatal. Their nostrums and quackeries too are remarkable. Thus the first thing they do if they get a cut is to put some mud on it and if the wound still bleeds, some chewed grass, which they think act as hæmostatics. When they go home they apply a paste made of the leaves of some plants, alone or mixed with cowdung, which forms more or less a plaster-like coating on the ulcer. It is left there till it falls off. When the ulcer spreads and it becomes increasingly difficult for them to walk and attend to their ordinary work, it is then that they go to the hospital for treatment.

Tea garden hospitals usually have accommodation for a limited number of in-door patients. It is surprising that coolies who find it difficult to walk would much rather prefer to stay at home without any treatment than seek admission as in-patients. It might be thought that this is because a coolie has a large family to support and his wife has children to look after; this cannot be taken to be a serious deterrent factor in his aversion to stay in hospital. In Cachar I have seen at least three to four cases of Naga

sore as in-door patients in every hospital in Dr. Ramsay's practice, who, when they come to stay, bring their wives and children along with them. The practice in the gardens in Sylhet that I visited is to pay full wages to those who cannot attend to their work on account of sickness, while in Cachar I have seen an entirely different practice being followed. The company pay doles in the form of provisions, such as rice, dal, meat, etc., to all who accompany the sick and stay in the hospital.

The former is undoubtedly cheaper than the latter. I have been given to understand that the latter is only a tentative measure to attract these people to hospitals and to make the treatment more popular.

It would be superfluous to say that coolies go bare-footed.

Males are given hard work, such as hoeing, while females and children are given lighter work, such as plucking, manuring, etc.

Upper class Indians who have to go out to the fields generally wear shoes. I have seen many going bare-footed. They always keep their bodies covered.

Coolies are able-bodied and healthy, and bathe every day in shallow running hill streams.

The Coolies' idea of the source of infection.—There is a vague idea among the coolies that the source of the infection is from exposure to a plant, *Mimosa pudica*, Linn, which grows wild in Assam.

Epidemicity.—Patterson (1908) observed an epidemic of this disease in Tezpur in 1908 and described it in the following manner:—

"This year the typical phagedænic ulcers have swept like a plague up the whole of Assam on both banks of the Brahmaputra and temporarily incapacitated many thousands of coolies from work during the busiest months of the tea-making season. On the south bank, Nowgong, Golaghat and Jorhat suffered heavily, and in Dibrugarh district most of the factories have had their labour forces literally decimated. The aggregate loss of labour throughout the valley must be enormous."

It has already been mentioned that the disease is practically confined to one place, and that neighbouring and contiguous gardens often escape. It does not sweep over the whole place in the sense that one garden after another is affected. The epidemic is more or less local. In this respect it differs from other epidemics, e.g., of cholera.

The disease does not follow any distinct line of human communication nor travel from one place to another.

Yearly recurrence of the disease at one place is not the rule. One year one garden may be badly affected, next year it may be free.

The general epidemic usually recurs once every three to five years. Endemic and sporadic cases are met with every year.

PART III.

DESCRIPTION OF *ULCUS TROPICUM*.

Ulcus tropicum is a widely distributed disease in the tropical and sub-tropical regions of both hemispheres of this globe. A variety of names has been given to it: e.g., Ulcer of Yemen, of Aden, of Cochin China, of Annam, of Mozambique, according to the locality where it is found. At present all these ulcers have been grouped under one term—*Ulcus tropicum*. Various ulcers having phagedænic characters and showing spirochætes and fusiform bacilli have been described as *ulcus tropicum*. Thus the hospital gangrene of pre-antiseptic days was thought by La Dantec, by Crocket and by Manson to be allied to this disease, while Blaise and Brault asserted that the latter might be complicated with the former. Gangrenous-looking ulcers seen in debilitated conditions, in street beggars, in cachectic conditions among soldiers, sailors, etc., have been described under this term by Adams, Corpus, Sceube, Muhlen and various other observers, simply on the strength of their finding spirochætes and fusiform bacilli in all these ulcers. Stelwagon's remarks on this term seem to be very appropriate:—

"The term seems to be both a comprehensive and an uncertain one in the tropics, being largely, if not wholly employed to designate the occasional accidental terminal ulcerative condition of several diseases, such ulcers being found with oriental sore, frambœsia, tuberculosis, syphilis and other diseases. It doubtless very often means the addition of a pyogenic or other factors to one or other of the diseases named and which to a variable extent change the ulcerative character of the already existing disease."

In the light of researches of the present day on these ulcers, as described by various authors, if one were to analyse them, he would be tempted to class them as follows:—

- (1) *Ulcus tropicum* pure or phagedænic ulcer.
- (2) Hospital gangrene.
- (3) Ulcers met with in debilitating conditions, in warfare, in street beggars, etc.
- (4) Terminal ulcers—usually of the form of gangrene.

I will now make an attempt to describe very briefly the conditions in each of the above diseases, compiling them from the various works on the subject, a list of references to which will be found at the end.

Ulcus tropicum is a rapidly spreading phagedænic ulcer which is commonly met with in warm countries. The ulcers are almost invariably found on the exposed parts of the body: they occur most commonly on the legs, ankles and feet; less frequently on hands and forearm. They begin as a small itchy painful papule having the appearance of a mosquito-bite, and in some cases they start from often a slight trauma. The ulcer quickly spreads, assumes its characteristic appearance, has a foetid discharge and is usually

covered over with a greyish yellow slough. Self-limitation is usually the rule. Besides cocci and similar micro-organisms, fusiform bacilli and spirochætes are found in numbers.

Hospital gangrene is a rapidly spreading necrosis of tissue caused by various pyogenic and putrefactive organisms in conjunction with anaerobic bacilli, the latter probably playing a very important part in the spread of the disease. There is no tendency for this disease to limit its spread. Fusiform bacilli and spirochætes have been observed to be present in large numbers in these forms of ulcers.

Ulcers met with in debilitating conditions, etc.—These forms of ulcers which start from various skin diseases are very commonly met with in street beggars. Street beggars are museums of various forms of skin diseases, which are induced by their uncleanly habits favoured by the poor nutrition of their bodies. Ulcers are secondary to the skin diseases which are invaded by a variety of pyogenic organisms. These ulcers seldom have the characteristic appearance nor do they ever spread so rapidly as in *ulcus tropicum*. Previous authors make little reference to the bacteriological findings in these ulcers as it is not clear whether fusiform bacilli and spirochætes have been recovered from them.

Terminal Ulcers.—These are met with in hospitals in terminal conditions and are of the nature of gangrene which has a tendency to spread rapidly: they are found in connection with tuberculous ulcers, cachexia of malaria, kala-azar, dysentery, profound anæmia and other similar conditions.

My best thanks are due to Dr. D. C. Chakravarti, F.R.C.S., Surgeon, Campbell Hospital, for drawing my attention to a case he has been treating in the hospital for some time past. The patient is a boy about 14 years old, extremely cachectic who has a gangrenous ulcer with a greyish tenacious slough and a foetid discharge on the lower third of the leg. I happened to go to the hospital after the leg had been kept in a eusol bath for a long time and the ulcer was dressed. I got numerous spirochætes and fusiform bacilli in a smear from the slough.

Bacteriology of Ulcus Tropicum.—I will narrate here very briefly the bacteriological findings of cases of *ulcus tropicum* as mentioned by various authors.

Plaut (1894) first drew attention to the presence of spirochætes and fusiform bacilli in these forms of ulcers. Vincent (1896) found spirochætes in only 40 out of 47 cases of *ulcus tropicum*. He thought that the fusiform bacilli, which were a constant factor, were pathogenic and were the cause of tissue necrosis. Crendiropoulou (1897) obtained an anaerobic bacillus—*Bacillus l'Yemen*—which when cultured and inoculated into animals, produced ulcers which resembled these sores. Prowazek (1907) first brought forward the hypothesis that *Spironema schaudini* was allied to *Spironema vincenti*, was pathogenic, and was the cause of *ulcus tropicum*.

Shattuck (1907) in his "Notes on Chronic Ulcers occurring in the Philippines" mentioned that 94 per cent. of such cases could be classed as syphilitic. Caboïs (1908) was convinced that there was destructive *ulcus phagedænicum* due to *B. phagedænicus*. Gros (1908), on the other hand, found a Gram-negative diplococcus in some cases, but he failed to obtain any spirillum while smears were rich in fusiform bacilli. He did not associate the spirillum of Vincent with these ulcers.

Bulkey (1910) in his extensive observations on skin diseases in the Far East doubted the existence of these sores as a specific entity.

Eggers (1915) found various spirochætes from a study of 2,874 specimens in only 9.3 per cent. of his cases. He thought that a spirochæte described by him as Eggers' type A (13 microns long, 3 to 4 regular convolutions of considerable amplitude) was the typical organism of *ulcus tropicum*. Mendelson (1919) reported 100 cases and asserted that 10 per cent. showed spirochætes—all of Eggers' Type A. He was inclined to look on this organism as the same as the *Spironema schaudini* and he thought it to be a superimposed infection on already existing ulcerations. According to him this spirochæte is not limited to a disease of distinct clinical features: in fact it can be found in different diseases with great varieties of clinical features.

Kritchevsky and Seguin (1921) do not think that these two organisms growing in symbiosis are the cause of Vincent's angina, a disease almost similar to *ulcus tropicum*. They contend that under the name of fusiform bacilli several organisms have been confused.

(i) Plaut's bacillus—a big fusiform bacillus, motile, Gram-negative with many cilia: very big and visible under the ultramicroscope; can be very well stained according to Fontana-Tribondeau methods.

(ii) Bacillus of Schmallmire—long needle-shaped, thin, sometimes curved, sometimes spironemacea type, feebly motile and rotating on its own axis; Gram-negative: non-ciliated: an obligatory anærobe. Grows flocculent colonies in deep serum agar. Odour acid but not putrid. This is non-pathogenic to animals.

(iii) Fusiform bacilli—Non motile: Gram-negative: non-ciliated: when stained with Giemsa, reddish chromatic granules are constantly seen in their protoplasm. It is an obligatory anærobe and cultures are strongly putrid in odour: these authors do not think that these organisms are by themselves pathogenic.

The bacilli found by various investigators like La Dantec, Petit, Boinet, Blaise and others have not been mentioned as they have been considered to be a doubtful ætiological factor in the causation of the disease.

Corpus (1924) in his study on these ulcers came across spirochætes which he thought were the exciting causes. He arrived at positive findings in 35.5 per cent. of his cases.

Castellani, Manson, Stitt, and Scheube all believe in spirochætes and fusiform bacilli as the organisms responsible for this condition.

Is ulcus tropicum the same as Naga sore?—Patterson (1908) first drew attention to an epidemic of Naga sore prevailing widely in Assam and showed that from a clinical standpoint the disease was similar to *ulcus tropicum*, as described by various European writers. Fox (1921) made a bacteriological study of a few cases of ulcers and found spirochætes and fusiform bacilli in a majority of them; in some, the exact number of which he does not mention, he failed to obtain spirochætes.

Is the disease studied in Assam a distinct clinical entity?—From the descriptions, which have already been given of these ulcers, one would not hesitate to pronounce the opinion that they belong to a distinct clinical group. Necrosis before suppuration, fœtid discharge, tenacious slough formation, deep circular ulcers, indurated and raised margins, absence of fever and of enlargement of glands are features which are distinctly characteristic. When they occur among a large number of the population, and mostly on legs and feet, there is no reason to incriminate them with syphilis. However, some doctors, who have had little or no experience of tropical diseases, have often mistaken them for syphilitic ulcers; this led them to try antisymphilitic measures, but with no success whatsoever.

Discussion on the nature of the cases obtained in Assam.—In order to investigate the nature of these ulcers, which is the subject of study embodied in these pages, one has to take into consideration the clinical and bacteriological findings relating to them. From the descriptions given of the signs and symptoms of *ulcus tropicum*, one cannot find any marked difference between *ulcus tropicum* and the ulcers met with in Assam. Fox (1921) analysing the difference, points out that *ulcus tropicum* does not appear in an epidemic form. But Ruge, Muhlen, Verth and Adams all mention its epidemic prevalence. The only point of difference seems to be in the onset of the disease as a painful papule in *ulcus tropicum*. All observers, however, agree that trauma plays some part in its ætiology, though at times the injury may be so slight as to escape notice. They point out that at first there is a breach in the continuity of the surface of the skin through which the specific organisms—spirochætes and fusiform bacilli—gain entrance into the wound and cause the appearance of the painful papule or the purulent bleb.

On carefully questioning those who mentioned the appearance of a papule at the initial stage, I learnt that poisonous herbs, insect bites and exposure of the feet to irritating manures gave rise to intense itching of those parts. Scabies, localised papular and pustular eruptions accompanied by intense itching were also very common. These parts when scratched caused a breach of the continuity of the surface of the skin through

which the specific organisms gained entrance. Thus it will be clear that the papules are not secondary to the invasion of the wound by the specific organisms.

Regarding the question of pain which is frequently met with in *ulcus tropicum*, I could not find anybody complaining of those papules being painful; on the other hand they were very irritating.

From the bacteriological findings regarding the cases met with in Assam, which have been already mentioned, it will be seen that in only 5 cases out of 386 ulcers, or in 1.3 per cent., was I able to obtain both these organisms, while in 66.06 per cent. of cases neither of them could be found. So whilst these ulcers clinically resembled *ulcus tropicum* in every detail, they differed as far as the bacteriological findings were concerned.

Much has been made of the presence of spirochætes and fusiform bacilli in ulcers. Definite diseases have been diagnosed through the identification of the symbiosis living of spirochætes and fusiform bacilli, and through the membranous character of the ulcer. But one should bear in mind that the mere presence of a spirochæte or a fusiform bacillus does not establish that the ulcer is caused by these organism. Spirochætes or fusiform bacilli alone or growing in symbiosis are often encountered in ulcerative and gangrenous conditions of the lungs, Vincent's angina, mercurial stomatitis, pyorrhæa alveolaris, cancrum oris, various ulcerations on skin, gangrene, noma and in various other conditons. Differentiation of one spirochæte from another is not easy. It is not seldom that besides these *Spirochæta vincenti*, other spirochætes are met with. Even authors like Meyer and Gerber confused the spirochæte of angina with the usual mouth spirochæte. Saprophytic spirochætes, on the other hand, are very commonly met with. It has not yet been found possible to establish the pathogenicity of these organisms, encountered so frequently in ulcers, by cultural and inoculation experiments, which till now have met with negative results.

The source of these organisms.—When one takes this fact into consideration, that these organisms have been encountered in ulcers situated below the knee, one would naturally believe that contamination with the soil is the cause of the presence of these organisms in such ulcers. These organisms have on rare occasions been found on ulcers situated on the buttocks and on the nape of the neck. When coolies feel tired during work they often sit on the ground and thus the buttocks come into contact with the soil. Their habit of putting a lump of earth on wounds is likely to be responsible for the presence of fusiform bacilli in ulcers on such parts of the body.

I have already mentioned the five cases in whom repeated examinations failed to show the presence of fusiform bacilli, but in whom, when they stopped treatment for some days, pulled off their

dressings, and walked about in the mud, infection with this organism took place.

Thus it can be suggested that wounds become contaminated with fusiform bacilli from the soil and it seems probable that a certain type of soil is charged with these organisms much more than others.

Are these ulcers septic in origin?—What is usually meant by sepsis is an invasion of an ulcer by pyogenic cocci which have a great tendency to invade deep tissues, and enter the circulation through lymph and blood channels unless arrested by the defensive barriers of the human system. As a result of this, constitutional and local symptoms in the form of fever, malaise, and enlargement of neighbouring glands are commonly met with. A strikingly different condition has been observed in the cases in Assam. It seems highly improbable that these ulcers are the result of an invasion by common pyogenic organisms.

Nature of the organisms responsible for the conditions seen in Assam.—The causative organisms in cases of *ulcus tropicum*, so far described, are *Treponema schaudini* and fusiform bacilli. There has been a consensus of opinion that the organisms described from *ulcus tropicum* are of the same nature as those from Vincent's angina of the throat, and that *Treponema schaudini* of Prowazek is identical with *Treponema vincenti*. The determination of the cause and effects can only be effected by finding the organisms in the majority of the cases and by producing similar results from cultural and inoculation experiments. From the presence of these two organisms growing in symbiosis in only 1.3 per cent. of the cases examined in Assam, one cannot without grave doubts connect them as the factors responsible for the ulcers. The same remarks would equally apply to fusiform bacilli being alone liable to cause such conditions. As neither of these organisms were found in 66.06 per cent. of cases, weight is added to the argument that there must be some other factor which is responsible for the production of these ulcers.

I have already mentioned the five cases of typical ulcers on the feet of coolies in which repeated examinations failed to show any spirochæte or fusiform bacillus. For some reason or other, best known to themselves, they discontinued their daily visits to hospital for a few days. They took off their dressings, walked about with their ulcers exposed and came back to the hospital for treatment, as the swelling had increased and it was painful on walking. Examinations then showed enormous numbers of fusiform bacilli, and clearly prove that these bacilli are secondary invaders.

Corpus, Mendelson and Eggers all mention that in a small percentage of their cases they could find a spirochæte.

An organism, which I have very constantly come across in these sores, is a diplococcus—round, of a moderately large size—growing inside pus cells. Pus cells with diplococci at all stages

of growth can easily be seen in any smear from such a case. Thus cells with scanty infection, moderate infection, and very heavy infection about to cause the cell to burst and clumps of organisms lying free will be seen.

I have no special reason to connect these diplococci with the ulcers, except their constant presence in leucocytes, the peculiar situation of their growth and the negative finding of spirochætes and fusiform bacilli in a large proportion of cases at all stages of the disease. This is a hypothesis brought forward tentatively, and unless it is supported by cultural and other experiments, proves very little. However, I am glad to mention that Col. Acton, Professor of Pathology and Bacteriology in this School, is making an attempt to solve this side of the problem and till his results are published, it is best to refrain from making any remarks on these diplococci.

Mimosa and Naga Sore.—The mimosa is a sensitive, shrubby herb with stem and rachis copiously bristly and prickly. It is not confined to Assam alone but grows wildly throughout the hotter parts of India. There is no truth in the coolies' belief that mimosa gives rise to such a condition. Our personal experience is that this plant minus the thorns is harmless when rubbed on the skin.

PART IV.

AN EPIDEMIC—IS IT AN INSECT-BORNE DISEASE?

The views held by the previous observers regarding the transmission of the disease from one place to another were:—

- (1) Direct transmission.
- (2) Indirect transmission, through flies.

Ruge and Muhlen mention that inoculation experiments with the pus of these ulcers containing spirochætes and fusiform bacilli, produced negative results, but they were inclined to believe that these ulcers are directly transmitted. Blaise inoculated himself with a negative result and could only produce atypical ulcers in guinea-pigs. Corpus thinks that the disease he encountered in the Philippines was contagious, being usually found in school children who were in constant contact with one another, although he mentioned the ulcers being found only on the legs and feet below the knee. Fox made an attempt to produce the sore in men and animals with an emulsion in saline of the discharge from the sore. Except in one case in a man where a typical Naga sore developed, his experiments met with negative results. My observations do not lend support to this method of transmission. Parts of the body which naturally come into contact with ulcers remain unaffected. Thus I have seen ulcers situated behind the knee surrounded by slough on a very large surface, but there was no tendency for these parts to be ulcerated.

The indirect method has been thought to be by means of insects. Fox mentioned 14 coolies on one tea garden who developed Naga sore on

the site of the puncture, when inoculated with cholera vaccine. He also mentioned the report from a doctor of the formation of Naga sores on unhealed scars of vaccination. A similar occurrence is reported by Blanchard where tropical phagedæna supervened on vaccine pustules.

The presence in large numbers of small flies at the time of the year when these ulcers are met with in Assam, has been thought by various observers to be associated with an epidemic of Naga sore. This belief has been found to be current in the tea gardens of Assam not only among the coolies but also among Indians and Europeans. These flies have been identified as *Siphonella funicola*, Meij. They are often called mango flies. They make their appearance towards the end of April and can be seen till the end of July or the beginning of September. They are frequently seen flying round the eyes whence the name of "eye-flies." As soon as a badly smelling wound is exposed, these flies are at once attracted to it and settled on the ulcer. In fact the patients find it most annoying: they have constantly to move their hands to drive away these pests.

These flies have been thought by Patterson, Fox and Wright to convey mechanically the infective material from an ulcer to a healthy wound. Wright succeeded on one occasion in infecting himself on his arm in this way.

I have done several experiments with these flies on myself, on laboratory assistants, on our peon and on a few coolies, but I have never met with any success.

The experiments are described below:—

A. Stray flies were caught and a few kept in a wide-mouthed bottle as controls; the rest were fed in another wide-mouthed bottle on an ulcer which showed a rich infection with spirochætes and fusiform bacilli. These flies were then fed within an hour on the exudate from some scratches on the skin of either the arm or the leg of a healthy man, made with the sharp point of a needle which had been previously sterilised by burning in a flame. The part was then lightly bandaged up with a clean piece of cloth which was not sterilised.

The feeding experiments were repeated once, sometimes twice a day on the same wound for as long as the flies were alive. It may be mentioned that the scab had to be removed every day from the wound, as otherwise the flies would not feed on it.

(Control experiments were not done as they were found unnecessary.)

Results.—This experiment was performed many times without any success.

B. Three patients were selected, one having a typical spreading phagedænic ulcer with numerous spirochætes and fusiform bacilli, the other two with small atypical ulcers. Stray flies were caught and fed in a wide-mouthed bottle on the positive case; the flies were then transferred to another wide-mouthed bottle with a view to re-

PLATE I.

Showing fusiform bacilli and spirochaetes in a direct smear. Stained with Giemsa.

PLATE II.

Showing diplococci in a direct smear. Stained with Giemsa.

PLATE III.

Fusiform bacilli as seen in the gut of Siphotella 36 hours after ingestion.

duce the chance of direct infection, if such was possible, and then fed on the ulcers of the two atypical cases one after the other. This was to ensure that the flies had fed not only on the infective material but also on other two ulcers.

The three patients were then made to sit side by side inside a large mosquito net in which a large number of the flies, previously fed on the three ulcers, were let loose. From time to time the flies were disturbed, so that, as far as possible, all the flies were induced to feed on the three ulcers. This experiment was repeated for six consecutive days.

Results.—Every day smears were taken to see if they had been infected with spirochaetes and fusiform bacilli through flies. The two atypical ulcers remained the same clinically as well as bacteriologically. No marked change could be noticed in the healing process of these ulcers.

C. Some of the flies which had fed on typical cases were collected and taken to the laboratory for dissection.

In the feeding experiments it was the rule to take some of the flies to the laboratory for dissection. In every case it was found that the flies had fed on the infective material, as we found fusiform bacilli and spirochaetes in their gut.

The distribution of the disease on the body does not bear out the fact that these flies can act as mechanical carriers. Injuries are not confined to the legs alone but other parts of the body are also subjected to such injuries, to a lesser extent. On the other hand Naga sores are mostly found on the legs and in only a certain class of people.

Thus experimental and other observations do not support the belief prevailing so extensively in Assam that these flies can be held responsible for an outbreak of this disease, merely because the seasonal appearance of the two coincides so closely.

Spirochaetes and fusiform bacilli are readily taken into the gut by these flies. These organisms can be recovered from the stomach and crop for about six hours (average period) after a feed, and after 36 hours from the intestine and rectum.

I have not found any evidence to lead to the belief that multiplication of these organisms can take place in the gut.

I would now refer to Plate III. The drawing has been made from a slide showing these organisms in the gut of a fly 36 hours after a feed. The fusiform bacilli here will be seen to have assumed a different shape and size; thus they have not only become smaller but very distinctly rounder and broader while the chromatin granules have considerably swollen up. In some only one granule is seen, in others two. These bodies are constantly found in the gut of the flies which are dissected a long time after a feed, while such bodies are never seen in stray flies, nor in those which had been fed on ulcers in which fusiform bacilli are absent.

Treatment.—Dr. Hugh Smith in Sylhet and Dr. G. C. Ramsay in Cachar mention that they

have found in Electrolytic Chlorogen the only drug on which they can rely for the treatment of these cases. Dr. Ramsay has made extensive observations on this line and he advocates prolonged baths in Pot. Permanganate at the beginning, followed by a bath and a cold compress with E. C. diluted in water. Dr. Hugh Smith, who has also a vast experience in the treatment of such cases, on the other hand, is in favour of using iodoform and a charcoal poultice for rapid removal of the slough. When the slough has once disappeared, both these workers would have the wounds dressed in normal saline soaked in lint.

A casual remark on the treatment made to me by some of the Indian doctors practising in the tea gardens in Assam is interesting. Many of them have expressed the opinion that normal saline is a specific. What I am inclined to believe is, that the ulcers have the natural tendency to take a turn towards recovery as soon as steps are taken to remove the offending discharge every day and to keep the ulcers clean.

I have been told that antimony in the form of urea stibamine, arsenic in the form of salvarsan, and local treatment of various sorts had been tried but there has not been any success.

Prevention.—Before any measure can be formulated one should take into consideration the various factors which contribute to the aetiology of this disease. As has been pointed out elsewhere and also by various other observers, cuts, abrasions and injuries constitute a large proportion of these cases; it is natural, therefore, that one should advocate that steps be taken to prevent this. One cannot recommend a change of occupation for the coolies, as their duties in the fields expose them to such cuts. Such action would mean that the largest industrial concern of Assam would have to be closed down. The only possible solution that one finds as a protection against cuts and injuries is to recommend the wearing of putties. Dr. Ramsay, with the help of the managers of the various gardens in Cachar comprising the estate, tried to introduce these among the coolies but met with opposition. If the system of wearing putties can be made compulsory throughout the tea districts in Assam, the gardens where cases of this disease are met with every year will certainly derive the greatest benefit; also it will materially reduce the number of traumatic ulcers. Intolerable itching of the legs from herbs, caterpillar stings, etc., will also be remedied. In those gardens where leech-bites are very frequently met with, this will give an additional protection.

The next point to discuss is what should be done when the coolies have already injured themselves. Dr. Ramsay* was the first to introduce the method of sealing up the wound with Friar's balsam as soon as a cut is detected. In his practice I have found the sirdars carrying pots

* My information is from Dr. Hugh Smith, but I am open to correction.

containing tincture of iodine and Friar's balsam.* The sirdars are really in charge of the supervision of the work of the coolies and remain with the latter as long as they work in the fields. The coolies report to the sirdars as soon as there is a cut and the latter will at once apply the medicines. Dr. Ramsay is positively certain that this has materially reduced the number of his cases.

I have no comments to make on this excellent method of preventing the organisms responsible for the causation of Naga sore from penetrating into the wound. If I am allowed to go a step further I would like to suggest (1) that the sirdars may be trained that injuries and wounds should be carefully cleaned, before they are touched up with iodine, as I have myself observed some of them dabbing the antiseptic on the mud on the wound; (2) that the wounds should then be protected from contamination with the specific organisms by some cotton-wool and bandage, as there is strong reason to believe that these organisms grow in the soil. Cannot the field inspector—Tilla Babu—be taught in first aid and his services be utilized?

There would not be, I am sure, any contrary opinion when I suggest that coolies having any cut or injury on their legs should be persuaded to stay in the hospital during the ulcer season. This might be looked upon as a very expensive affair but when one compares the number of injuries with that of the ulcers following them, one would not hesitate to act according to what I have said. My information from some of the sirdars is that a very large proportion of these injuries turn septic at the season and assume the characteristic appearance of the ulcer.

Thus in Rajghat, a garden in Sylhet, the average duration of absence from work in 1926 was about 41.4 days. If these people could be persuaded to stay in the hospital, probably it would have taken an average of three to four days for them to have been able to resume their work.

The best means by which they can be induced to stay in the hospital is by giving them a sum equivalent to their daily wages. In the case of a female, if the children cannot be made to go to work without the mother, they too should be likewise remunerated. Against this it has been argued that people with very slight injuries would seek admission. But obviously it would depend on the medical officer to choose his cases—whom to admit and whom not to admit in the hospital—and not on the opinion or wish of the patients.

Among those gardens I visited, I noticed in Cachar alone that there has been a growing tendency and eagerness among the patients to come and stay in the hospital. They bring with them their wives and children. All are given provisions every morning and are allowed to cook

their own food there. This, I think, is more expensive than the plan that I have advocated. In most of the tea gardens the ulcer cases attend the hospital every morning where they are dressed. It must be admitted that, apart from the question of pain, walking prevents the healing and retards the progress. Besides, these people when they are at home attend to their domestic duties as much as their condition permits. Rest is the principal part of the treatment and it is not likely that this can be carried out at any other place than the hospital.

CONCLUSION.

Whatever the nature of the invading organisms may be, one can safely assert from the facts, which have already been mentioned, that the contamination of the wound takes place from the soil, and it seems probable that certain soils are charged with the organisms much more than others.

I would here like to mention a case which I was able to follow from the beginning to the end. The man hurt himself below the ankle with a bamboo splinter. The wound was at once cleaned and dressed with tincture of iodine and bandaged up. In spite of the change of his dressings, daily an ulcer formed, slough appeared on the third day and the ulcer began to spread rapidly for five or six days, when it assumed the typical characters. The diameter then was an inch and a half and its depth as far as the deep fascia. The ulcer was kept covered all along and I am positively certain that no fly ever sat on it. The man walked about bare-footed and his dressings used to get soaked with muddy water. When this ulcer had almost healed up he hurt his other foot in the same way at the front of the ankle. Within a minute the injury was dressed as before. Notwithstanding this, the ulcer spread as before and after a week it occupied almost the front of his ankle. As it was kept constantly covered with dressings, flies never got the chance to settle on this either. But, as I have mentioned before, he had to walk about in mud as we were experiencing heavy showers. It is very likely that these injuries got contaminated with the specific organisms from the soil, which turned them into characteristic ulcers.

Whether soil is the only source of infection, I am not prepared to say. Dr. S. Datta, F.R.C.S., Surgeon, Carmichael Medical College Hospital, mentioned to me a few cases in coolies he came across in the out-patients' department of that hospital during the rainy season, where he found a phagedenic condition of the ulcers, which occurred chiefly on the legs, as a result of some injuries met with while working in coal. Smears were examined and spirochaetes were found. The patient with the ulcer on his leg, whom I had the privilege of examining in the Campbell Hospital through the courtesy of Dr. Chakravarti and whom I have already referred to, is also a coolie who works in coal in a ship.

The recurrence of the widespread epidemic in Assam every 3, 4 or 5 years can be accounted

* The attention of the writer has been drawn by Dr. Strickland to a letter written to him by Dr. Hugh Smith of Sylhet stating that he has also been practising the method of treating wounds, as soon after the injury as possible, with iodine and tinct. benzoin co.

for in the following way:—It is only when the temperature, humidity and rainfall reach the optimum for the growth of these organisms in the soil almost all over the place that this widespread epidemic is seen.

I have already mentioned the results of the experimental observations showing how far the eye-flies, *Siphonella*, can be incriminated in the spread of the disease; the results were almost entirely negative.

Regarding the nature of the invading organisms, it seems not at all improbable that these spirochaetes and fusiform bacilli, which so long have been looked upon as being responsible for these ulcers, are merely saprophytes, the nidus of the sore forming a good medium for them to grow upon. If this view can be accepted, then it is certain that we have not yet been able to arrive at the cause. I have mentioned the constant presence of some intracellular diplococci in these ulcers, but further work is necessary before the two can be logically connected with each other.

ACKNOWLEDGMENTS.

In publishing this report I wish to express my thanks to Dr. Hugh Smith, M.B., B.S., Medical Officer, Balliserra Valley and to Dr. G. C. Ramsay, M.D., O.B.E., Medical Officer-in-charge, Labac Central Hospital, Cachar, without whose valuable assistance I would never have been able to proceed with the enquiry.

I am specially indebted to Dr. C. Strickland, Professor of Medical Entomology, and to Lt.-Col. H. W. Acton, Director and Professor of Pathology and Bacteriology in this Institution, for the valuable help offered by these officers. It was Dr. Strickland who made all arrangements for me to undertake this enquiry.

The Indian staff of the Medical Department in Sylhet and in Cachar and the managers and their assistants in various gardens I visited helped me in every possible way they could and deserve my best thanks.

A CRITICAL EXAMINATION OF THE ANTIMONY TESTS FOR KALA-AZAR.

By L. EVERARD NAPIER, M.R.C.S., L.R.C.P. (Lond.),
 (Officiating Director, Kala-Azar Commission,
 Indian Research Fund Association).

LIEUT-COL. R. N. CHOPRA and his co-workers have during the last year communicated three papers on the subject of the antimony test for kala-azar (Chopra, Gupta and David, 1927; Chopra, Gupta and Basu, 1927, 1927a). A fourth paper which was to have been read had time permitted at the F. E. A. T. M. Congress last year will doubtless be published with the

proceedings of this congress within a year or so. The first is a preliminary paper recording the observation of the reaction on which the test is dependent and suggesting that it might be used as a diagnostic method in kala-azar. In the second paper the writers give their further experience with the test and compare it as a test for kala-azar with the aldehyde test. In this paper they also describe a simple test for kala-azar in which one or two drops of blood are received into a small tube containing 2 per cent. potassium oxalate and then tested with 4 per cent. urea-stibamine solution in the ordinary way. The antimony test was done in 70 cases of kala-azar; all the results are reported as positive. Some, but by no means all, of these were proven cases of kala-azar. However, of the six cases in which the aldehyde reaction was negative and the antimony test positive, five had been definitely diagnosed by the finding of the parasite. The test was also tried in certain other conditions such as leprosy. Dr. Muir has investigated the aldehyde reaction in leprosy; he found that in a small percentage of cases the serum showed a certain degree of opacity, but he concluded by saying "the question of differential diagnosis between leprosy and kala-azar is not likely to arise." The serum of the most advanced case of leprosy seldom shows the complete opacity, even after standing for 24 hours; there is almost always some opalescence visible. Dr. Avari in Bombay and Dr. Muir in Calcutta have sent the present writer some of their "most positive" results and only on one or two occasions has he observed the completely opaque white-of-egg reaction. Even doubtful reactions occur only in clinically advanced cases of leprosy, so that, except that it makes it impossible by this test to diagnose concomitant kala-azar in a patient suffering from an advanced degree of leprosy, this is not a practical disadvantage of the aldehyde test. The fact that such a large number of positive results were obtained in so small a series of cases suggests that, in addition to the cases being selected ones, Col. Chopra did not adopt such a rigid standard for the positive reaction in reading the results of the aldehyde test as that laid down by the present writer. There is, however, no doubt that the antimony test gives a greater percentage of definitely negative reactions in leprosy than does the aldehyde test.

In the third paper these writers summarised their observations with the test over a period of some eight months, both in kala-azar and in other conditions. They reported having done the test in 256 cases of kala-azar; they only mention 34 of these as having been definite cases of kala-azar in which the diagnosis was made by finding the parasite. The diagnosis was, in the large majority of instances, made on clinical evidence combined with that of the serum tests, and was, therefore, in a number of instances actually dependent on the antimony test itself. During the period when these figures

were collected, Dr. C. R. Das Gupta, the clinical assistant to the present writer—who was at that time on leave—performed 46 spleen punctures on cases in which the antimony test was positive and the aldehyde test doubtful or negative; of these, 17 showed leishmania and 29 no leishmania in the smears. Experience has shown that the presence of the parasites can be demonstrated by the first spleen puncture in about 95 per cent. of cases of kala-azar, so that of the cases in which no parasites were found it seems certain that at least 26 were not, although clinically very like, cases of kala-azar.

The ætiology of the disease in these non-leishmanial cases with enlarged spleens is a distinct problem. As they are encountered in a kala-azar endemic area, Col. Chopra has suggested that perhaps they are really cases of kala-azar in which the parasites have died out or are very scanty.

The present writer (Napier, 1927a) has suggested that one of the sequelæ of kala-azar is a condition in which there is marked enlargement of the spleen, loss of weight, leucopœnia, and occasional bouts of low irregular fever; the aldehyde reaction is doubtful—there is sometimes a considerable degree of opacity, although not complete opacity—but parasites cannot be found even on repeated spleen puncture, or demonstrated by cultural methods. The 29 cases referred to above, in which no parasites were found, probably included some of the cases of this group; others were undoubtedly cases of chronic malaria.

Whatever the ætiology of these cases may be, the practical point is that they do not show the very slightest improvement on being treated by antimony in any form whatsoever, and it is essential that they should be differentiated from true, treatable cases of kala-azar.

Col. Chopra and his co-workers did not include these cases in the table in this paper because of the uncertainty about their ætiology and because they were not satisfied that they were not cases of kala-azar *sine* leishmania.

The aldehyde test in the diagnosis of kala-azar.—About 85 per cent. of the kala-azar patients who attend the out-patient department of the Calcutta School of Tropical Medicine give a definitely positive aldehyde reaction; as we know from performing spleen puncture in some thousands of such cases over a period of a number of years that very seldom does a patient not suffering from kala-azar give a definitely positive reaction, these patients are put on treatment with the feeling of certainty that at least 99 per cent. of them are cases of kala-azar.

On the other hand, it is usually possible to exclude a certain number of patients as being definitely not cases of kala-azar. The aldehyde reaction appears to become definitely positive about the 5th month of the disease in most cases. As histories are notoriously unreliable, we take the size of the spleen

as an indication of the length of duration of the disease. When the spleen is 4 inches below the costal arch the aldehyde reaction should be definitely positive; therefore, allowing a margin, we assume that all patients whose spleens are 6 inches or more below the costal margin and whose aldehyde reaction is not definitely positive are *not* cases of kala-azar, and again experience has shown that very rarely is this assumption wrong.

It will be seen that by means of the aldehyde test a definite diagnosis can be made in the majority of cases of kala-azar (of the class seen in the out-door department of this institution), and that in a percentage of cases of other diseases clinically simulating kala-azar, a definitely negative diagnosis can also be made. There still remains a group of cases in which other diagnostic methods must be applied.

By applying this rule to these 46 "doubtful" cases in which a spleen puncture was done, referred to above, 8 could have been excluded as being definitely not cases of kala-azar, as the spleen was 6 inches or more below the costal margin; in none of these were parasites demonstrated.

It is thus seen that, whereas the antimony test failed to differentiate this doubtful group—in 60 per cent. of which the parasite was not demonstrated—from the true kala-azar cases, by means of the aldehyde reaction, not only were these cases selected for further investigation, but a certain number of them could be weeded out as definitely *not* cases of kala-azar.

There is no doubt whatsoever that a positive result is obtainable at a much earlier stage in the disease with the antimony test than with the aldehyde test, nevertheless the former test does not always give a positive or even doubtful result during the first few weeks of the clinical manifestations of the disease.

Col. Chopra and his co-workers lay emphasis on the fact that the reaction occurs constantly after the 15th day of the disease. The fixing of the day of onset is very difficult, as patients obviously in an advanced stage of the disease often state that they have only been ill for a few days; it is therefore advisable, as already suggested, to take the degree of splenic enlargement also as an indication of the duration of the disease.

The dilution method.—After Col. Chopra made the original observation that the serum of kala-azar patients was precipitated by certain solutions of the pentavalent compounds of antimony, the present writer worked out a technique for applying this phenomenon to the diagnosis of kala-azar; recognising the fact that when the strong (4 per cent.) solution of antimony was added to undiluted serum a positive reaction was liable to occur in conditions other than kala-azar, he suggested the use of weaker solutions of the antimony preparations. He applied this test to

some 60 sera of which 44 were from cases of kala-azar diagnosed by spleen puncture and was able to show that the results compared quite favourably with those of the aldehyde reaction.

Col. Chopra also recognised the danger of these "false positive" results in the antimony test and introduced the dilution method in which the serum is diluted 8 to 10 times with distilled water and then tested in the ordinary way with 4 per cent. antimony solution.

The present series.—There has been a certain amount of misunderstanding about this test, mainly because many of the persons who have used it have neither followed Col. Chopra's technique carefully enough nor realised sufficiently the limitations of the test.

On his return from leave, the present writer felt that some of these misunderstandings might be cleared up if he examined the blood of a series of cases, using Col. Chopra's three methods and the aldehyde test, and confirmed the diagnosis in as many cases as possible by spleen puncture. The antimony test, the dilution modification and the aldehyde test were performed by the present writer, but in every instance the results of the two former tests were read by Col. Chopra, Dr. Gupta or Dr. Basu, usually the first-named, and their readings only are used in this paper. The tests were carried out over a period of about five months, from December to May; the patients were seen in the kala-azar out-patient department of the Calcutta School of Tropical Medicine and many of them were subsequently admitted to the Carmichael Hospital for Tropical Diseases for treatment. Spleen puncture was performed as a routine measure in the hospital if parasites were not previously found in the peripheral blood, but in the out-patient department only in those cases in which there was any real doubt about the diagnosis. Thus, if both aldehyde and antimony tests were strongly positive, or if on the other hand they were both negative and there was no clinical reason to suspect kala-azar, a puncture was not usually done. Another group of patients in which a puncture was not done consisted of those who did not attend a second time. So that out of a total of about 400 patients who attended the department a puncture was done in only 165 cases. In 98 instances in which the antimony and aldehyde tests were both strongly positive, a puncture was not done; these were almost certainly all cases of kala-azar.

In more than half the cases a culture was also done at the same time and in only two instances was the culture "positive" when a direct examination of the smears was "negative." This confirms previous observations that in at least 95 per cent. of cases of kala-azar the first spleen puncture smear shows the presence of leishmania.

Tables I and II show the results of the aldehyde and two antimony tests in the 165 cases in which a definite diagnosis was made.

The aldehyde test.—The technique used for this test is that suggested originally by the present writer (Napier, 1922); 1 cubic centimetre of serum is placed in a small test-tube (4 inches \times $\frac{1}{2}$ inch) and a drop of commercial formalin is added. The readings are taken as follows:—

Positive results.—The serum becomes solid and completely opaque within 20 minutes = +++.

The serum becomes solid and completely opaque within 2 hours = ++.

The serum becomes solid and completely opaque within 24 hours = +.

Doubtful results.—The serum becomes solid and markedly opalescent but not completely opaque within 24 hours = (+).

The serum becomes solid and slightly opalescent within 24 hours = ±.

Negative results.—The serum solidifies but remains clear = (-).

The serum remains fluid and clear = -ive.

Results in this series.—The test was positive in 57 cases; of these 55 were shown to be cases of

TOTALS ..		65	..	65	65	

kala-azar and one of the two cases in which parasites were not found had received a certain amount of treatment. So that for all practical purposes one can conclude that in an untreated patient a positive reaction indicates kala-azar.

In 74 instances the result was doubtful; of these 37, that is just half, were cases of kala-azar.

In 33 instances the result was negative; of these 7, that is 21 per cent., were cases of kala-azar.

Now it has never been claimed for the aldehyde reaction that it could be used for making a "negative" diagnosis, except in a few instances of marked splenic enlargement, as there are other methods available. The main merit of the aldehyde test is that by applying it a very large number of kala-azar cases can safely be selected for treatment without further investigation.

If, however, it is desirable to reduce the number of doubtful cases still further, this can be done at the risk of making a small percentage of wrong diagnoses. For this purpose the length of duration of the disease and the degree of splenic enlargement must be taken into consideration. In the following table, the cases have been grouped according to their splenic enlargement.

It will be seen that in group "A" (spleens less than 3 inches) a negative result is of little value—of the 16 cases in which it occurred, 6 were cases of kala-azar—but in the other two groups out of 17 negative results, only one was in a case eventually diagnosed as kala-azar. In the first two groups a "doubtful" diagnosis gives little indication of the nature of the case, but in group "C" (6 inches or more) it suggests that the case is probably *not* one of kala-azar—in only 4 cases out of 20 was the parasite found. Thus a "negative" diagnosis can be made by means of the aldehyde test in an additional 37 cases with an error of 5. Or applying the rule to the corresponding groups in Table IV (duration of disease), a "negative" diagnosis can be made in an additional 35 cases with an error of 4.

By classing "negatives" in group "A" as doubtful, and "doubtfuls" in group "C" as negative, the diagnostic results summarised in the two following tables are obtained:—

TABLE III(a).

	Agree with pro- tozoological find- ings, i.e., correct.	Disagree, i.e., prob- ably incorrect.	Doubtful.

6 inches or more ..	34	5	0
TOTALS ..	87*	7	70

* These figures can be accepted for purposes of comparison with the antimony test, but they do not show up the aldehyde test in the best light, i.e., as stated above, more than half the cases in this series were selected *because* the aldehyde reaction was doubtful. The cases in this series in which there is a positive aldehyde reaction are those in which parasites were found in the peripheral blood or in which the patient was admitted to hospital. Amongst the out-patient population we diagnose more than 80 per cent. by means of the aldehyde test alone.

TOTALS ..	84	6	71

The antimony test.—The technique used in this test is that suggested by Chopra and his co-workers. Separated serum is placed in a fine glass tube, about 0.5 c.cm. calibre, sealed at one end; this is placed in a small rack, or more conveniently stuck in a tray of plasticine, and 4 per cent. urea-stibamine is added slowly by means of a Wright's pipette. The solution should not be added too slowly as a certain amount of mixing at the junction of the fluids is desirable; on the other hand, they should not be intimately mixed. The sera are grouped as follows:—

"(1) *Strongly positive sera* (+++). The precipitate here forms immediately and is thick and flocculent. The precipitate conglomerates into a thick mass, generally at the junction of the serum and antimony solution and is difficult to break by shaking the tube. The precipitate is insoluble and will not dissolve if the tube is kept for 24 hours or longer.

"(2) *Positive sera* (++ or +). In this class are included those sera in which a definite flocculent precipitate forms, but the precipitate is not so thick as in the first group..... In this class the precipitate is obviously flocculent..... The precipitate has the same tendency to collect together into a mass at the junction of the two fluids, though the mass is not so thick. The precipitate sometimes settles at the bottom of the tube and is quite insoluble after 24 hours.....

"(3) *Doubtful sera* (±). Under this category come the sera in which definite precipitate, or in some cases varying degrees of haziness, appears at the junction of the two fluids. The precipitate or haziness, however, has not a flocculent character. If the tubes are allowed to stand for a few hours sometimes the precipitate entirely dissolves. In other cases the precipitate still remains, even after 24 hours.

"(4) *Totally negative sera* (—). In this group are included those sera in which no precipitate whatever is formed and there is not even the slightest haziness at the junction of the two fluids."

For the sake of convenience in most of the tables only two groups of positive results are given, namely, strong positive +++, and weak positive or +, the ++ readings being included in the latter group.

The brand of urea-stibamine used in the first few tests was Stiburea of the Union Drug Co., but later, as Col. Chopra was of the opinion that it gave more consistent results, Urea-stibamine (Brahmachari) was used as well, the tests being done in duplicate in most instances. A glance at Table V will show that there is little to choose between the two preparations; the latter gives a slightly higher percentage of positive readings in both groups of cases, but the results are not more specific.

We have used for this analysis the Urea-stibamine (Brahmachari) results, except in the few instances in which Stiburea only was used; that is to say, the results analysed are the sum of columns 2 and 7 in Table V. These results are summarised in Table VI.

TABLE VI.

Summary of antimony test results.

The result was negative in 20 cases, of which 4 were cases of kala-azar.

Summing these results we find that by this test a correct diagnosis was made in 103 or 62.8 per cent. cases, a doubtful one in 22 or 13.4 per cent., and an incorrect diagnosis in 39 or 23.8 per cent. cases.

These figures and percentages are based on the assumption that one spleen puncture reveals the presence of parasites in every case of kala-azar in which it is performed. Now this is not so. As we have stated above, it is positive in only about 95 per cent. of cases, so that, had no culture been done in any instance, we should have to allow for the addition of another 5 cases of kala-azar in which the first spleen puncture was negative; as, however, a culture was done in about half the cases, an allowance of three for the imperfection of spleen puncture as a diagnostic measure will be ample. This will mean an addition of three to the correct results and a deduction of three from the incorrect results, making the final results:—

Correct diagnosis in 106 or 64.6 per cent. cases.

Incorrect diagnosis in 36 or 21.9 per cent. cases.

Doubtful diagnosis in 22 or 13.4 per cent. cases.

The unsatisfactory point about this table is the very large number of incorrect diagnoses. A diagnostic method which gives one misleading

result for every three correct ones, in a disease in which more exact methods are available, does not at first sight appear to be of much practical value.

If, however, the size of the spleen and the length of duration of the disease be taken into consideration by excluding certain groups of cases the number of incorrect diagnoses can be considerably reduced, although, of course, this procedure will effect a reduction in the number of correct diagnoses also. In the Table VII the cases are grouped according to the splenic enlargement.

The first thing that is obvious when this table is examined is that the standards for "positivity" must be adjusted; only "strongly positive" reactions should be considered as indicating kala-azar, "weak positives," indicated by +, should be classed as doubtful. This will reduce the number of positive reactions to 53, of which 43 were in proved cases of kala-azar. Further, by excluding all cases of group "C" (in which the spleen is 6 inches or more below the costal margin) the positive results are reduced to 33, of which 30 are definitely proven cases of kala-azar.

From the point of view of making a negative diagnosis, if group "A" cases (in which the spleen is less than 3 inches below the costal margin) be excluded and both ± and — results be considered as "negative," then a negative diagnosis can be made in 18 cases with an error of only 1. Thus we have:—

TABLE VII(a).

	Agree with protozoological findings, i.e., correct.	Disagree, i.e., probably incorrect.	Doubtful.
Group "A" less than 3 inches	7	0	32
" " "B" 3 inches to 6 inches	28	3	36
" " "C" 6 inches or more	12	1	45
TOTALS ..	47	4	113

In the following table the cases are grouped according to the length of duration of the disease.

If only "strongly positive" reactions are considered as indicating kala-azar and all cases of group "C" (in which the disease has lasted for a year or more) are excluded, there are 31 "positive" results with 6 errors. And if for the negative diagnosis ± and — results in groups "B" and "C" only be taken, there are 26 "negative" results with 5 errors.

TABLE VIII.

Antimony test results and duration of disease.

Group.	Reading.	Leishmania present.	Leishmania not present.	Total.
"A" History of duration of 3 months or less.	+++ ++ or + ± —	8 20 3 4	1 3 5 4	9 23 8 8
"B" History of duration of more than 3 months but less than 1 year.	+++ ++ or + ± —	17 16 4 0	5 13 6 7	22 29 10 7
"C" History of duration of 1 year or more.	+++ ++ or + ± —	16 8 1 0	4 8 3 5	20 16 4 5
TOTALS	97	64	161

Antimony test not done .. 1
Duration not noted .. 3

Thus we have:—

TABLE VIII(a).

	Agree with protozoological findings, i.e., correct.	Disagree, i.e., probably incorrect.	Doubtful.
Group "A" 3 months or less.	8	1	39
Group "B" more than 3 months, but less than 1 year.	30	9	29
Group "C" 1 year or more	8	1	36
TOTALS ..	46	11	104

It is obvious that much more satisfactory results are obtainable by taking into consideration the splenic enlargement rather than the duration of the disease according to the statement of the patient.

The dilution method.—The technique for this test is exactly the same as for the original test, except that dilute serum is used. The serum is diluted with nine parts of distilled water; it is then placed in a small test-tube and the 4 per cent. urea-stibamine is added. Except in the first 29 cases, the Brahmachari brand was used. The results are read as follows:—

A heavy flocculent precipitate = +++ or strongly positive.

A fine flocculent precipitate = + or positive.

A homogeneous cloud without flocculi = ± or doubtful.

No change in the mixture = — or negative.

The readings are shown in Table IX.

TABLE IX.

Summary of dilution method results.

Result.	Reading.	Leishmania present.	Leishmania not present.
Positive ..	+++ + ± —	31 37 68 13 18 1	5 14 19 10 36
Doubtful ..			
Negative ..			
Not done ..			
TOTALS	100	65

The test was "positive" in 87 cases; of these 68 were cases of kala-azar and in 19 the parasite was not demonstrated. It was doubtful in 23 cases, of which 13 were cases of kala-azar and 10 probably not. And it was negative in 54 cases, of which 18 were cases of kala-azar.

Summing these results we see that by this test a correct diagnosis was made in 104 cases or 63.4 per cent., an incorrect diagnosis in 37 cases or 22.6 per cent., and a doubtful one in 23 cases or 14.0 per cent.

Here again the number of incorrect diagnoses is much too great for the test, in this form, to be of any practical value.

In Table X the results are grouped according to splenic enlargement.

TABLE X.

Dilution method results and splenic enlargement.

Group.	Reading.	Leishmania present.	Leishmania not present.	Total.
"A" Spleen less than 3 inches below costal margin.	+++ ++ ± —	6 12 7 11	0 4 5 14	6 16 12 25

TOTALS	99	65	164

Test not done

.. 1

Again it is obvious that only +++, i.e., "strongly positive," reactions must be considered as indicating kala-azar and that in group "C" all positive reactions must be ignored. This will mean that a positive diagnosis is made in 22 cases with an error of only 1. A "negative" diagnosis can be made only in group "C" where ± or — reactions may be looked upon as negative results; under these conditions, 11 diagnoses would be made with a single error. Summing these results we have:—

TABLE X(a).

	Agree with protozoological findings, i.e., correct.	Disagree, i.e., probably incorrect.	Doubtful.
Group "A" less than 3 inches.	6	0	53
Group "B" 3 inches less than 6 inches.	15	1	50
Group "C" 6 inches or more.	10	1	28
TOTALS ..	31	2	131

Thus by this method the degree of accuracy in diagnosis is very satisfactory, although the number of cases in which a diagnosis can be made is low. Actually the results of this test are more satisfactory than the figures indicate, as Col. Chopra and his colleagues did not always distinguish between "positive" and "strongly positive" reactions, and wrote the word "positive" or the sign + when the reaction was really very marked indeed. The necessity of distinguishing between these two types of reaction is quite evident if Table X be perused.

In Table XI the results are arranged according to the history of the duration of the disease. Satisfactory results cannot be obtained by applying the same rule to the figures in this table.

The Blood Test.—The technique of this test devised by Chopra, Gupta and Basu (1927) is as follows:—

"All that is required are a 2 per cent. solution of potassium oxalate, a 4 per cent. solution of a urea-antimony salt such as urea-stibamine, two small test-tubes and a few Dreyer's tubes, which simply consist of 2-inch pieces of glass tubing 3 to 4 mm. in diameter sealed at one end. . . . One or two drops of blood obtained from a finger pricked with a needle are allowed to mix well with about 0.25 c.c. of a 2 per cent. solution of potassium oxalate.

A little of this solution is transferred into a Dreyer's tube and a 4 per cent. solution of the antimony compound is added by means of a capillary pipette along the side of the tube. The heavy antimony solution sinks to the bottom, and in cases of kala-azar a flocculent precipitate

forms almost immediately at the junction of the two fluids. This precipitate soon settles down at the bottom of the tube with the red corpuscles entangled in it."

TABLE XI.

Test not done .. 1
Duration not noted .. 3

The blood was taken in the out-patient department and dropped into oxalate solution; this mixture was then handed over to Col. Chopra's department where the tests were performed. At first the blood was dropped from the syringe but later, as the results were unsatisfactory, at Col. Chopra's suggestion the blood was taken from the finger. Two different sets of figures are given. The test was only done in 104 cases in which the spleen puncture had been done, so in addition a series "probable cases of kala-azar" are included; these are cases in which both the aldehyde reaction and the antimony test are definitely positive, and were almost certainly cases of kala-azar.

Table XII gives the results of these tests.

Thus, out of 45 patients who were almost certainly not suffering from kala-azar 27 gave a "positive" blood test, and of the 8 patients who gave a "negative" blood test 4 were certainly cases of kala-azar, whilst a fifth was also probably suffering from this disease.

It is apparent that whichever method is used, the results of the blood test are entirely unsatisfactory.

It is only fair to state that although the above-mentioned writers suggested this test, they did not make any claims as to its specificity.

Diagnostic value of combined results.—Col. Chopra has pointed out that the two tests,

SUMMARY.

Probably correct diagnosis	=	88	or	50.9 %
Probably wrong diagnosis	=	32	or	18.5 %
Doubtful diagnosis	=	53	or	30.6 %
TOTAL ..		173		

i.e., the antimony test and the dilution method, should not be considered separately, but that a diagnosis should be made on the combined results of the two tests. It will be necessary, in order to eliminate the large number of incorrect results which would be obtained if a positive result were taken as indicating kala-azar, to take the patient's condition into consideration and to adjust the standards of positivity as has been done in the separate reading of the tests. The most satisfactory division of the patients is, as has been shown above, according to the size of the spleen. The following rules for making a positive and a negative diagnosis, respectively, are suggested.

Positive diagnosis.—All cases of groups A and B in which the result of the antimony test is +++, and of the rest any case in any group in which the dilution method is +++.

Negative diagnosis.—All cases of groups B and C in which the result of the antimony test is doubtful or negative, i.e., ± or —, and of the remainder in group C any case in which the result of the dilution method is ± or —.

By applying these rule the following results are obtained:—

	Total.	Agree.	Disagree.
Positive diagnosis ..	57	50	7
Negative diagnosis ..	23	21	2
Doubtful ..	85
Total ..	165	71	9

SUMMARY AND CONCLUSIONS.

THE ANTIMONY TEST.

The antimony test is a much more delicate test than the aldehyde test, that is to say it is positive at a much earlier date in the disease, but it is not positive in every case of kala-azar; in this series the test was entirely negative in 4 instances and "doubtful" in 8 others.

The changes occurring in the serum of a kala-azar patient, which are indicated by a positive antimony test result, also occur to a less extent in the serum of patients suffering from certain other diseases, such as chronic malaria and certain other conditions of splenic enlargement, phthisis and leprosy, therefore this delicacy of the reaction is a distinct disadvantage; in 35 instances in this series the result of the test was positive in cases in which the parasite was not demonstrated by spleen puncture.

For the test to be made one of clinical value, it is essential that the standards of "positivity" should be readjusted and that the condition of the patient should be taken into consideration; for this purpose the following rule is suggested:—

A positive diagnosis.—This should be made only in cases in which the spleen is less than 6 inches below the costal margin and in which there is a strongly positive reaction, that is to say, a reaction in which a solid plug of coagulum forms at the junction of the two fluids, which plug is not moved when the tube is tilted and is dislodged only by violent agitation.

A negative diagnosis.—This should only be made by means of this test in cases in which the spleen is 3 inches or more below the costal margin and in which the serum remains quite clear or becomes cloudy but without showing definite flocculation.

THE DILUTION METHOD.

This test is much less sensitive; in this series in 18 cases of kala-azar it was entirely negative and in 13 others it was doubtful.

This lack of sensitiveness is the distinct advantage in that the test is less frequently positive in conditions other than kala-azar; in this series it was strongly positive only in 5 cases in which the parasite was not demonstrated by spleen puncture.

Again, in the case of this test it is necessary to readjust standards and to take the condition of the patient into consideration; for this purpose the following rule is suggested:—

A positive diagnosis.—This should be made only in cases in which the spleen is less than 6 inches below the costal margin, and in which there is a strongly positive reaction, that is to say, in which a heavy flocculent precipitate forms.

A negative diagnosis.—If the spleen is 6 inches or more below the costal margin and the reaction is negative or doubtful, that is, one in which there is no definite flocculation.

THE DOUBLE TEST.

By means of either of these tests, although the error is small, in only a small percentage of cases can a definite diagnosis be made, but by doing both tests and taking both readings into consideration, as well as the size of the patient's spleen, a diagnosis can be made in a much larger number of cases with only a slight increase in the possible error. The following rule is suggested:—

A positive diagnosis.—This should be made when the antimony test is strongly positive in cases in which the spleen is less than 6 inches below the costal margin, or in any case in which the dilution method gives a strongly positive reaction.

A negative diagnosis.—This should be made when the antimony test is negative or doubtful in any case in which the spleen is 3 inches or more below the costal margin, or when the dilution method gives a negative or doubtful reaction in any case in which the spleen is 6 inches or more below the costal margin.

The blood test.—The results obtained here indicate that the test is of no value as a diagnostic method in kala-azar.

My thanks are due to Col. Chopra and his colleagues for their whole-hearted co-operation throughout this investigation, and also to my assistant Dr. C. R. Das Gupta.

MALARIA AS A CAUSE OF CATARACT.

By E. W. O'G. KIRWAN, F.R.C.S.I.,

MAJOR, I.M.S.,
Officiating Professor of Ophthalmology,
Medical College, Calcutta.

ONE would expect in a country like India, where malaria is so prevalent, that cases of cataract with malaria as a causation would be common. In looking up as far back as 1919 the ophthalmological literature of the ocular complications of malaria, I am unable to find any case of cataract with malaria as a cause.

Conditions ascribed to malaria and due to the intense sun, dust, heat and general diseases are

as common in tropical regions where malaria infection is not usual as where malaria is rife.

Elliott in his book "Tropical Ophthalmology" discusses the ocular complications, but no mention is made of malaria as a cause.

Among 12,000 cases of malaria, Manson found that after practically every attack a slight icteric tinge of the conjunctiva was visible in the lower retrotarsal fold and extending on to the bulbar conjunctiva. Of the sequelæ of malaria, dendritic ulceration of the cornea is most frequent, although it is not very common. It is never seen with the primary attack, but appears after from 20 to 50 paroxysms. Intra-ocular hæmorrhage he found very rare, only 2 cases among the 12,000. Both of these were of the malignant tertian type and in one of them both eyes were affected. He saw 3 cases of ocular motor nerve lesions after definite malarial attacks, in men previously healthy and free from syphilis.

Pereyra reports several cases of hæmorrhagic retinitis in malaria; this he states is a frequent complication, mainly in the quartan type and less frequently in the tertian. The hæmorrhages were caused by direct lesion of the retinal vessels by the malarial toxins, leading to an abnormal permeability and indirect lesion through thrombosis of the choroidal vessels.

Kiep in Macedonia during 1916—1918 found 10 cases of retinal and pre-retinal hæmorrhages, which he assumed were due to occlusion of the retinal capillaries by plasmodia.

During the epidemic in Omak in 1924, Adrianoff examined the eyes of 428 cases of malaria. In these cases were found peculiar silverwhite bands in the region of the macula along the blood vessels. In one case, there were opacities of the vitreous and remnants of pigment on the anterior capsule of the lens. Seven cases had dendritic keratitis, one neuralgia of the left trigeminal nerve, one severe plastic uveitis and one bilateral optic neuritis.

Most authors seem to agree that the most frequent lesion of malaria is *herpes corneæ* and that retinal hæmorrhages, either sub-hyaloid or flame-shaped, are common.

From a large clinical experience of darkroom work in India, I can say that there is no characteristic fundus condition which can be ascribed to malaria. Recently, I have come across the following three cases of cataract which appear to me to be due, undoubtedly, to malaria.

Case I.—Mrs. U. B. P., age 38 years, European.

History.—The patient has been residing in Bengal for a period, off and on, of 10 years. In 1922 she resided in a very malarious district and had many severe malarial attacks, lasting over a period of seven months. The attacks were resistant to quinine treatment by the mouth but were controlled by quinine injections. In March 1923, she first noticed that her vision had begun to fail and had very gradually become worse.

Physical Examination.—When seen by me in March 1928 the vision in the right eye was 6/18, in the left eye 6/24. Cornea normal, no keratic precipitates, pupils equal and regular, vitreous normal. The fundi showed no abnormality. Fields normal. With a dilated pupil the lens of both eyes showed well marked striæ

of the cart-wheel pattern, principally in the anterior cortical layer. There were also small opacities in the posterior cortical layer. The patient was in good health and not anæmic. The urine contained no albumen or sugar and there was no evidence of lues, no oral sepsis and no evidence of intestinal trouble. There was no family history of hereditary cataract. The patient complained of very bad headaches, especially after close work.

I saw her again six months later. The vision was still the same and the opacities in the lens had not increased. The patient was in good health and has had no further attacks of malaria.

Case II.—Mr. R. R. K., age 21 years, Indian.

History.—Dim vision in the right eye for one year. He is a resident of a very malarious district in Bengal and has a long history of attacks of malaria occurring for the last five years. The attacks yield to quinine treatment.

Physical Examination.—The patient is a well nourished man, not anæmic. His spleen is enlarged two inches below the costal margin. The urine contains no albumen or sugar, the teeth are good, the Wassermann reaction is negative. No evidence of intestinal disease. No history of trauma.

Vision in the right eye, finger movements only; vision in the left eye, 6/6. Right eye cornea normal. No keratitic precipitates. Pupil active and regular. The lens, mature cataract. Left eye, normal. The lens showed no opacities.

The patient was operated on on the 27th April, 1928, capsulotomy with button-hole iridectomy, and was discharged from the hospital on the 18th May, 1928, when the vision in the right eye corrected with glasses was 6/12. The fundus showed no abnormality.

The case is an interesting one as the cataract was a monocular juvenile one and the only causation can be ascribed to malaria. Juvenile cataract is not uncommon in Bengal and the greater number of cases are due to syphilis.

Case III.—Mrs. J. R. L., age 45 years, European.

History.—The patient has been residing in Orissa, India, for a period, off and on, of 12 years. During this time, she has lived in a malarious district and has suffered from many attacks of malaria. She states that every year she suffers from malaria and has been accustomed to take large doses of quinine. Since 1925, her vision has begun to fail in both eyes and has gradually become worse.

Physical Examination.—When seen by me in November 1927 the vision in the right eye was 6/12, in the left eye 6/24. Cornea normal, no keratitic precipitates, pupils equal and regular. With a dilated pupil, the lens of both eyes showed peripheral striae. There was a large central opacity in the left lens with a less marked central opacity in the right lens. The opacities were principally in the anterior cortical layer and there were smaller opacities in the posterior cortical layer. The fundi showed no abnormality. The patient was again seen by me in September 1928. She stated that she was still suffering from attacks of malaria which were controlled by quinine. The spleen was enlarged and palpable. The vision in the right eye was 6/9; left eye, 1/60. The cataract in the left eye was mature and the patient was advised operation. Her general condition was good and she was not anæmic. The urine contained no albumen or sugar, there was no evidence of lues, no oral sepsis and no history of intestinal trouble. No family history of hereditary cataract.

REMARKS ON THE OPERABILITY AND OPERATIVE TECHNIQUE OF VESICO-VAGINAL FISTULA.*

By KEDARNATH DAS, C.I.E., M.D.,

Calcutta.

At the Seventh Congress of the Far Eastern Association of Tropical Medicine held in

*Read at the September Meeting of the Calcutta Branch of the British Medical Association.

Calcutta in December 1927, Miss Scudder of Vellore, Madras, initiated a discussion on vesico-vaginal fistula and stated, as far as I remember, that she obtains about 80 per cent. recoveries after operations. I remarked at the meeting, that my impression was that it was not possible to get such results in Calcutta, from the type of case we get here.

In 1908, I reported a case of Cæsarean hysterectomy on a patient with an irreparable vesicovaginal fistula before the obstetric section of the Royal Society of Medicine.

At the discussion which followed, the President, Dr. Herbert Spencer thought that in the case reported by me "the vesicovaginal fistula should have been operated on and would have been cured by the author, who had successfully closed the rectovaginal fistula, the operation for which was not so successful as that for vesicovaginal fistula, which he thought could always be cured." Dr. Amand Routh "thought that the only way that Dr. Das could have cured the vesicovaginal fistula would have been to dissect off the bladder from its connections and draw it down into the vagina as an empty sac."

The above remarks led me to analyse the cases that have come under my observation up-to-date with a view to determine the feasibility of successfully closing these fistulae in every case. The case which I reported was so remarkable that the following brief summary will interest you.

The patient came under my care in the Campbell Hospital in October 1906, with the following conditions:—"The whole base of the bladder has apparently sloughed away. There is a chink representing the os externum, at the upper margin of the rent. The posterior wall of the vagina is represented by a small band of cicatricial tissue. The perineum is deficient, but the sphincter ani is not torn. Above the intact sphincter, there is a rectovaginal fistula about 1½' long. To begin with, I performed an operation for the repair of the rectovaginal fistula, with complete success. The next step was to attempt the repair of the vesicovaginal fistula. This was found impossible owing to absence of any healthy tissue in the neighbouring area. I then decided to close the vagina, but owing to the absence of any healthy tissue around the vaginal outlet, extension of the perineum to the desirable extent was not possible. I then decided to dissect the urethra and to bring it down to the posterior margin of the extended perineum so that the meatus urinarius was brought down to a lower level and a deeper plane. The effect of the operation was that the extended perineum acted as a flap valve and helped to retain the urine in the cloaca for a certain time with the help of a very slight pressure on the parts with a pad.

The patient remained in the hospital for about six months, but was naturally losing patience and took her discharge. She, however, came back after a month with some of my work undone. It appears that she went to another hospital, where as the result of examination, the anterior portion of the extended perineum was torn. I extended the perineum again and she left hospital in an ameliorated condition.

I lost sight of her for about two years, after which period she came to the hospital with amenorrhœa of four months duration and a swelling in the lower abdomen and to my surprise, I found that she was pregnant. An examination of the vulva revealed that the skin round the small opening of the cloaca had radiating folds, like those round the anal orifice, giving the impression of some sphincteric action. A pad over

the vulva kept her dry for about an hour. She got herself readmitted some weeks before her expected delivery for Cæsarean hysterectomy which was performed on January 4th, 1907. The stump was treated extraperitoneally. She made an uninterrupted recovery."

I must mention that at the time I reported the above case, my experience was limited to 8 cases only, but subsequent experience has convinced me that every case of vesicovaginal fistula cannot be considered *operable*. Altogether 94 patients have been dealt with.

From a rough analysis of these 94 cases I find that no attempt to relieve them by any operation was made in 17 cases, the causes being 9 for bad health the result of malaria, 1 for cancer, 1 for cystitis, 2 for sloughing away of urethra with a portion of the neck of the bladder and extensive cicatrization about the vulva, and 4 refusal of operation, as no assurance could be given for their recovery.

Of the remaining 77 cases, I attempted to give relief in some way in 7 cases in which closure of the fistula was considered impossible, i.e., by colpocleisis in 5, by an attempt at formation of a urethra in 1, and by forming an artificial hypospadias in 1. A short account of the last case which is extraordinary will be given below.

It will thus be seen, that excluding the 4 cases which refused operation, an attempt to repair the fistula was made in 70 cases, with only 13 complete recoveries, 10 after the first, 1 after the second and 2 after the third operation; the remaining 20 were inoperable. It should be mentioned that of these cases 6 were complicated with rectovaginal fistula, all of which were operated on in the first instance and all of them were cured, but 4 of them left hospital without having the vesicovaginal fistula repaired.

I stated above that in 1908 my experience of these cases was limited to 8. Further experience of the last 20 years has, however, convinced me that the type of cases we get in Bengal, does not warrant the assumption that every case of vesicovaginal fistula is operable and should be cured. I am sure obstetricians in the British Isles can have no idea of the feeble, physically wrecked, malaria-stricken Bengali woman who presents herself for the relief of her miserable condition. In my series, 22 per cent. were inoperable, 19 per cent. were cured, while 59 per cent. were relieved.

I am afraid I have not been able to present a brilliant record. I can only say, I have tried my best, but could not achieve a better result. But at the same time, I should like to record the supreme satisfaction I felt at the look of gratitude and satisfaction of the 13 patients, when they were discharged from the hospital. I tell my students, that one successful operation for vesicovaginal fistula, counterbalances the glamour glory and "kudos" of one hundred Cæsarean sections.

In view of the expressed opinion of Dr. Herbert Spencer and Dr. Amand Routh, who believed

that every case of vesicovaginal fistula should be cured and the poor results obtained by me, I tried to obtain statistics from other hospitals in India.

The records of the Eden Hospital for the last 8 years show that during this period 95 patients were admitted with vesicovaginal fistula, of whom 78 were operated on and 28 were cured, showing that 18 per cent. were inoperable and 36 per cent. recovered. I am indebted to Lt.-Col. Green-Armytage for the above information.

The clinical reports of the Madras Maternity Hospital for 14 years show that out of a total of 503 cases, 188 recovered, a percentage of 37 per cent. This may be considered to be a fair average.

In comparison with the statistics of the Madras Maternity and the Eden Hospital, my results are decidedly poor, and the evident conclusion is that either the technique is faulty or that the surgeon lacks in skill. While I admit that I must be lacking in technical skill I should at the same time observe that usually cases rejected from the premier gynaecological hospital in Calcutta, viz. (the Eden), are admitted in the Campbell and the Carmichael.

To illustrate the utter impossibility of attempting to repair a vesicovaginal fistula, I will narrate the history of the following case:—A Brahmin girl about 15 was admitted to the Campbell Hospital as she had been refused admission in the Eden Hospital. The whole of the lower half of the bladder, with the anterior vaginal wall and the urethra were absent. The openings of the two ureters could be seen high up in the cloaca, with a small chink in the middle representing the os uteri. By separating the labia a little, the remains of the bladder could be seen moving up and down with respiration. There was no tissue behind the symphysis pubis. The only thing possible to ameliorate her condition was to transplant the ureters into the rectum, but I did not attempt it, as I had no experience of that operation. I then suggested to the girl that I could so arrange that the urine should dribble from the lower abdomen, instead of through the lower passages. She thought that she would be able to go about and do her household duties much better if that was done and consented to the operation. Accordingly, I separated the posterior portion of the remains of the bladder, with the ureters, opening the uterovesical pouch, dragged it forward and fixed the edges to a supra-pubic opening, making a sort of artificial hypospadias. She recovered and became satisfied with her new condition. I cannot imagine how, with the sloughing away of more than half the bladder and the entire urethra, we could successfully repair the fistula!

The operability depends not only on the local condition of the parts, but also on the general condition of the patient, including her blood condition. During the last 8 years I refrained from operating when I felt that the condition of the patient was such that it precluded the possibility of success. Bad general health and bad blood condition, conduce to oozing, which prevents union. With increased experience, I choose my patients for operation better and have improved my results. While at the Campbell Hospital, in a series of 53 cases, I refused to operate only in one case, and attempted to do something in the remaining 52. Of these only 6 were cured (11.5 per cent.). In the subsequent

series of 41 cases in the Carmichael, I operated on 18 only with 7 recoveries (39 per cent.).

Regarding the technique of an operation for the repair of a vesicovaginal fistula, special attention should be paid to the following details.

(1) Proper position of the patient. An exaggerated lithotomy position with the buttocks raised 8 inches above the horizontal plane.

(2) Proper anæsthesia—Chloroform.

(3) Labia well retracted with temporary silk sutures to the corresponding thigh.

(4) Thorough denudation, with avoidance of hæmorrhage as far as possible. For this purpose I have devised two special knives and a special forceps with 2 to 3 rat teeth. The forceps is provided with a stem with a milled-head screw; which is worked with the fore-finger of the right hand, so that the amount of pressure may be gauged without injury to the tissues, at the same time relieving the fatigue of the fingers inevitable in the operations (*see Figures*).

(5) Proper suture needles and suture material. I prefer the small and medium cleft-palate needles—right, left and rectangular. For suture material, I prefer fine silk-worm gut.

(6) In the after-care, I try, if possible, to avoid leaving a catheter in the bladder.

AN OPERATION FOR THE RADICAL CURE OF CONGENITAL OBLIQUE INGUINAL HERNIA IN CHILDREN.

By P. BANERJEE, F.R.F.P.S.G.,

MAJOR, I.M.S.,

Resident Surgeon, Medical College Hospital, Calcutta.

HERNIAS in children may be truly congenital, that is existing from birth or may be acquired, that is they may descend later into a patent vaginal process which existed from birth. But both forms are ordinarily termed congenital. Acquired hernia of the type in which the peritoneal sac is pushed down as a result of intra-abdominal pressure may be said to be unknown in the very young. From the average of the reports of various observers of the frequency with which the peritoneo-vaginal process remains patent, it appears that the vaginal process remains unobliterated in 59 per cent. of children during the first four months and in 44 per cent. even during the fifth month. In spite of the fact that the peritoneo-vaginal process remains open in such a large percentage of cases, hernia in a child from

birth is a rare occurrence. All such hernias are ordinarily divided into two kinds, (1) congenital hernia, (2) funicular hernia.

In the descent of the testis through the inguinal canal a fold of peritoneum moves before it. This process of peritoneum is divided into three sections in accordance with its position in relation to the testis. Its lowest portion, which lies in front of the gland itself covering it in front and on either side, is called the vaginal process, the portion of it above the testis and which more or less surrounds the cord, is called the funicular process and the uppermost portion of it which lines the inguinal canal is known as the inguinal process. It is possible for the entire peritoneal canal to remain open and abdominal viscera to be pushed into it. In such an event the viscus lies above and in front of the cord whereas in the scrotum it lies to the outer side and somewhat behind the testis. This form of hernia is known as "congenital hernia." Such a sac shows three fairly marked constrictions at the points where the passage of the sac from the abdomen into the scrotum narrows it down, namely (1) at the internal abdominal ring, (2) at the external abdominal ring, and (3) at the neck of the scrotum.

When the peritoneal canal is closed only just above the testis and epididymis, remaining open in the upper part, a hernia may descend into the upper portion forming what is known as "hernia of the funicular process." In such a case the hernia may later descend to the bottom of the scrotum and it is then difficult to distinguish it from the ordinary congenital variety. But at operation the testis with its tunica vaginalis will be found behind the hernial sac.

It is usual, however, for it to descend up to a point above the testis thus enabling us to distinguish between this form of hernia and the complete congenital kind.

The above considerations permit us to regard all oblique inguinal hernias in children as practically congenital. These sacs are naturally very thin and of fine texture and show no thickening and cicatrization in their walls and are also said to be less adherent to their surroundings.

A congenital hernia is not often strangulated but when strangulated, this strangulation usually occurs during early infancy. It is important, therefore, that it should be operated on at the earliest possible opportunity.

It is maintained by some that if controlled by a truss, a congenital hernia in a child may become cured by itself. But the result is very uncertain. The arguments against such a course of action are that (1) a truss in a baby or a small child is irksome and painful, (2) an intelligent mother or nurse is required to be able to reduce the hernia, to put on the truss and take it off and to know when to put it on and when to take it off, (3) the truss owing to the rapid growth of the child needs to be frequently changed.

The operation that I describe is easily and quickly done without any mutilation of tissues

and may be performed under local anæsthesia with a few whiffs of ether, if necessary. Extensive separation of the sac from its coverings is not called for; nor is it necessary to separate the cord from the sac thus avoiding hæmorrhage, damage to the constituents of the cord and mutilation of surrounding tissues.

Operation.—An incision about an inch and a half long is made immediately over the external abdominal ring and the coverings of the sac are cut down upon anteriorly till the sac is opened. The sac is pulled down till the internal abdominal ring is seen and comes within reach. The distance from the internal to the external abdominal ring in a child is about half an inch. Now, extending the incision of the sac up to the internal ring, evert its edges and pick up with a purse-string suture of fine catgut on a small intestinal needle the wall of the sac at the neck from inside avoiding the cord. I have done this in several cases and have found no difficulty or ill-effects. No damage is done to the spermatic artery, or the vas and there is very little or no hæmorrhage. The purse-string suture is tied and the opening in the lower part of the sac due to the longitudinal incision closed with a continuous fine catgut suture along with the coverings, which have been incised. The skin incision is closed with horse-hair sutures. No bandaging is necessary. The skin sutures are covered with cotton-wool soaked in Friar's balsam and covered over with a piece of gauze kept in place by two or three strips of sticking plaster.

In this method no attempt is made to remove the sac which I consider unnecessary. If it is left alone and not kept open by abdominal contents, being serous its walls will collapse, become adherent and later atrophy. The neck of the sac brought together by purse-string suture will close by adhesions and cicatrization.

REPORT ON SOME CASES OF FIBROIDS AND UTERINE HÆMORRHAGES TREATED BY RADIUM.

By K. S. RAY, M.A., B.Sc., M.B., Ch.B. (Edin.), M.L.C.

THE usefulness of radium in the treatment of fibroids and uterine hæmorrhages, though quite well known and firmly established in Europe, has not until recently received the same recognition among the practitioners in Bengal. This was mainly due to want of proper facilities for the radium treatment on scientific lines. So far the only institution where radium was available was at Ranchi. The expenses for the journey and for the treatment stood in the way of many patients and they had to go through a lot of difficulties and inconveniences to undertake the long journey to Ranchi. Moreover, the success of radium treatment also depends largely on the co-operation which the radiologist receives from the specialists in different departments. Very often the co-operation of a surgeon, unless the radiologist is also an experienced surgeon, is necessary.

The appendix will show a record of 27 cases of uterine fibroids treated by radium at the Calcutta Polyclinic. Radium is not available at any of the large hospitals in Calcutta, but private enterprise has supplied this deficiency and the Calcutta Polyclinic is now able to undertake radium treatment.

The present paper is intended only to deal with the treatment in cases of chronic metritis, uterine fibroids and menopausal hæmorrhages. The menorrhagia or metorrhagia associated with these conditions respond very satisfactorily to radium treatment.

Methods employed.—The following method which is recommended by Dr. Hayward Pinch was followed in most of the cases:—

The cervical canal is dilated and a tube of 50 milligrams of radium screened with 2 millimetres of lead and 3 millimetres of rubber is introduced into the uterine cavity for 24 to 30 hours.

One such exposure may suffice. If not, one or two more applications may be necessary. If the patient be past the child-bearing period, there is no objection to induction of menopause which usually results after 2 or 3 exposures.

The internal administration may be supplemented by external radiation by flat applicators screened with 2 millimetres of lead and rubber applied over the fundus and ovaries. In some cases, however, as will be found from the appendix, marked improvement followed even in those cases where external application was not made. In some, smaller doses than 50 milligrams were also found effective. For instance, 25 milligrams sheathed in lead and rubber inserted into the uterine cavity by dilating the cervix and kept for 36 to 48 hours gave excellent results.

Menorrhagia.—The improvements so far as menorrhagia is concerned have been found to be as follows:—

The results of treatment were slightly different in cases nearing the menopause from those of younger age. In both classes, in some cases but not in all, there was an increased flow at the next menstrual period. In women past the child-bearing period and nearing the menopause, the successive periods showed a decrease in the flow and in most cases after a month or two, complete amenorrhœa occurred. In younger women, the subsequent periods gradually became normal and in some cases complete amenorrhœa resulted. There is one interesting difference noticed in respect of the latter group. Periods reappear after 6 months or 1 year or in some cases 2 years after the last exposure. In one case as stated in the appendix, the periods not only reappeared but very profuse bleeding set in 6 months after she had an exposure of radium at Ranchi and she improved in health after a second exposure. The periods stopped and there has been complete amenorrhœa since.

Uterine fibroids.—The results so far as uterine fibroids are concerned have been very remarkable. Hæmorrhage, as has been said previously, was controlled in every case. As regards diminution

of size of the tumour it is noticeable, especially if the fibroid is of a myomatous nature. Hence, this method of treatment of fibroids is in many ways far superior to operative removal, and the risks and troubles of abdominal operations can be safely avoided.

In one or two cases the size of the tumour was diminished first, but subsequently enlarged again. This was probably due to insufficient dosages and in both cases where the enlargement was noticed, radium in higher doses was reapplied with the result that the size of the tumour was reduced almost to vanishing point. The pressure symptoms gradually disappeared.

The immediate arrest of hæmorrhages after radium application in many cases may be due to plugging of the vagina and uterus while the radium is inside the uterus, and to a certain extent to the degeneration and destruction of the endothelial cells lining the fine arterioles and capillaries of the uterine mucosa, thus facilitating the formation of clots inside the lumen of the arterioles and capillaries. The late arrest of hæmorrhage of fibroid origin after prolonged or frequently repeated irradiations can be ascribed to the production of fibrosis from the organisation of the largely increased number of fibroblasts which develop in response to the stimulation of the Gamma rays emitted by the radium.

In conclusion I offer my best thanks to Drs. Kedar Nath Das, Bamandas Mukherji, Sundari Mohan Das, N. N. Basu, S. N. Bagchi and M. Sanyal, and to Lt.-Col. Green-Armytage, I.M.S., and other leading gynaecologists in Calcutta for referring their cases to me at a period when the radium treatment was quite new in Calcutta.

APPENDIX.

Case No. 1.—Mrs. R. D., Hindu, aged 24. History of menorrhagia 6 or 7 years, amenorrhœa for 6 months, 2 or 3 years ago followed by severe bleeding during the periods.

Diagnosis.—Fibroid uterus.

Treatment.—Radium.

1st application—21 hours } Interval 2 months.

2nd application—48 hours }

Result.—Ten days after the 1st application the periods started and continued till two months later. Examined 2 months after 1st application—very little change noticed. Marked improvement after 2nd application—no bleeding.

Dose of radium used.—1st application 25 mgms. 2nd—50 mgms. inside the uterine cavity with brass and rubber screening.

Case No. 2.—Mrs. M. K., Hindu, aged 14.

History of 1st menstruation—3 years back. Two months interval between periods for first 8 months. After this bleeding for 16 days (stopped on taking medicines). During 2nd 8 months—interval between periods varied from 13 days to 2 months, period each time lasting for a week. Bleeding for 45 days (stopped by taking medicines).

After 2 months again bleeding for a month (stopped again by medicines and local treatment). Then for 4 months—periods regular each month but lasting each time for 7 days. Next 2 months—irregular periods.

Again bleeding for about one month in spite of medicines per month, injections and local treatment; stopped, however, by absolute rest.

Treatment.—Radium.

1st application—24 hours } 25 mgms.

2nd application—48 hours }

Result.—Bleeding continued profusely for a fortnight after which the periods were normal.

Case No. 3.—Mrs. C. G., Hindu, aged 32 years, married at 12, multipara, last child at 25. History of leucorrhœa since the birth of the last child, ruptured perineum, menorrhagia, no sign of malignancy in cervix but it easily bled on examination. Multiple tear in cervix and a patch of erosion. Uterus healthy.

Treatment.—Radium applied in cervix.

1st—25 mgms. for 24 hours.

Result.—Reported 2 natural periods since application. Now free from all complaints.

Case No. 4.—Mrs. A., Hindu, aged 50. Multipara. History of menorrhagia 10 years. Anæmia, uterus enlarged to the size of a foetal head at brim, freely movable; appendages not palpable.

Treatment.—Radium applied on 2 occasions at one month's interval.

Result.—Menopause set in with diminution in size of growth.

Case No. 5.—Mrs. U. D., Hindu, aged 36. Children—8.

Last child 1½ years ago. Menorrhagia—duration 8 or 9 days, passes clots, very painful, last menstruation 16 days ago, slightly anæmic. Cervix—small tear, feels normal; uterus retroverted, bulky and replaceable; appendages not palpable. Re-examination—5 months later.

Menstruation 18 days ago, lasted 8 days, profuse but 2 previous ones less profuse, passed clots; uterus retroverted, bulky and tender; cervix—bilateral tear appendages not palpable.

Diagnosis.—Fibroid uterus.

Treatment.—Radium applied.

1st 25 mgms. 24 hours; a 2nd application was made a week after. Hæmorrhage stopped with diminution in size of uterus within a month of last application.

Case No. 6.—Mrs. S. D., Hindu, aged 32.

No children or abortions. Complaints of excessive menstruation stopped since for 2 days, pain.

Diagnosis.—Fibroid uterus.

Treatment.—Radium applied, 1st 60 mgms. 48 hours and 2nd 60 mgms. 24 hours.

Result.—Bleeding continued for 3 days after the 2nd application after which the patient never reported again.

Case No. 7.—Mrs. J. D., Hindu, aged 26.

Two children both dead, no abortions.

History of dysmenorrhœa—15 days, passed clots; periods lasting 7 days. Last menstruation 7 days ago.

Diagnosis.—Fibroid uterus, size of an orange.

Treatment.—Radium applied.

1st 25 mgms. inside and 10 mgms. outside—24 hours. *Result.*—Not known, the patient did not report herself again.

Case No. 8.—Mrs. C., Hindu, aged 52.

Five children, last child—17 years ago. Bleeding for last 2 months.

Irregular, profuse and painful menstruation lasting 15 to 18 days, constipation; anæmia; tenderness all over lower abdomen, outlet—slightly relaxed, uterus retroverted, replaceable, enlarged to foetal head, feels very hard; appendages not palpable, bloody discharge present.

Diagnosis.—Fibroid uterus.

Treatment.—Radium applied.

1st 45 mgms. inside and 10 mgms. outside 24 hours—slightly bleeding.

2nd 35 mgms. 24 hours—slightly bleeding.

Reported after a week. Bleeding practically stopped excepting staining now and then. Reported 3 months later. No bleeding for 8 days. Radium again applied—3rd 25 mgms. 24 hours (after cervix dilated up to 14[Hg]). Reported 1 year later. No complaint—report of internal examination was as follows:—

Outlet—relaxed, cervix atrophied, uterus super-involut, movable, appendages not palpable.

Case No. 9.—Mrs. S. R., Hindu, aged 43.

Children 6. Last child 9 years; no abortions. Profuse bleeding stopping for 7 months after one radium exposure at Ranchi a year ago. Again profuse bleeding.

A submucous fibroid polypus (sloughing) removed 2 years ago. Cervix healthy, uterus bulky, feels hard, freely movable, appendages not palpable.

Treatment.—Radium applied.

1st 40 mgms. 24 hours (cervix dilated up to 10[Hg]).

No bleeding from 2nd day of application.

Case No. 10.—Mrs. D., Hindu, aged 30.

No children or abortions.

Menstruation—regular, painful and profuse, lasting 4 to 7 days passing clots.

Menstruation stopped on the previous day, hæmorrhage —7 years; pain in left leg radiating upwards, in each period—4 years, constipation. Pale, outlet normal, cervix—small cyst in anterior lip, uterus enlarged to tennis ball, very hard, freely movable.

Diagnosis.—Fibroid uterus.

Treatment.—Radium applied.

1st 45 mgms. 24 hours.

Reported one month later—menorrhagia less, pain slightly less.

2nd 55 mgms. 24 hours. Reported 1 month later—one period due in the middle of the last month suppressed. Pain, etc., same as before. Reported 1½ years later. No menses since last report.

Case No. 11.—Mrs. S. D., Hindu, aged 45.

Children 6. Last child 22. Abortion 1.

Menorrhagia for last 2 years. Frequent micturition, enlargement of lower abdomen, excessive hæmorrhage.

Uterus—tilted cervix—left, old laceration in left side of cervix, tumour—size of 2 fingers above umbilicus.

Diagnosis.—Fibroid uterus.

Treatment.—Radium applied.

1st 50 mgms. plus 10 mgms. 30 hours. Examined one year later, uterus diminished in size up to symphysis pubis but again enlarged.

2nd same—24 hours. Tumour again diminished in size and pressure and symptoms relieved. Hæmorrhage stopped.

Case No. 12.—Mrs. K. D., Hindu, aged 36.

Two children, one died four days after birth. Last child 15 years.

Menstruation regular, complains of excessive hæmorrhage, watery discharge. Uterus enlarged to foetal head, freely movable, cervix bulky, appendages not palpable.

Diagnosis.—Fibroid uterus.

Treatment.—Radium applied.

1st 45 mgms. 24 hours. Examined 1 month later, periods started a week after radium. Discharge of blood on 3rd day moderate. Period stopped on 4th day.

2nd 55 mgms. 24 hours. No marked improvement noticed.

Case No. 13.—Mrs. J. D., Hindu, aged 50.

Children 9, last child 16 years.

Menorrhagia last 10 years, anæmic, uterus enlarged to size of foetal head, freely movable, appendages not palpable.

Diagnosis.—Fibroid uterus.

Treatment.—Radium applied.

1st 45 mgms. 24 hours. Tumour diminished in size and bleeding stopped.

Case No. 14.—Mrs. M., Hindu, aged 45.

Children 7, last child 17 years.

Menstruation regular, profuse, painful lasting 7 to 8 days.

Last menstruation 25 days ago.

Complains of constant pain over lower abdomen and back—2 months. Poor appetite, anæmic, soft systolic murmur at apex.

A hard mass felt over abdomen just above pubis—tender.

Outlet—incomplete tear, cervix enlarged to foetal head, feels very hard, normal in position, appendages not palpable.

Diagnosis.—Fibroid uterus.

Treatment.—Radium applied.

1st 85 mgms. 24 hours. Nausea after 1st application, no relief of pain.

2nd 55 mgms. 24 hours. Nausea. A week after nausea was relieved and tumour diminished in size and menopause set in.

Case No. 15.—Mrs. K. B., aged 40.

Child 1. No abortion.

History of kala-azar in the middle of 1923. Amenorrhœa then for 10 months. After that irregular and painful menstruations for 2½ years. Unbearable pain, profuse hæmorrhage and clotted blood, 3 or 4 months.

Diagnosis.—Uterine fibroid.

Treatment.—Radium applied.

1st 45 mgms. 24 hours. Examined 3 months later, size that of a small orange.

2nd 45 mgms. 24 hours. Reported 7 months later. Patient much improved in health, weight increased, spleen diminished in size.

Fundus small, slightly retroverted, no tumour felt.

Case No. 16.—Mrs. S. M., Hindu, aged 45.

Children 11. Last child 10 years. Abortion a year ago.

Bleeding off and on for 1½ months, backache 8 months ago. Severe hæmorrhage 15 days after a period; appetite bad; constipation now and then. Uterus enlarged to small foetal head.

Diagnosis.—Fibroid uterus.

Treatment.—Radium applied.

1st 55 mgms. 24 hours.

2nd after one month 45 mgms. 24 hours. Size reduced to half.

Case No. 17.—Mrs. S., Hindu, aged 43.

Children 4. Last child 22 years.

Menorrhagia, backache.

Uterus normal in position, slightly bulky in size, movable.

Cervix—consistency normal, old tear.

Appendages. Right ovary enlarged and palpable.

Diagnosis.—Fibroid uterus.

Treatment.—Radium applied.

1st 45 mgms. 24 hours. Bleeding continued after removal. Examined 2 weeks later. No bleeding since.

Case No. 18.—Mrs. S. D., Hindu, aged 42.

Children 3. Last child 8 years. No abortion.

Complains of weakness, swelling, palpitation, defective eyesight, menorrhagia, daily fever.

Dysmenorrhœa, menorrhagia for 1½ years. Last menses started 2½ months ago and stopped 20 days ago. Uterus enlarged.

Diagnosis.—Fibroid uterus.

Treatment.—Radium applied.

1st 45 mgms. 24 hours.

One month later, 2nd 24 hours.

Two months later, 3rd 24 hours. Marked improvement since last application.

Case No. 19.—Mrs. J. H., Hindu, aged 45.

No child. Abortion 1 (20 years ago).

Complains of headache, giddiness, weakness, discomfort in abdomen, frequent micturition, swelling of ankles, constipation. Menstruation used to last 15 to 20 days, now and then amenorrhœa for 3 or 4 months. Menstruation at present lasting for 4 days with profuse bleeding followed by leucorrhœa for 15 days. Enlarged uterus up to the umbilicus.

Diagnosis.—Fibroid uterus.

Treatment.—Radium applied.

1st 60 mgms. 24 hours. Marked improvement in general health and diminution of size of tumour and free from all symptoms.

Case No. 20.—Mrs. G., European, aged 39.

Child 1.

Profuse bleeding for 2 years, lasting 12 to 14 days, clots passed, anæmia, palpitation, indigestion.

Uterus—retroverted, enlarged to duck egg.

Cervix—normal.

Diagnosis.—Fibroid uterus.

Treatment.—Radium applied.

1st 45 mgms. 48 hours. No hæmorrhage, general condition good, some watery discharge.

2nd 45 mgms. 48 hours. Hæmorrhage for 6 days. Reported 2 weeks later.

3rd 45 mgms. Reported 5 months later, complained of throbbing pain in rectum, passing of mucus, continued whitish discharge from uterus, inflammation of lips, prolapsus rectum.

No more hæmorrhage since last application. Rectal troubles also disappeared with improvement in general health.

Case No. 21.—Mrs. G., Hindu, aged 44.

Uterus enlarged up to umbilicus, 1½ years.

Diagnosis.—Fibroid uterus.

Treatment.—Radium applied.

1st 50 mgms. 24 hours. Reported one month later. No bleeding yet, although 7 days passed since menstrual date.

2nd 50 mgms. 24 hours. Reported 2 months later. Tumour very much smaller, size that of an orange, after 6 months again increased in size but decreased after another application. The patient is still under observation.

Case No. 22.—Mrs. B., Hindu, aged 23.

Children 3. Last child 6 years. No abortion.

Puncture—1 at 8th month 3 years ago.

Complains of bleeding, 2 months, pain over lower abdomen off and on. Bleeding profuse for the last 3 years. Before regular and profuse. Cured after one year ago after which bleeding normal for 8 months. On examination—excess adipose tissue over abdominal wall. Slight tenderness over left lower abdomen.

Outlet—normal.

Cervix—external os patulous.

Uterus antroverted, slightly bulky in size, freely movable, feels hard.

Appendages not palpable.

Diagnosis.—Fibroid uterus.

Treatment.—Radium applied.

1st 24 hours. Reported 1 month later. Bleeding increased passing clots.

2nd 32 hours. Reported 3 months later. No bleeding last 15 days. Uterus small. No fever for 8 days. Reported 1 year after. No complaint. No periods since.

Case No. 23.—Mrs. M. D.

Child 1 died one month after birth.

Complains of excessive hæmorrhage, tumour in abdomen, pain on micturition.

On examination—cervix healthy, uterus enlarged to 4 months pregnancy.

Diagnosis.—Fibroid uterus.

Treatment.—Radium applied.

1st application—24 hours. Reported 2 weeks later. No bleeding for last one week.

2nd application—65 mgms. 24 hours. Patient improved and free from symptoms.

Case No. 24.—Mrs. E., European, aged 49.

Children 2 alive, abortions 4, last child 7 years.

Complains of excessive hæmorrhage from uterus.

Irregular periods for 1 year, stop for a month or two and reappear. Excessive bleeding off and on 4 months ago.

On examination—uterus freely movable, enlarged to 2 months pregnant. Cervix normal.

uterus.

applied.

1st 50 mgms. 24 hours.

2nd 50 mgms. 24 hours. One month after free from symptoms. No period 6 months.

Case No. 25.—Mrs. M. D., Hindu, aged 39.

Children 8, last child 9 years ago, no abortion.

Complains of hæmorrhage (no bleeding for last week). Excessive menorrhagia since 1921, duration 15 to 29 days. Cured in 1924 after which temporary improvement for 2 or 3 months. Bleeding increased again.

On examination—outlet—lax, uterus slightly bulky, retroverted fixed especially on right side, os patulous, cervix—healthy.

Diagnosis.—Fibroid uterus.

Treatment.—Radium applied.

1st 70 mgms. 24 hours. Reported 1 week later. Bleeding increased. Reported 2 weeks later.

2nd 60 mgms. 24 hours. Reported 4½ months later. No bleeding last 3 months. Great improvement in general health.

Case No. 26.—Mrs. R. K., Hindu, aged 35.

Children 4, last child 10 years, abortion 1.

Complains of excessive hæmorrhage for last 3 years. Passes clots. A polypus removed in 1927 after which she was better for 6 to 7 months. Bleeding began again every 15 days lasting 2½ months, more or less continuous.

Menstruation. Started at 15. Regular at first.

Treatment.—Radium applied.

1st at Sevasadan in 1926.

2nd 24 hours 50 mgms. Two years later.

3rd two weeks later. No bleeding since 1st application.

Case No. 27.—Mrs. S., Hindu, aged 49.

Children 6, last child 13 years; no abortion.

Complains of excessive bleeding for last 3 months.

Menstruation regular before.

On examination—cervix healthy, uterus bulky, movable, appendages not palpable.

Diagnosis.—Fibroid uterus.

Treatment.—Radium applied.

1st 40 mgms. 24 hours. Reported one month later.

2nd 40 mgms. 24 hours. No bleeding since.

A Mirror of Hospital Practice.

TWO CASES OF (?) TICK FEVER FROM POONA.

By M. N. PAI,

LIEUTENANT, I.M.S. (T. C.),

Indian Military Hospital, Poona, M. L.

It appears from Col. Megaw's article in the June number of the *Indian Medical Gazette* (1928) that Indian tick typhus has not yet been reported from Western India; the following two cases are of interest as both of them occurred among the men of the 2nd Lancers who had been grazing their horses in the neighbourhood of Poona, where ground rats and squirrels are found in large numbers.

Case No. 1.—The patient was admitted into the Indian Military Hospital, Poona, on 5th September, 1927, his complaint being pain and enlargement of the right testicle, fever and constipation.

Previous History.—There was no history of syphilis or gonorrhœa; he had been in Poona for the last 10 months, and had received 1 c.c. T. A. B. vaccine in March 1927.

Condition on Admission.—The patient was a young man not anæmic, teeth and tongue coated, throat congested.

Respiratory and Circulatory systems.—Normal. Liver not enlarged.

Spleen palpable two fingers' breadth below the costal margin in the left nipple line. Glands not enlarged. The right testicle was enlarged and tender. Epididymis and cord normal. No discharge from the penis.

Blood.—No malarial parasite was found in his blood on three successive examinations. Moderate leucocytosis, 16,000 per c.mm.

The patient was put on quinine for two days and the local condition of the testicle was attended to, but the patient's temperature still kept up and while the testicular pain lessened he began to complain of severe arthritic pain in all the joints though there was no effusion or swelling of any of them. His blood culture was found to be sterile and the Widal result negative.

On the seventh day after admission he developed a macular rash on the ankles and wrists. It became petechial in nature next day and extended to the forearms, arms, chest and abdomen. By the ninth day the whole body including the face, neck and back was covered profusely with a dark purplish rash. The rash on the

back was not unlike that seen sometimes in secondary syphilis. His Wassermann reaction, however, proved to be negative. From 12th September, 1927, onwards the temperature came down by lysis, the pains in the joints subsided and the rash became more persistent. The temperature reached normal on the sixteenth day, but the rash persisted till 21st October, 1927. He made an uninterrupted recovery. No ticks were found on his body.

Name—Sowar Surat Singh. Age—26 years. Disease—Tick Typhus (Spotted fever).
Date of admission—5-9-27. Date of discharge—22-10-27. Result—Recovered.

A CYST OF THE MEDIAL MENISCUS OF THE KNEE.

By K. G. PANDALAI, F.R.C.S.,

MAJOR, I.M.S.,

Second Surgeon, Government General Hospital, Madras.

THIS condition is rare and on a search of the records of the Madras General Hospital, no case has yet been reported. It is known that cysts occur in most tissues of the body, but cartilage

Case No. 2.—The second case was that of a Lance Dafadar, who was admitted into the Indian Military Hospital, Poona, on 29th September 1927, his complaint being fever of four days' duration and slight cough. This case was similar to the above in details except that there was no orchitis and the temperature came to normal on the twentieth day. The points of interest in these two cases are the marked arthritic-like pains without any effusion in the joints, the moderate leucocytosis at the onset, the appearance of the rash on the ankles and wrists rapidly spreading over the whole body including the face and neck, the persistence of the rash for more than four weeks, and the fall in temperature with the commencement of the rash.

The negative blood culture, and negative Widal differentiated this fever from typhoid.

The insidious onset, the fall of temperature with the appearance of the rash, spreading over the whole body including the face and neck, the negative Weil-Felix reaction, and the presence of joint pains differentiated it from ordinary typhus.

My thanks are due to Major G. S. Wallace, O.B.E., R.A.M.C. A. D. of P. H., Southern Command and Major D. Pottinger, M.C., R.A.M.C., Specialist in Medicine, Poona District, for seeing these cases in consultation with me and for assisting me in making a definite diagnosis.

seems only exceptionally to be the seat of such a lesion. A recent paper(1) on the subject of cysts in cartilage by Zadek and Jaffe discloses the fact that only three cases have been reported in the literature. The case which is now recorded is, therefore, of more than ordinary interest.

Mr. H. R., aged 21 years, student, Hindu, well-nourished, was admitted on 3rd August, 1925, for a rounded, tense and somewhat painful swelling on the inner part of the knee-joint of two years' duration. He was an ardent tennis player and attributed the condition to the strain of his favourite game. The swelling was tense and elastic, one inch in diameter and appeared to be fixed to the joint capsule. It was slightly tender and movement of the joint was somewhat limited both in flexion and extension. There was no heat or redness locally and X-rays did not reveal any abnormality in the bones. Clinical examination did not reveal any other pathological condition elsewhere.

Operation was performed on 4th August, 1925, and demonstrated the fact that the swelling was attached to and was a part of the medial meniscus which was therefore removed *in toto*. The capsule of the joint was closed with a few sutures of interrupted catgut and the wound closed. Healing took place by first intention, all pain and discomfort in the knee disappeared completely, and there has been no further trouble up to date.

i.e., about $2\frac{1}{2}$ years after the operation. On cutting into the swelling in the cartilage, it was found to be a cystic cavity three-quarters of an inch in diameter containing thick, clear, jelly-like fluid. Unfortunately, a microscopic section could not be obtained.

Comment.—The age of the patient (21), the long duration (2 years) and the history of repeated trauma are noteworthy. Hitherto, trauma had been noted in 50 per cent. of the cases although the internal semilunar cartilage had been noted to be the favourite site in previous cases, this case demonstrates that both cartilages are equally liable.

(The author's meaning is not quite clear; surely, "medial meniscus" is a pseudonym for "internal semilunar cartilage."—Ed., I. M. G.)

A CASE OF DOUBLE MONSTER.

By M. UMAR, F.M.S.,

Medical Officer, Bijnor, U. P.

THE patient, M., was aged 20, caste Chamar, of Nabada, District Bijnor.

History.—Labour pains were slight, and there was prolapse of one leg from the vagina. Duration of labour, one day.

When the patient came to the hospital, the membranes were ruptured, pregnancy was of full term and the woman was a primipara. The abdomen was unduly large which suggested twins. The temperature was 101.4°F . and the pulse was 120 to the minute. As is customary in India, the patient had been treated by *dais* and digital examination proved that some sort of medicine had been put into the vagina.

Abdominal palpation.—Two globular masses were felt. As a leg was protruded there was no doubt the case was a breech presentation. Fœtal heart sounds could not be heard. The os was fully dilated. Chloroform was given and the other legs were brought down in succession. The appearance was remarkable; all four legs were in one pelvis and there were two ani.

The monster was delivered with great difficulty, but there was no rupture of the perineum. There were two separate heads each with a neck branching from a single trunk. There were four arms, one cord and one placenta. The labour finished at 1-30 p.m., and the placenta was delivered five minutes after the fœtus. There was slight post-partum hæmorrhage. Immediately ergotinine gr. 1/100 was given hypodermically and a hot intrauterine douche. The woman is doing well.

A CASE OF LANDRY'S PARALYSIS.

By A. K. M. ABDUL WAHED, B.Sc., M.B.,

House Surgeon, Presidency General Hospital, Calcutta.

A BOY, aged 10, was admitted to the Presidency General Hospital, Calcutta, on the 12th April,

1928, in a condition of what appeared to be almost total paralysis or paresis of voluntary muscles.

That the onset of the weakness was rapid could be gathered from the mother's somewhat vague story which ran like this: "The child who was in normal health fell down two weeks ago and was found later to be quite helpless." No history of fever immediately preceding the onset was given.

On examination, complete loss of power without appreciable wasting was found to be present in the lower limbs. In the upper limbs voluntary movement was limited to flexion and extension of the elbows, but these movements could not be performed against slight resistance. Weakness was marked in the muscles of the back, consequently the sitting posture could not be maintained. Weakness was also present in the sterno-mastoids, trapezius, and in the muscles of the face though the latter muscles were involved to a lesser extent.

Ocular muscles, muscles of respiration and deglutition were completely spared.

The affected muscles were in all cases flaccid but not wasted. General nutrition was good. The tonus in the extensor muscles was diminished to a greater extent than that in the flexors—foot drop and wrist drop being very prominent.

As regards deep reflexes knee-jerks, ankle-jerks, wrist and finger-jerks, supinator, biceps, and triceps jerks were all absent and as to superficial reflexes, epigastric, abdominal and cremasteric were present. The plantar reflexes were indeterminate.

Sensation to pin prick, cotton-wool, heat and cold was normal. There was no loss of postural sense or of tactile discrimination. There was, however, some tenderness on pressure over the calf muscles.

Heart and lungs were normal.

The case was obviously one of peripheral neuritis and all the common toxic causes were in turn excluded.

There remained for consideration beri-beri and Landry's Paralysis or Polyneuritis.

Against the former the following points were predominant:—

- (1) The extreme rapidity of onset.
- (2) The complete absence of any sensory changes with the exception of tenderness on pressure of the muscles.
- (3) The complete absence of any involvement of the heart with such widespread paresis.
- (4) The absence of œdema and wasting.

The patient completely recovered after a six weeks' stay in hospital. He was treated by massage and faradisation to the affected muscles with re-education. *Oleum morrhue* was given internally.

I have to thank Major H. G. Alexander, I.M.S., Surgeon Superintendent of the Presidency General Hospital and Captain T. H. Thomas, I.M.S., for permission to publish the case.

Indian Medical Gazette.

DECEMBER.

THE TREATMENT OF KALA-AZAR.

Just over thirteen years ago kala-azar was looked upon by the medical profession as a fatal disease and making a diagnosis of kala-azar was tantamount to giving a death sentence. There was no specific treatment for the disease. Actually a certain number of patients recovered. It is not possible to say how many because even at the present day, although we know that a certain number of persons get a mild form of the disease in which spontaneous cure occurs, we do not know how large this number is. Even amongst those in whom the disease was well developed a few, but a very few, recovered.

The history of the discovery of the specific treatment, in the form of intravenous tartar emetic, and its introduction into this country by Sir Leonard Rogers and others is so well known that it is unnecessary to repeat it. The treatment with the antimony tartrates was such a great advance on any treatment which had been used previously that many were prepared to be satisfied with it. To those who had seen emaciated patients come into the wards of a hospital, apparently improve slightly, then go downhill again and eventually die or leave the hospital in a hopeless condition, this new (at that time) treatment, during which the patient steadily improved eventually to walk out a robust individual, so changed that in some instances he was not at first recognised by his own people, seemed almost too good to be improved upon. Nevertheless, there *was* considerable room for improvement. Amongst those who underwent treatment the death-rate was decidedly high; it is difficult to say how high it was as the records on this point were very seldom obtained or, at any rate, reported, but in one of the large Calcutta hospitals the death-rate amongst in-patients undergoing treatment with the antimony tartrates during one year was 15 per cent. and in the out-door department 25 per cent. (but this latter figure includes patients who discontinued treatment too early and died of kala-azar on this account), and in well-conducted treatment centres in the mofussil, where conditions are probably less favourable, death-rates as high as 50 per cent. have been reported. The treatment by means of these salts extended over a very long period during which an average of 30 injections had to be given, consequently a very large number of patients failed to complete the full course of treatment. There were certain very disagreeable symptoms associated with their administration, such as coughing, vomiting and joint pains,

which also encouraged patients to discontinue their treatment too early. And, finally, a small number of patients showed no improvement when treated by these salts.

For about eight years the antimony tartrates were employed almost exclusively in the treatment of kala-azar. It is true that as far back as 1916, pentavalent compounds of antimony had been prepared and at least one had been employed successfully in the treatment of the disease. Work on these compounds was continued during the intervening period but it was not until 1924 that they began to come into general use. Up to the present a large number of pentavalent antimony compounds have been prepared and tested; some of them have proved failures and have not been issued to the general medical public; others have been placed on the market by reliable British, Indian and German manufacturers. Almost all the latter have proved infinitely superior to the tartrates. The death-rate amongst patients treated was, in the case of one drug which had an extensive trial but has now been superseded, 10 per cent., but the average death-rate is about 5 per cent., and in the case of one compound which is only recently available for the public, the death rate in a very large series was 2 per cent. The toxicity of these compounds being very low, in most instances one-tenth that of the antimony tartrates and in some even lower, very much larger amounts of antimony can be given in each individual dose and the full course thus completed in a much shorter period; a course of 12 injections occupying a period of three to four weeks is usually advocated, but with one drug, already referred to above, a course of 8 injections given within a period of a week has produced a very high percentage cure-rate. Symptoms such as coughing, vomiting and joint pains are not associated with the administration of these drugs, and a certain number of patients who show no improvement during treatment by the antimony tartrates react very readily to the pentavalent compounds.

At first the pentavalent compounds were so expensive that only well-to-do patients undergoing treatment in their own homes could afford to buy the new drugs; a full course cost about Rs. 40, excluding the doctor's fees, and it was, therefore, quite out of the question for provincial governments to consider issuing these compounds to dispensaries. Three years ago we wrote, "It is obvious that the only real obstacle to the introduction of the new antimony compounds into general use is the present very high cost. There are two factors which influence the price—firstly, the process of manufacture is an expensive one, and, secondly, there has, up to the present, been very little competition in the manufacture of these compounds. It is not suggested that manufacturers have been profiteering but it is obvious that if a number of commercial firms can produce pentavalent compounds

of proved leishmanicidal value, healthy competition will be started and the various manufacturers will be compelled to study economy in the process of manufacture It seems, therefore, desirable that in order to combat any attempt at 'cornering' any of these compounds reputable chemical manufacturing firms should receive every encouragement to manufacture and place on the market any pentavalent compound that has been thoroughly tried and shown to be of definite therapeutic value in the treatment of kala-azar. . . . " This is exactly what has happened. New commercial interests and new compounds have come into the market and at the present day the manufacturers who were retailing their compound at the rate of Rs. 25 a gramme are prepared to supply the same drug to provincial governments at as low a price as Rs. 1-8-0 a gramme. This has made it possible for a province like Assam to use the pentavalent compounds exclusively; during 1925 over 60,000 persons were treated for kala-azar in this province, almost all by sodium antimony tartrate. During the succeeding year about 10 per cent. of a total of nearly 50,000 persons were treated by one of the pentavalent compounds, but it was not until the middle of last year (1927) that the price was reduced to a figure which made it possible for this drug to be used exclusively in all hospitals, dispensaries and kala-azar treatment centres. During 1927 about 33,000 persons were treated for kala-azar; the allowance for each patient would be about 2 grammes, so that if this annual figure were maintained the expenditure for this one drug alone for one year would be about a lakh of rupees. This is no small sum to ask a comparatively poor province to pay, and the authorities concerned would probably hesitate to ask for so large a sum did they not realise that the disease is one of such great economic importance and that this extra expenditure now will probably save the province many times this amount during the next few years. The immediate result of the change from sodium antimony tartrate to a pentavalent compound is the reduction of the death-rate amongst those undergoing treatment from at least 15 per cent. to about 5 per cent., or the saving of the lives of at least an additional three thousand odd persons. This, and the fact that the treatment occupies a much shorter period, will tend to popularise it and to encourage the patients to continue treatment until they have had a full course. These are extremely important points now and will be even more so during the next few years. Assam has been subject to epidemic waves of kala-azar; the peak of the last wave was probably during the years 1923-24, and the inter-epidemic period is now rapidly approaching. It is during this period that the treatment campaign in the province should be intensified rather than relaxed. If the few smouldering foci of infection which would normally form the sparks to light the next epidemic blaze could be smothered by the aid of this new and more effi-

cient treatment, it seems probable that the disease might be stamped out altogether in the province. If this effort is made one can at least predict with certainty that, even if there is another epidemic, it will be an abortive one with a very limited distribution. Although these remarks apply more especially to Assam where the epidemic periodicity is most marked, they are also applicable to other provinces where kala-azar is a serious problem, for example, Bengal and Bihar.

At the time that we wrote the above-quoted sentences we also added a warning, "There is, of course, the danger that useless and even dangerous antimony compounds will be produced and sold at a cheap rate by unscrupulous persons, either as one of the antimony compounds whose value has been proved, or as 'an improvement' on one of these compounds. To-day it is very necessary to repeat this warning. The manufacture of certain of the pentavalent compounds is covered by patents and they are sold under proprietary names, but in the case of others the composition and method of manufacture is published so that anyone can make them and put them on the market. Here is an obvious danger. Quite recently it has been pointed out in a paper in the *Indian Journal of Medical Research* that the commercial samples of one of the pentavalent compounds, of which the calculated antimony content is 35 per cent., contained amounts of antimony varying between 19 per cent. and 43 per cent. This sort of thing is very unsatisfactory. In this particular drug, one of the main constituents is in very loose combination, so that it is really more like a mixture than an actual compound; under these circumstances it is difficult for the manufacturer to be certain that the antimony content of each batch will be exactly the same, but it is certainly desirable that it should vary only within certain limits.

As time goes on commercial competition will become more and more acute and there will be still further cutting of prices; up to a point this will be to the advantage of the buyer, but presently in order to compete with their rivals manufacturers will be tempted to modify their methods of preparation and this may be done to the detriment of the drug which they are making. Furthermore, there is at the present time nothing to prevent anyone putting any brown-coloured soluble powder into ampoules, labelling it with the name of any non-proprietary pentavalent antimony compound, and selling it to the public at a huge profit.

Surely it is time that legislation were introduced to protect both the public and the conscientious manufacturers! It would not be necessary to lay down very rigid standards, but it should be insisted that a preparation is what it purports to be. If it has a known chemical formula, the percentages of the constituent substances should be approximately correct and the toxicity should not be greater than that of the

pure substance. In the case of proprietary compounds, the toxicity and the percentage of constituent substances should be approximately that which the manufacturers specify and should not be allowed to vary in different batches.

In the meantime we can only repeat our advice of three years ago, that "the public, and more especially the medical profession, should be warned against using any preparations that have not had a very thorough clinical trial by a disinterested observer at some well-recognised institution," and we might now add, "and that do not bear the name of some reputable firm of manufacturing chemists."

ERRATUM.

In the November Number "A Case of Eclipse Blindness" was contributed by Kidar Nath Dutt, L.S.M.F. (Punjab), Canal Dispensary, Chanda, S. V. P. (Bahawalnagar) and not by S. C. Sen Gupta, L.M.F., etc.

SPECIAL ARTICLES.

NOTES FROM AN OPHTHALMOLOGIST'S LEAVE DIARY.

By R. E. WRIGHT,

LIEUTENANT-COLONEL, I.M.S.,

Madras.

DURING the past year I was fortunately enabled to visit a number of well-known ophthalmological clinics in the West and although a detailed account of my experiences which might appeal to the eye specialist would prove tedious to most readers, it may be of interest to record some of the more striking points which presented themselves and which may stimulate reflection on the advances of ophthalmology in certain directions.

BARRAQUER'S OPERATION.

Prof. Barraquer's clinic at Barcelona was naturally a centre of attraction. Of late years one has heard and read so much of phacærosis, which he has placed on a practical footing, that to see the originator of the method at work in his own clinic was eminently desirable; the more so as I had essayed to give his method an extended trial shortly after its introduction and had published a considerable series of cases in an article which was not optimistic as to the extended applicability of the method to an Indian clinic (*British Journal of Ophthalmology*, 1925). I quite realized that the method might prove a very valuable one in India in selected cases and briefly stated the case for extending this procedure in our cataract treatment here (*G. O. H. Report*, 1926). A further careful study of a series of 50 cases was made (Green's method) early in 1927 with Dr. Koman Nayar, the analysis of which was presented at the Oxford Ophthalmological Congress in June last (*vide Trans. Oph. Soc., U. K., 1927*).

I was fortunate in having Major Dick, Professor of Ophthalmology, Lahore, with me at the time of my visit. Prof. Barraquer afforded us every facility for seeing his work and I may say at once that we were both greatly impressed with what we saw. I

must omit the many interesting features of his excellent institution which appealed to one. It will suffice to say that it is stamped with up-to-date efficiency in practically every branch of ophthalmological science which it touches, and the perfection of organization and administration of this large private clinic stimulated one's envy and admiration. Phaco-opsis was the chief object of our visit, but even in this connection my remarks must be strictly limited.

The patient is carefully examined and prepared, the conjunctiva treated till surgically clean, sedatives are given, bromides for 3 or 4 days, and Sedol or Pantopan immediately before operation. The theatre ritual is exacting, almost formidably so, as compared with most other eye clinics the world over. The pupil is dilated, the orbicularis infiltrated with novocaine, a conjunctival flap is used, one mesial suture is always inserted, and two lateral ones if considered necessary. Barraquer's needles and suture materials are the finest in use, and the delicacy of his tackle is in contrast to that of very many operators. He does a peripheral iridectomy before tumbling the lens and having tied the conjunctival sutures, places eserine ointment in the lower sac, stitches the lids together, skin surface to skin surface near the cilia, applies half per cent. perchloride of mercury ointment to the lid margins and puts on a simple gauze wool strapping dressing. Subsequently, the patient is placed in a semi-recumbent position and allowed to move on the second day. In the few cases I saw the eyes presented a wonderfully quiet appearance on the fourth day with a full chamber, a round active pupil, and presumably quite safe and comfortable, going about the home with only a shade.

The technique in good hands is undoubtedly adapted to the removal of the lens in its capsule with a minimum of trauma to the vitreous face, it affords possibilities of a low iris-prolapse rate, and a relative freedom from vitreous adhesions to iris and section. Such considerations are, to my mind, of far-reaching importance in any procedure for removing the lens in its capsule.

FOCAL SEPSIS AND EYE DISEASE.

The so-called "focal" infections of the eye have claimed the attention of many ophthalmologists, but beyond those which are apparently associated with teeth, tonsils or sinuses, there is much speculation and little in the nature of proof. With such a vast area as the alimentary canal for the collection of harmful products, both chemical and organismal, and the transmission of such to the blood-stream and hence to the eyes, this source of trouble must be considered. Although examples of infection of the eye from the former sources are familiar to most ophthalmologists, as clinical associations if not actually proven bacteriologically, the conception of focal sepsis of such origin has come to occupy a position which is perhaps out of proportion to the recorded facts. One hears for instance of wholesale removal of a patient's teeth on account of incipient

cataract. Very often the cure is more pernicious than the disease. In cases of unilateral disease with a local focus there is considerable excuse for such measures, but when one comes to think of conditions such as bilateral cataract, glaucoma, or uveitis as due to focal sepsis, it is unreasonable to confine one's attention to teeth, tonsils or sinuses when the whole alimentary canal or respiratory system is not above suspicion.

Col. Kirkpatrick emphasised the rôle of the bowel in certain forms of chronic iridocyclitis here. I have also been particularly interested in this question for some time, but with a few exceptions have never satisfied myself even clinically that definite pathological conditions of the alimentary canal could be positively associated with eye disease. Even the dysenteric iridocyclitis described in the Mediterranean area during the War does not find a place here in our diagnoses. One of the possible exceptions which I have mentioned elsewhere is interesting, namely, the curious moonstone-like cataract frequently seen in bad hookworm infections. It is not maintained for an instant that it is due to the presence of hookworm; indeed, similar cataractous changes are seen in other intense anæmias, but it is a more definite association than, for example, cataract and dental infection, not even excluding the ubiquitous pyorrhœa alveolaris. On the other hand, in heavily infected districts such as Cochin, there does not seem to be an undue excess of cataract amongst adolescents. Similarly, I had come to regard a certain type of quiet iridocyclitis as associated with alimentary disease.

In discussing this subject with some of my colleagues late in 1926, the idea of intestinal lavage was propounded as perhaps being just as efficacious as radical teeth, tonsil or sinus procedures. The question arose as to how to put such a method into practice. The administration of voluminous draughts of normal saline to wash out the whole tract, as is sometimes practised for hyperpiesia, was suggested, but it was not always practicable even with intelligent patients. Then the idea of introducing an Einhorn's tube was considered and in turn the Plombière douch. My veterinary friends demonstrated the method of washing out dogs from anus to mouth by merely holding them end up and introducing a nozzle with a small head of pressure. By this means an unlimited amount of fluid may be run straight through with apparently little discomfort to the animal. Parasites come tumbling out, tape worms with heads complete, hookworms and so on, and the dog gets a new start with a clean alimentary canal. This much impressed me with the desirability of finding out what could be done in this respect in the human, for when one remembers the enormous area of the intestinal canal, even if we except conditions of stasis with an undamaged mucosa as not likely to lead to the absorption of harmful products, chemical or organismal, we, in India, have to consider this area extensively

damaged by the dysenteries, malnutrition, or parasitic traumatism, as a possible source of sepsis not less important perhaps than infections of teeth, tonsils or sinuses. I determined while on leave to make some enquiries on these matters.

A visit to a leading British spa showed me that although there was a firm belief in the association of alimentary disorders and the various groups of rheumatoid affections, little had been accomplished by bacteriologists and chemists to put the matter on a scientific footing. Enquiries into the methods of intestinal lavage did not get me further than demonstrations in the high Plombière method of douching out the large intestine. One curious negative observation in this connection was the relative paucity of uveal infections in a hospital for the treatment of chronic rheumatic affections (I refer to the Royal Bath Hospital, Harrogate).

I was subsequently enabled to discuss this matter with Dr. J. Wheeler, Professor of Ophthalmology, New York University, and through his kindness with two professors of medicine, Drs. Coleman and Max. Einhorn. The last-named was inclined to the view that the unimpaired alimentary mucosa was not a likely source of trouble in connection with obscure involvements of the uvea. For instance, he considered that the evil effects of alimentary stasis and constipation were unduly stressed. His investigation into the condition of the alimentary canal, more especially with regard to ulceration of the upper parts of the tract by means of his well-known duodenal tube, were extraordinarily interesting and instructive. As a result of a visit to his clinic one felt that should one ever be unfortunate enough to develop a gastric or duodenal ulcer, the comparative comfort of his apparently effective treatment would be preferable to more drastic surgical measures. Although the Einhorn tube may be introduced by the mouth and passed the whole way through to the anus, it is not adapted to giving man a complete wash through.

It is hardly necessary to remind the reader that a normal intestinal mucosa in adults of the hospital population in India must be rather exceptional. What with the various parasitic worms (chief amongst which is the hookworm), the dysenteries and the changes produced by affections of the deficiency group, there would appear to be ample facilities for even organismal invasion of the blood-stream. Apart from metastatic involvement of the eye, which he had not investigated particularly, Dr. Coleman considered that invasions of the blood-stream by alimentary organisms was a definite factor in disease and in co-operation with Burbank he had interested himself in it for a considerable time. Hadio-poulos and Burbank have recently produced experimental evidence of infective arthritis in animals, due to organisms isolated from the alimentary canal (*Journal of Bone and Joint Surgery*, 1927).

It is here, perhaps, well to consider what the term focal sepsis, when used in connection with the eye, connotes. In the grosser forms of endocular inflammation such as acute iritis, one may be dealing with either a bacteriæmia or toxæmia. In the first case, the local infection may be part of a general organismal invasion, e.g., syphilis, tuberculosis or leprosy, in which the actual organisms may be demonstrable in the tissues of the eye, or of a selective infection where the supposed organisms carried in the bloodstream have a special affinity for some of the eye tissues. I say "supposed organisms" designedly for sympathetic ophthalmitis may be an example.

It must strike many observers as somewhat curious that amongst the large clinical group of endogenous inflammations (infections?) of the eye, it has not been possible more often to demonstrate organismal invasion. This may be on account of the difficulty in prosecuting a bacteriological investigation in this important organ. One does not lightly undertake an exploration of the interior of the globe in order to make cultures from materials so collected and thus prove the matter. In 1926, I was enabled by means of a grant from the Indian Research Fund Association and with the assistance of Mr. Theodore of the King Institute, Guindy, to undertake cultures from a large series of tissues removed from eyes at the time of operation. Our results are published in the Report of the Governing Body of the Indian Research Fund Association, 1926-27; they were negative. We had hoped to find some known organisms or perhaps some organism as yet undescribed in eyes either blatantly diseased or in a condition of latent infection. It was finally considered that the whole question of suitability of media would have to be reconsidered before pushing the investigation further. The chief endogenous organisms which have been so far isolated from or demonstrated in the eye tissues are those of syphilis, tuberculosis, leprosy, gonorrhœa and cerebrospinal meningitis, and *streptococcus viridans*.

With regard to toxæmias, here again the question must be considered as at least a two-fold problem. The toxin (?) circulating in the blood may prove injurious to the eye in general with the other parts of the body, e.g., as in arteriosclerosis, or it may have a special selective action on the intra-ocular tissues, and many think that tuberculosis is commonly an example. The toxin may even be developed locally as in the so-called iritis phakogenetica, where the products of lens krystallin degeneration (or chemical alteration) set up an irritative iritis. Naturally there may be hypersensitivity either in the organ or the individual.

One would think that the term focal sepsis ought to be restricted to localized areas of disease, determining pathological changes in distant or non-contiguous tissues by virtue of either the transportation of the causative virus or the toxins produced by its action. Ordinarily, the

term focal sepsis is used in connection with teeth, tonsils and sinuses, but here the majority of proven instances in my experience are of the nature of local spread along blood or lymph channels and generally unilateral, so much so that unilateral uveitis in a patient without any of the great systemic infections is more apt to have the focus close by. Again we do not usually start to discuss focal sepsis in ætiology until we have ruled out syphilis, acute gonorrhœa, or acute infective fevers like relapsing or rheumatic. Leprosy is not spoken of in connection with focal sepsis, but a localized distant area of tuberculosis or chronic gonorrhœa is. So that we use focal sepsis in current parlance in a mixed sense (1) where a hypothetical seat of disease of unknown area, location and cause is the possible source of the trouble under investigation, and (2) where an adjacent or distant localized area of known disease is the starting point, e.g., a frontal sinusitis or a localized area of pulmonary tuberculosis.

Abnormal chemical constituents in the bloodstream (or even the lack of normal constituents) may determine local eye changes which, in our ignorance, we are apt to ascribe to some particular diseased area elsewhere. If the eye trouble is not recognized as a clinical type, we turn to the possible foci and eliminate them, sometimes drastically. Should the condition abate, we claim a *propter hoc* result. Some of the radical procedures are harmless, e.g., tonsillectomy, others lamentable, such as the wholesale removal of teeth at present fashionable in some centres of learning. The removal of the large intestine has fortunately had a limited vogue. If we try to work back from the eye towards the source of trouble, we are faced straightaway with the possibility that apart from metastatic endocular conditions, the endothelium of the uveal capillaries may have done those things which it ought not to have done, or left undone those things which it ought to have done. If this is vague, it is no more vague than going further afield and blaming, for instance, chronic intestinal toxæmia. At least a method is available (that of Marx), which claims to determine whether the endothelium of the eye capillaries is functioning normally.

Of late the work of Duke-Elder has enabled us to think more concretely about the rôle of the capillary endothelium in its relation to the regulation of the fluid content of the eyeball. Numerous ophthalmologists had speculated in this field, and felt gradually being driven back to an ætiology which was determined by chemical changes in the vitreous, but it required especial training in methods of experimental research, associated with an intimate knowledge of physics and chemistry to deal with questions affecting the electro-dynamic equilibrium in the capillaries and surrounding tissue fluids in the way he has done, and to state the case for and against in scientific, unambiguous terms. It remains for the expert biochemist

and physicist with special ophthalmological training or the co-operation of an ophthalmic surgeon to try to elucidate similar complex problems, as for instance the determination of blood chemistry, intraocular chemistry and the changes in the intermediate capillary endothelium associated with the formation of senile cataract. This condition at present is but a name like primary glaucoma; we use the word senile to cloak our ignorance, for sensility *per se* does not produce cataract.

It is obvious, I think, that when we talk of focal sepsis as productive of certain eye conditions, we are hardly scientific unless we establish a fairly constant association clinically with a fairly constant beneficial result following our attack on the supposed focus in toxæmias, or, alternatively, unless we establish a definite bacteriological proof in endocular infections. In spite of enquiries and observations during the period of my trip West, it was disappointing to note that there is very little good evidence in favour of the obscure chronic infections of the uvea or other parts of the eye owing their origin to the so-called focal sepsis of alimentary origin.

TEACHING OF OPHTHALMOLOGY IN AMERICA.

One of my chief reasons for visiting the States was to see to what extent the teachings of Duane and Jackson in connection with refraction and muscle balance had influenced practice there. My intention of going might never have been fulfilled had it not been for the invitation of my friend Dr. John Wheeler, Professor of Ophthalmology, New York University, to whom, for his kindness and hospitality, I am deeply indebted. He not only allowed me to see his own work but made it possible for me to meet and see the work of numerous other distinguished ophthalmologists. It would be invidious to mention here the names of all those to whose generosity I am indebted; I can but acknowledge the unfailing courtesy of all those ophthalmologists with whom I came in contact.

In the time at my disposal I was able to visit New York, Washington, Boston, Baltimore and Philadelphia, and thus see something of ophthalmology as taught and practised in the Eastern States. I may say at once that in general the teaching and practice of refraction work and that in connection with the external muscles of the eye is considerably in advance of similar teaching in England and on the continent of Europe, although the practice sometimes falls short of the teaching. These subjects constitute by far the greater part of the ordinary ophthalmologist's daily work and it is of the utmost importance that a correspondingly large amount of his early training and subsequent study should be devoted to them. It is surprising how much time is spent even by distinguished ophthalmologists on the elaboration of some minor point of operative technique which has probably been in use elsewhere for years, or the invention of some superfluous instrument, to the apparent neglect of the more common and difficult but

more important problems in connection with errors of refraction and muscle balance.

The treatment of heterophoria and heterotropia is carried out along sound straightforward lines and operative work on the extrinsic muscles is freely practised for anomalies of convergence and divergence, elevator spasm and so on with excellent results, cosmetic and symptomatic. The technique in connection with muscle operations, such as recessions and resections, as practised in the leading clinics of New York is uncomplicated and efficient. In my opinion, time spent on refraction and such subjects with the undergraduate is mis-spent unless the particular undergraduate intends to take up ophthalmology as a specialty. This difficult branch of ophthalmology can only be mastered by prolonged study and practice, but naturally it is a great boon to the graduate who wishes to specialise in ophthalmology to obtain systematic teaching of an attractive and practical type rather than to spend years of work in a hospital refraction-room finding things out for himself.

Ophthalmology is a subject which, except for a few lectures and demonstrations, might readily be cut out of the modern undergraduate curriculum to make way for some of the newer departments of the basic sciences. It is a post-graduate subject but essentially one in which no deep knowledge can be acquired without an exceptionally good ground work of the basic subjects which there is hardly time to absorb in the course of the modern curriculum. It is necessary, therefore, even in the post-graduate teaching of ophthalmology to cater for anatomy, physiology, pathology including their foundations and their correlated subjects.

One of the finest courses of post-graduate teaching in the world, possibly the finest in several branches, is carried out in the Graduate School, Philadelphia, where a full course of three years is available under distinguished ophthalmologists who have carefully organized the teaching of the various subdivisions of the specialty. This course appears to me to be superior to any organized in England of recent years, in fact to any I have seen elsewhere. In illustration of the value of this teaching, I might perhaps mention two recent works which are the outcome of its organization and which will give an idea of the way in which some of the subjects are dealt with. I refer to "The extrinsic muscles of the eye" by Peter and "An introductory course in ophthalmic optics" by Cowan. The latter particularly shows how a difficult, and, to the ordinary eye specialist, uninteresting subject may be taught in an attractive way. As regards physiology those who keep in touch with current ophthalmic literature will be familiar with the work of Dr. Adler. I am indebted to the kindness of Dr. de Schweintz for bringing me in contact with many of the teachers in this school and with the department of ophthalmology in the University of Pennsylvania, where he formerly held the chair now occupied by Dr. Holloway. It will be obvious,

without further mention of subjects or names, what an important position the Graduate School of Philadelphia occupies.

PLASTIC SURGERY.

The plastic surgery of the lids and socket as carried out by Prof. Wheeler of New York is in a class by itself both in design and execution. It makes the work of Gillies which has excited the admiration of many, appear crude in this field (and I have had the opportunity of seeing both). His whole skin grafts to replace a lower lid are practically invisible in a fortnight. His technique for the reconstruction of a badly contracted socket is, in his hands uniformly successful. If Dr. Wheeler has made this field all his own, it is not to the exclusion of other important branches of surgical and medical ophthalmology. To have had the opportunity of following his work daily for a considerable period is an experience which it would be impossible adequately to record. The soundness of judgment embodied in his teaching was salutary, particularly in the adoption of a conservative attitude in connection with certain operative procedures where the best interests of the patient were served by some safe alternative. I understand that he is shortly to become Chief of the Clinic of the Ophthalmological Department of the new Medical Centre in New York, probably the largest centralized group of medical clinics in the world.

INTRACAPSULAR EXTRACTION.

Prof. Knapp's demonstration of his technique for removing the lens in its capsule left the impression that it was a simple and safe way of performing intracapsular extraction for those who consider that the Smith technique offers greater possibilities of trauma or who have not mastered the Barraquer procedure. It has been modified by many and is similar to that advocated by Prof. Sinclair of Edinburgh. Like the Smith and Barraquer techniques, it has a limited field of applicability. I believe every case of cataract must be taken on its merits. There is no universally suitable technique for the treatment of cataract if we appreciate what safety first must mean to our patients.

TRACHOMA.

The Rockefeller Institute is one of the great attractions to the medical man visiting New York, especially so to one from the tropics with a longstanding interest in bacteriology and tropical research. As an ophthalmologist what I wished to see most was Noguchi's work on trachoma; as a part-time research worker I was much more interested in the man himself. He very kindly gave me a whole morning although busy packing up for West Africa. He sailed a few days later never to return; the loss to medical science caused by his death, as by that of Stokes, who preceded him in that field, is inestimable. He explained how the idea had occurred to him

of getting successful transmission to the chimpanzee through cultures from trachoma cases rather than by direct transmission. At first it had seemed almost foolish to think that one of the very ordinary-looking organisms plated out from Indian (American) trachoma would produce any result when implanted on the conjunctiva, but in due course one of the isolated organisms, a short flagellated rod, did produce the appearances which he then demonstrated to me on the conjunctiva of the chimpanzee. Moreover, he was able to recover the same organism from the animal's conjunctiva, and the animal infected on one side transferred the disease to the sound eye.

The lesions in the chimpanzee were certainly indistinguishable from what many ophthalmologists would term trachoma and under the microscope the appearances were also similar. Some histopathologists no doubt might cavil at the preparations, but personally I was not inclined to do so as after long intimacy with sections of trachoma I have come to the conclusion that as yet there is no pathognomonic histopathological appearance in this disease or group of diseases.

Dr. Noguchi invited criticism, but it was obvious to me that the only efficient criticism was the confirmation of his work in other parts of the world. He had at all events definitely established the fact that organisms cultivated from human trachoma cases could produce a similar condition in not only the chimpanzee but *rhesus*. He considered the implantation with the cultured organism the key to the problem. In repeating his work, it would be necessary to acquire his technique with semi-solid media. For this I regret there was no time although I was anxious to make another attempt to investigate trachoma in India along Noguchi's lines in view of the negative results which Cunningham and the writer obtained in 1922 with direct implantation on the conjunctiva of the monkey (*sinicus*), and into the subdural space and testicle of the rabbit.

TISSUE CULTURE.

Dr. Kirby, whose work on the growth of the lens epithelium *in vitro*, will be known to most ophthalmic specialists (*American Academy of Oph. and Oto-Lar.* 1926), introduced me to Dr. Carrel in connection with whose department in the Rockefeller Institute this work had been fostered. He was also investigating the artificial production of choroidal neoplasms in chick embryos. The technique of growing living tissues *in vitro* is fascinating, but it would be impossible to go into the various aspects of the subject which interested me. Dr. Carrel kindly gave me a morning in his laboratory and explained the various types of technique. He discussed modes of cell growth, the nature of fibroblastic proliferation, the fibroblast and the macrophage, all of exceeding interest and importance from the point of view of histopathology. (Those interested might refer to the *Journal of Experimental*

Medicine, 1926.) He showed me sub-cultures from his original tissue growths which, it will be remembered, stimulated such universal interest in the English-speaking world when they were successfully started before the War. He is confident that work along the lines to which he had devoted himself will, at no very distant date, result in the elucidation of the cancer problem.

Cell growth *in vitro* and observations on the capillary circulation is a subject which has claimed considerable interest of recent years and rightly so, inasmuch as appearances which are seen under the microscope in fixed tissues or in tissues growing under artificial conditions are so liable to misinterpretation. It is of the greatest importance to the pathologist to know where the various cells concerned in repair processes come from, their relation to the endothelial elements of the blood and lymph vessels and the rôle of the different white blood cells and connective tissue cells in this respect. To the physiologist no less than to the pathologist, the behaviour of the capillaries is of intense interest.

In this connection, I was fortunately able to see something of the work of the Clarks and Sandison of Philadelphia which bids fair to overthrow some of the conceptions formed as the result of Krogh's classical researches (see *American Journal of Anatomy*, 1925-26). The technique of the Philadelphia workers is adapted to the observation of mammalian rather than reptilian tissues. The method adopted of implanting a transparent double-walled cell composed of two coverslip-like pieces of transparent material open at the sides, with a space between of 5 μ like a double window, in the ear of a rabbit, so that the living tissue is enabled to grow in between the faces of the cell, is one of the most ingenious pieces of technique I have ever seen. The animal's ear can be placed on the microscope stage and the behaviour of the tissues inside the transparent cell observed with the oil immersion lens. Continuous observation over prolonged periods, 24 to 48 hours, are thus rendered possible by two observers working and resting alternately. Under these circumstances, the behaviour of the capillary flow, of the endothelium of blood and lymph vessels, and of the so-called fixed connective tissue cells and Rouget cells may be continuously observed. The haphazard behaviour of the red cells in the capillaries reminds one of the appearances seen with the corneal microscope, with the movement sometimes in one direction sometimes in another, as if the stream velocity varied with the condition of the surrounding bed. Capillary contractility is apparently independent of Rouget cells or other adventitious cells and is a property of the endothelial wall. It was somewhat upsetting to have old beliefs, such as the power of the capillary endothelium to form fibroblasts, endothelial leucocytes, tissue macrophages, and foreign body giant cells, badly shaken. When the researches of these workers on the mammalian capillaries and cells (as distinct from the

reptilian) is concluded, it will form a great advance in our knowledge of tissue changes.

BRAIN SURGERY.

The ophthalmologist of to-day is, or ought to be, in a position of indispensable co-operation with the neurologist and brain surgeon. Through Dr. Derby's kindness I was enabled to pay a visit to Prof. Harvey Cushing's clinic at the Peter Bent Brigham Hospital, Boston, which emphasised the great importance of careful fundus examinations and field-taking to the brain surgeon. In an ophthalmic clinic of this kind where large numbers of brain tumour cases are dealt with, it is essential that the assistants should be expert ophthalmoscopists and capable of undertaking careful quantitative perimetry, and this is so. Dr. Cushing, Professor of Surgery, Harvard Medical School, kindly allowed me to see not only his technique but definite types of tumour or tumour-equivalent cases in the wards, and to examine their eye grounds. One could not help feeling on coming away from this magnificent embodiment of organized clinical research how far we have to go in this respect in India. As yet we are not in sight of the threshold. Numbers of cases such as I saw at the Peter Bent Brigham Hospital find their way to the ophthalmologist. Here I see relatively large numbers but one can do little or nothing for them because as yet we have no organization capable of dealing with brain surgery. The work of Cushing and his collaborators on the aqueous, as an analytical study undertaken in connection with their work on the cerebrospinal fluid (*Journal of Medical Research*, 1914 *et seq.*), led me to make enquiries along these lines. It is hardly necessary to go into this matter now as it would appear that Duke-Elder's recent researches have probably eclipsed this older work.

OTHER CLINICS.

In a visit to Boston in search of new ideas in ophthalmology, the centre of interest was naturally the Massachusetts Eye and Ear Infirmary. The activities of this well-known clinic, such as Dr. Derby's light sense research in the pre-glaucomatous eye, Dr. Verhoeff's pathological investigations, and Dr. Lancaster's work in the field of refraction, will be familiar to readers of ophthalmic literature. A brief, but highly instructive personal introduction to some of Dr. Verhoeff's wonderful material reminded me by contrast that the teaching of ophthalmological pathology had not appeared so prominent as many other post-graduate subjects. Apparently Vienna still holds almost a monopoly in the post-graduate teaching of this subject, but there would not appear to be any need for Boston students to wander far afield. I think post-graduate pathology suffers and has always suffered from the fact that it absorbs an immense amount of ill-paid time and effort and consequently it requires

a special and somewhat uncommon mentality of its devotees.

Some readers may not recollect that in the Massachusetts General Hospital, Boston, may be seen the room in which ether anaesthesia was first administered for a surgical operation and the actual sponge used on that memorable occasion. Close by in the clinic of Dr. Ayer a more modern procedure claimed my attention, namely, the method of cistern puncture as a diagnostic procedure. This technique not only enables one to gain more important information with regard to cerebrospinal fluid than lumbar puncture, but may also be used for the subarachnoid introduction of drugs in the treatment of intracranial affections associated with lues. Articles in connection with the latter subject have appeared in the literature during the last few years. Cisternal puncture, once the method is acquired, is no more dangerous and less trying to the patient than lumbar puncture. The two procedures, together with explorations of the posterior horns of the lateral ventricles under local anaesthesia through drill holes in the occiput, constitute valuable clinical methods in the investigation of conditions in which secretion, circulation or elimination of the cerebrospinal fluid is interfered with, and ought to be available in large clinics here.

Dr. Wheeler kindly arranged a personal demonstration by Dr. Uribe Troncoso of his new instrument for examining the angle of the anterior chamber, the gonioscope. It is difficult to judge of its value without prolonged observations, and so far the inventor has not published any extended work on its value as a diagnostic aid. It is certainly not so easy to use in ordinary cases as an instrument like the ophthalmoscope for it necessitates a contact glass on the cornea and all that this entails.

The photography of the eye grounds as a means of maintaining permanent records of changes which take place in the fundus has become an established clinical method. Although this procedure has been on a practical footing for a considerable time, it is only within the past few years that it has been taken up with any degree of enthusiasm by eye specialists. The various apparatuses now on the market, although expensive, are essentially practical and the method is useful not only in clinics, but also in private practice. The method will, no doubt, in the future occupy a permanent place in the literature in connection with eye ground records although in centres where ophthalmoscopic artistry is available (e.g., Hamblin's, London), it will be cheaper and more satisfactory for the specialist to send his private patient from time to time to have an accurate picture in colour made of the fundus.

The New Wilmer Ophthalmological Institute of the Johns Hopkins Hospital was in the making when Dr. Wilmer kindly extended his hospitality to me in Baltimore. It was interesting to see modern ideas with regard to practice,

teaching, and research applied to the organization and construction of the ophthalmological section of this great seat of learning. Dr. Wilmer, like a number of distinguished ophthalmologists, is a great believer in many of the obscure pathological events in the eye having their origin in a tuberculous infection elsewhere. It must be admitted that numbers of cases of endophthalmitis of one sort or another which are vaguely put down to focal sepsis have a tuberculous lesion somewhere in the body and appear to respond to anti-tuberculous measures. I was interested to see that specific therapy is used very very carefully. I have always regarded the specific therapy of ocular tuberculous lesions as a thing apart. Eyes may be rapidly lost if one carries out the ordinary methods advocated in the treatment of tuberculosis in other parts of the body.

All the latest mechanical aids to diagnosis are incorporated in this institution, which will be largely devoted to research, surgical, biochemical, physiological and pathological. The staff of workers had been collected and when I left, it only remained to have the various departments housed. Already work had begun and important papers had been issued, as for instance that of Woods and Burkey, on lens protein and its fractions. These authors found that α krystallin and β krystallin showed organ specificity just as whole lens protein, and they produced serologically pure fractional antigens. Under certain circumstances, the β krystallin undergoes spontaneous precipitation with resultant clouding of the lens; this is ordinarily prevented by the integrity of the α krystallin.

One cannot but notice the value of the social systems which co-operate with some of the great eye hospitals overseas. That in Boston particularly claimed my attention. Here, the social workers' organization was an integral part of the hospital system, and was housed in the hospital buildings. The follow-up system was elaborately arranged and house-to-house visiting enabled medical relief to be continued and applied not only in the case of the actual patient, but also to the other members of the family. For instance, cases of interstitial keratitis were kept under observation in their own homes, the parents were approached and the whole matter explained to them sympathetically, and lines of procedure were suggested.

NATIONAL INSTITUTE FOR THE BLIND.

I will conclude with a reference to the National Institute for the Blind, Great Portland Street, London. The Secretary kindly explained to me the system under which the care of the blind was organized in England and Wales. The elaborate machinery which has been evolved deals with a blind population of approximately 47,000 (about 70 per cent. of these are unemployable) and about £1,000,000 per annum is available for their welfare. Of this more than half is raised by voluntary subscriptions, the Ministry of Health and local bodies being responsible

for the rest. There are a number of institutions all over the country both for primary education, secondary education and industrial training. The institute in Tottenham Court Road is an example of the latter. Here one sees such instances of useful training as that of a man blind, deaf and dumb earning £2-10-0 per week. This institution does not nearly pay its way, as blind labour cannot compete with sighted labour. The staff of both voluntary and paid workers is naturally very large. It was pleasing to see that amongst those doing voluntary work of immense value were retired members of the Indian services.

It would seem that in India where there is crying need for organizations to deal with our blind, the great difficulties to be faced are lack of funds for the large blind population which, according to the Census report of 1921, amounts to 37,162 in the Madras Presidency alone; and lack of experienced administrators as voluntary workers willing to give up a large part of their time to this cause. If we take 70 per cent. of the Madras Presidency blind to be unemployable, at present the existing institutions do not deal with more than 2 per cent. of the remainder, and the voluntary subscriptions for this work do not amount to £2,000 per annum.

A NOTE ON THE EARLY HISTORY OF GRANT MEDICAL COLLEGE, BOMBAY.

By S. L. BHATIA, M.C., M.A., M.D. (Cantab.),

M.R.C.P. (Lond.),

CAPTAIN, I.M.S.,

Dean, Grant Medical College, Bombay.

IN the year 1835, Sir Robert Grant, shortly after he became Governor of Bombay, directed his attention to the desirability of establishing a medical school in this Presidency. He was deeply interested in this subject. As a preliminary measure he encouraged the spirit of scientific enquiry amongst the medical officers of the Government, and so the "Medical and Physical Society of Bombay" had its origin. Early in 1837, soon after this Society was founded, the attention of its managing committee was directed by Government to the subject of medical education. A former medical school in Bombay, the earliest of its kind in India, was instituted by Government under Mr. Elphinstone, but after six years of unsatisfactory existence, was abolished when Lord Clare was Governor. This was brought to the notice of the committee of the Medical and Physical Society, and it was asked to submit its considered opinion on the establishment of a new school. This time was well fitted for the proceedings of Sir Robert Grant. The Bengal Medical College which was started in 1835 had been in operation in Calcutta for two years and had achieved marked success. The committee of the Medical Society reported favourably, and Sir Robert Grant drew up a very able minute on the subject of medical education

in the Presidency, which advocated the establishment of a new medical school in Bombay. This minute was transmitted to Calcutta, then the capital of India, about the middle of 1838. It was approved by Lord Auckland's Government, but before this news reached Bombay, Sir Robert Grant unfortunately died. A public meeting was held in the Town Hall of Bombay on 28th July, 1838, at which a resolution was passed that a medical college be established in Bombay, which should bear the name of Sir Robert Grant. The Honourable Court of Directors of the East India Company sanctioned the scheme, and authorized that the proposed school be called Grant Medical College.

The fund subscribed by the public for this amounted to Rs. 44,800. The Court of Directors contributed an equal sum to defray the cost of the building. At last the foundation stone of the College building was laid on 30th March, 1843, by the Lord Bishop of Calcutta. It was completed in 1845, when it was handed over to Dr. Charles Moorehead, the first principal of the College, whose portrait is in the College Gallery.

With the College a teaching hospital was necessary. In 1838 Sir Jamsetji Jeejibhoy offered a sum of Rs. 1,00,000 on the condition that the Government offered an equal sum, the income from which was to be expended on a hospital for the treatment of the sick poor of all denominations. This proposal was submitted to Government shortly before the transmission of Sir Robert Grant's minute to Calcutta, and was noticed in a postscript to the minute, as calculated to facilitate the arrangements for the medical school. The Court of Directors acceded to the wishes of Sir Jamsetji Jeejibhoy and the committees which were to work out the details of Grant Medical College were also required to consider those of the proposed hospital, and to point out the most advantageous way of connecting the two institutions. As a result of this, it was finally determined to build the hospital in close proximity to the Medical College, and to designate it the Jamsetji Jeejibhoy Hospital. The foundation stone of the hospital building was laid on 3rd January, 1843, with masonic honours by R. W. the Provincial Grand Master of Western India, Dr. James Burns, K.H. The building was completed and was opened for the reception of the sick in the month of May 1845. The Indian General Hospital which was in existence before, was abolished, and its inmates were transferred to the new building.

Thus the College and the Hospital having been constructed, the curriculum commenced on 1st November, 1845, with 12 students. Drs. Charles Moorehead, John Peet and H. Giraud were the first three members of the staff, each in turn occupying the chair of the Principal.

The Memorial tablet in the main College Building bears the following inscription:—

"In the year of Our Lord, 1845, in the Reign of Her Most Gracious Majesty Queen Victoria,

under the Government of The Right Hon'ble Sir George Arthur, K.C.B., this building was erected at the Joint Expense of the Honourable East India Company and the friends of the late Sir Robert Grant, G.C.B., Governor of this Presidency, for the purposes of an Institution designated in honour of that Distinguished Statesman, the Grant Medical College, and designed to impart through a Scientific system the benefits of Medical Instruction to the Natives of Western India."

Its subsequent history for the last 83 years bears ample testimony to the fact that it has faithfully and creditably fulfilled the wishes of its founders.

Current Topics.

Sprue: An Analytical Study of 150 Cases.

By G. CARMICHAEL LOW.

(*The Quarterly Journ. Med.*, July 1928, p. 523.)

THE chief symptoms of sprue may be tabulated as follows:—

- (1) Loss of energy.
- (2) Loss of weight.
- (3) Dyspeptic distension of abdomen.
- (4) Morning diarrhoea. White frothy stools.
- (5) Sore mouth and tongue.
- (6) Anæmia, especially in the later stages.

Age.—The youngest case seen was 21, the oldest 75. Dividing up the ages into periods, the greatest number of cases occur in the middle period of life, broadly from 30 to 60.

Sex.—Many more males than females were seen, but I do not think that this means that the female is less susceptible than the male. The most likely explanation is that more males than females go abroad and consequently more of the former will be seen than the latter. In the series there were 112 males and 38 females.

Place of Infection.—The following table gives the details:—

China	27
Japan	1
Hongkong	4
Singapore	2
Manila	1
Federated Malay States	8
Penang	2
Burma	7
Assam	2
India	68
Ceylon	10
Bombay	7
Mesopotamia	1
East Africa	2
West Indies	1
Barbados	1
British Guiana	2
Mexico	1
Fiji	1
North Queensland (Australia)	2
				150

Previous Illnesses.—In 91 of the 150 cases, 61 per cent., a history of some debilitating illness was obtained. It is true that in many of the cases this had been acquired

some years before the symptoms of sprue developed, but in others a definite relationship between the two could be traced. There does seem to be a connection between the different forms of dysentery, hill diarrhoea, and possibly enteric, as predisposing factors. In two cases typical sprue developed on the top of amoebic dysentery, the stools definitely changing from those of dysentery to those of sprue. Syphilis also co-existed in a good number of the cases, and there is a definite condition which appears in that disease and closely resembles real sprue. This pseudo-sprue yields to anti-syphilitic remedies. I have had six such cases, but they have not been included in the 150 cases analysed because they are not sprue. The following table summarizes the conclusions:—

Amoebic dysentery	15
Dysentery, including bacillary and other forms	17
Dysentery and enteric	3
Dysentery and malaria	10
Enteric	5
Malaria	14
Diarrhoea	3
Hill diarrhoea	6
Syphilis	10
Sandfly fever	1
Dengue	4
Gastric influenza	1
Ankylostomiasis	1
Cholera	1
			91

Tongue Symptoms.—The inflammatory condition—the pathological syndrome of the disease—very frequently attacks the tongue, giving rise to a clinical condition of glossitis or, as it is popularly known, "sore tongue." When this occurs the organ is red, inflamed, congested, and very painful, the epithelium is destroyed, and often minute vesicles or little ulcers are seen along its margins. Alcohol, condiments, etc., cannot be taken owing to the intense pain they produce, and the irritation produced by the lesions may cause a profuse salivation.

On recovery from the acute or subacute manifestations the epithelium is seen to be denuded, leaving the tongue smooth and bare. It is now an ordinary colour and no longer painful. Exacerbations are, however, prone to occur with a renewal of the inflammatory changes. Finally, when complete recovery takes place, a new epithelium is developed and the tongue becomes covered again. In cases complicated with syphilis transverse fissuring is often seen, and patches of leucoplakia may appear, giving the well-known silvery tongue. This often gives the clue to the mixed infection.

Of the 150 cases, 101 had tongue lesions when seen, the symptoms varying in intensity and appearance with the state of the disease. The smooth bald tongue was common in the chronic advanced cases.

In most of the others, with the exception of 14, there had been a history of sore tongue or mouth at some period of the illness. The 14 (9 per cent.) had never suffered from tongue or mouth lesions at any time up to the time of being seen.

Mouth Symptoms.—These are similar to those of the tongue, the principal lesions being small superficial ulcers in the buccal mucosa. Patches of inflammation and congestion are also seen, these spreading back to the pharynx and even down to the œsophagus. Of the 150 cases, 44 were noted as having mouth symptoms at the time of the examination. One cannot, however, draw any hard and fast distinction between tongue and mouth lesions, most patients having one or the other at one period of the disease, and often both together.

In the series œsophageal symptoms, as evidenced by pain in swallowing, soreness and the feeling of a raw surface down the gullet were specially noted in 4 cases.

The teeth are invariably bad in sprue, pyorrhœa and root sepsis being very common. The part this chronic septic absorption plays in keeping up, or even aggravating, the symptoms is very important.

Diarrhoea.—The diarrhoea of sprue is peculiar. One of the earliest, if not the earliest, symptoms of the

disease is that it usually comes on in the early hours of the morning—from 3 or 4 a.m. onwards—the patient having to get up once, twice, thrice, or even oftener before breakfast. After this the rest of the day is quiet with no trouble, but next morning a repetition of the same thing takes place. After this has lasted for some time the characters of the stools change: they become very offensive, frothy, and of a white colour, the usual brown pigment disappearing.

As time goes on, and especially if the patient is not treated, the diarrhoea becomes excessive and occurs throughout the day as well as in the mornings. Twelve to fifteen stools a day may be passed, and rapid wasting now takes place. On strict diet and treatment the diarrhoea may be checked and then the stools become solid again, but without any colour in them.

The absence of colouring is interesting. Bile is still secreted, but the colouring matter, the bilirubin, is said to be changed in the intestine into a colourless substance known as leucobilin or leuco-urobilin. This is synonymous with urobilinogen. It is interesting that one of the signs of a return to normal is the gradual appearance of colouring matter in the stools again.

A chemical analysis of sprue stools shows great excess of fat, with the fatty acids in excess of the neutral fat, this indicating that a certain amount of splitting is taking place and that there is no pancreatic insufficiency in the sense of absence of lipase, but rather the reverse. Apparently, however, owing to lacteal destruction this is not absorbed, and is passed in the faeces unchanged.

The amount of fat varies, but may be as high as 70 to 80 per cent., with the fatty acids in the proportion of 5 to 1 of neutral fat, or even higher, up to 10 to 1. This helps one in diagnosing sprue from diseases of the pancreas, where the neutral fat is greatly in excess of the fatty acids, indicating a failure of the lipase ferment.

No parasitic helminths or protozoa are present, unless a mixed infection co-exists. The stools in the later stages of the disease tend to become very bulky, and food, if not of a proper nature, is passed undigested. The pathology of the disease explains the faulty assimilation that is taking place, for a large part of the intestine is out of action and cannot therefore absorb nutriment properly. Though careful and prolonged bacteriological researches have been conducted on the faeces in sprue, no specific micro-organism has been isolated. The possibility of a gastro-intestinal toxin as the cause of the disease cannot therefore

Out of the 150 cases a at some time or other, was obtained in 141. The majority actually had this when seen; others were in the remission stage, better for the time being, only to relapse again later; while others were convalescent and practically cured. In nine cases there was no definite history of diarrhoea, the tongue and mouth lesions, the wasting and blood changes, giving the clue to the diagnosis.

loss of weight. Here again the pathology explains this. Most of the absorbing surface of the small bowel is thrown out of action and the patient is being starved, though taking plenty of food. Finally, sufferers from sprue may become emaciated skeletons, with their ribs and other bones showing through the dry, atrophic skin with which they are covered. It was no uncommon thing for a man of 12 stone, say, to lose a quarter of his weight or more. Small people, especially women, may fall well under 6 stone. Loss of weight is constant and occurred in all the 150 cases. It was specially investigated in 100 of these, and losses of weight such as 4½ stone, 4 stone, 3 stone, and 2 stone were common.

Liver Dulness.—The liver is shrunken in sprue and the dulness to percussion is consequently diminished. This may be due to a special change in the liver itself, or only part of the general atrophy. Sokhey, Gokhall, Malandkar, and Billimoria (*Ind. Journ. Med. Res.*, XV, 1928, pp. 553–61) have studied thirteen cases to see if modern functional tests would throw any light on the efficiency of the liver in sprue. Their conclusions show "that in sprue the liver is not affected to such an extent as to show impairment by liver function tests." The following tests were employed:—Lævulose tolerance test, Van den Bergh reaction, nitrogen partition of blood, bromsulphalein dye test of Rosenthal and White (1925).

As has been said previously, bile is still secreted into the intestine. In the analysis, only 67 cases have been specially recorded as to the condition of the liver, but certainly, if looked for carefully, this shrinkage would be found to be commoner than the figures below indicate. Even then, 64 (42.2 per cent.) showed marked diminution of this organ.

Blood Condition.—In the early stages of sprue there may be no anaemia, but later, especially in the chronic cases, anaemia appears. In a certain type of case, which may be described as the "haemolytic type," a progressive loss of red blood corpuscles takes place, and a picture closely resembling pernicious or Addisonian anaemia develops. Many of these cases die with blood counts down to half a million reds per c.mm. or under. Though this is so, it does not mean that sprue is the same disease as pernicious anaemia, but it is possible that it is produced by similar causes, such as gastro-intestinal or other toxins. In the early and mild cases with little anaemia, the cure of the sprue cures the anaemia, and as long as the disease is cured or in abeyance the anaemia does not return. In the haemolytic types, however, even with apparent cure or at least amelioration of the symptoms, the anaemia may continue independently, and it is this class of case that resembles pernicious anaemia. The blood was investigated and counted in 114 of the cases: 7 cases were reported to have no anaemia, while 5 were reported anaemic but with no details of blood counts. An analysis of these counts shows the following:—

Under 1,000,000	1 to 2 Million	2 to 3 Million	3 to 4 Million	4 to 5 Million	5,000,000 or over	
1	7	14	43	45	4	= 114 cases

Flatulence and Abdominal Symptoms.—Flatulence with dyspepsia and gastric symptoms is one of the cardinal signs of real sprue. Due no doubt to the loss of tone in the intestine and the presence of many gas-forming organisms, this flatulence distends the abdomen until it becomes like a drum. It is very distressing and difficult to cure. In its absence the walls of the abdomen are seen to be soft and flabby, with little or no tone left in the muscles and with the panniculus atrophied away. This sprue abdomen is very characteristic. In the 150 cases there were 75 (50 per cent.) noted as having flatulence at the time of their examination. In fifteen definite abdominal pain was complained of, in four a general sense of discomfort only, and in one cramps in the abdominal wall.

Loss of Weight.—This may be taken to be a constant feature in the disease. No disease, with perhaps the exception of cancer, produces such a rapid and extensive

The leucocytes in sprue are about normal; where the anaemia is severe a leucopenia may occur, while in a few cases a leucocytosis may be met with, indicating some other infection.

Other Symptoms.—Symptoms other than those described as the classical ones of the disease were encountered in the series, some due to the disease itself, while others may have had little or no connection with it.

Of these, the following may be mentioned: Cachexia with pigmentation of face and skin; mental changes indicated by irritability of temper, fretful disposition, etc.; oedema of ankles and feet; pyrexia; dry skin; cramps in muscles and stomach; sudden vomiting (3 cases); appendicitis; haemorrhoids (common); petechial haemorrhages; stoppage of menstruation; auricular fibrillation; synconal attacks. Strangely enough, though tetany is described as a common symptom of sprue in all

text-books, it was not seen at all in the 150 cases analysed.

Treatment.—There is hardly any disease in which treatment is so important as in sprue, and unless the patient makes up his mind to undergo the drastic measures one has to adopt, there is no chance of curing the disease. Absolute rest in bed is the first essential, and no movements of any sort should be allowed for six weeks to two months. The patient must lie on his back and not get out of bed even to go to the closet. The bed-pan and bottle must be used. Diet is the second essential, and if one bears in mind the pathological lesions present in the intestines, then it will be apparent that, to begin with, the most easily digested and easily assimilated food must be employed, and in this respect nothing comes up to milk. The routine I adopt in sprue is as follows, and this was followed out more or less in all the 150 cases of the series.

It is best to commence with a comparatively small amount of milk until the diarrhoea and other acute symptoms disappear. Three pints of milk in the twenty-four hours will be found to be enough. The feeds should be given every two hours with the exception of 2 and 4 a.m., this making ten feeds a day, e.g., 6 oz. of milk per feed. On this alone the symptoms very quickly—almost at once in most cases—begin to improve; the diarrhoea ceases and the faeces tend to become solid. The weight, however, still goes on falling, as three pints of milk a day is not sufficient to maintain an adult's weight. Whenever signs of improvement appear, the milk should be gradually increased, and when amounts up to five pints are being taken and digested, the weight starts to go up. Progress as a rule now goes on without any untoward incident, and I gradually work up to a maximum of seven pints in the twenty-four hours. In small males and in females six pints may be all that can be digested. The total time devoted to the strict milk regime has generally been four to six weeks. If at the end of that time everything is satisfactory, then the gradual introduction of carbohydrates is begun. Sago or arrowroot may now be given. Later, eggs are started, first beaten up with the milk, then lightly boiled, then rusks and toast. By this time two months will have passed, and, if all is well, in the third month pounded fish, fruit in the form of bananas, pounded chicken, potatoes and spinach as a vegetable, may be given. A simple diet of this nature is continued as long as the patient is in hospital or in a nursing home, and then when leaving one should lay down a simple dietary which must be continued for the next six months at least. No irritating foods must be taken, absolutely no alcohol is allowed, and great caution must be observed against damp, cold, chills, and over-exertion.

Treatment has a marked effect on the blood. In early cases, as has been stated, there may be little or no anaemia. In later cases anaemia develops, but on drastic treatment being adopted this at once improves and the blood gradually returns to normal. In the hæmolytic types it is much more difficult to get improvement, however, and if the anaemia is in any way severe, transfusion of blood is undoubtedly the best method to adopt to cure this. This is well shown in the series of cases published by Dr. Cooke and myself (*Lancet*, 1927, 11, p. 960). In these a large quantity of blood, 500 c.cm. or over, was used, but more recently we have been trying small injections of whole blood, 10 c.cm. only, and in two cases this has seemed to supply the stimulus necessary to start the blood regenerating again. It must be borne in mind that sprue is one of the diseases in which auto-agglutination of the blood takes place, and special precautions have to be taken in transfusing to prevent bad effects appearing. It would seem that undue cooling of the blood is specially dangerous, and this must be guarded against. The grouping must also be carefully gone into.

Drugs may be employed, and of these arsenic comes first. It is best given by intramuscular injections, and the addition of iron is not prejudicial, but rather the reverse. Squire's arsenate of iron in doses of 7 minims every alternate day, or Fraise's preparation, can be employed. Iron is badly tolerated by the mouth in cases

of sprue, but some cases can take arsenic in the form of liquor arsenicalis (Fowler's solution) by the mouth, often with great benefit. The dose, small to begin with, should be gradually increased up to 7 or 8 minims three times daily, till signs of intoxication appear. After this a rest is given, this being followed up by another course, and so on. One of the chief signs of improvement, indicating that things are going well, is the gradual steady increase of the red cells. After the blood has returned to normal it should, however, be tested at intervals of two months or so, to make certain that the improvement is maintained.

Remarks.—From what has gone before it will be seen that sprue is a very important tropical disease, and an intestinal toxin, probably, best explains its symptomatology. Little has been said in the text about specific drugs. Yellow santonin had a vogue for a time, but personally I could never see any special results following its use. I have tried parathyroid and calcium lactate in a few cases not included in this series. The use of strawberries is remarkable in certain cases. It must be borne in mind, however, that some cases do not tolerate the berries, while in others they have no effect at all, and that it is only in a small group that occasionally wonderful results are met with. They should certainly always be given a trial when available. Lime would seem to be of value when the diarrhoea is present, and it may be given in the form of Batavia powder in drachm doses three times a day. This has been used in many of the cases analysed above. The so-called meat treatment has never given satisfactory results in my hands and is in every way inferior to the milk treatment. As regards going back to a tropical climate, we must consider each case on its own merits. It is better that such cases should not, but in certain instances necessity has compelled a return and no ill effects have arisen.

Warts and Their Treatment.

By A. C. ROXBURGH, M.D., M.R.C.P.

(*The Practitioner*, August, 1928, p. 80.)

THE essential feature of all types of true wart is a localised hypertrophy of the prickle-cell layer of the epidermis leading to a great thickening of this layer. Normally, mitoses can be seen only in the deepest or basal layer, but in warts mitoses can be seen in the whole thickness of the prickle-cell layer, showing that the cells are going on multiplying owing to some abnormal stimulus. In addition to mitoses, various degenerative changes can be seen which will be referred to later on.

If the thickness of one layer of skin is greatly increased the added tissue has to go somewhere, and the usual result is that in addition to the formation of a projection on the surface the interpapillary processes are elongated and widened. A great increase in the prickle-cell layer, the so-called acanthosis, leads, usually, to some degree of hyperkeratosis—thickening of the horny layer, and usually also to some parakeratosis—imperfect formation of horn cells, the cells still containing nuclei and tending to stick together as visible scales or flakes. If by pressure on the surface of the skin you forcibly prevent the increase of tissue from causing a projection on the surface, as it has to go somewhere it projects inwards and depresses the corium. Varying degrees and combinations of these secondary features account for the different varieties of warts.

The typical *plane* or *juvenile warts* common on the hands and faces of children are the simplest type of wart, and the type from which the other forms can be regarded as being derived by accentuation of one or another character. These plane warts are small, smooth elevations two or three millimetres across and perhaps half a millimetre high, and are the colour of the normal skin. They often occur in great numbers on the hands and faces of children. When looked at with a lens the surface can sometimes be seen to be not truly uniform, but showing a slight degree of "raspberry" appearance. Structurally they consist of a moderate thickening of the prickle-cell and horny layers with a moderate and fairly regular lengthening of the papillae caused by the downgrowth of the interpapillary processes.

The common wart is a development of the type of the plane wart, and is often found on the hands of children who have plane warts on their faces. Here the inter-papillary pegs of the prickle-cell layer have become much more pronounced and often irregular, the papillæ being drawn out between them; and the individual papillæ are more distinguishable on the surface, each with its cap of horny layer. In the common wart there is a considerable degree of lengthening of the papillæ and a considerable degree of hyperkeratosis.

The plantar wart is similar to the common wart except that, owing to pressure (as it occurs on the sole of the foot or heel) the lengthened interpapillary processes are forced inwards so as to invaginate the corium, and they become surrounded by a thickened ring of epidermis. The opening of the pocket containing the wart is narrower than the bottom of it as a rule. Owing to pressure on the nerve endings below, these plantar warts are very painful, just as corns are. They are often mistaken for corns. They occur chiefly under the ball of the great toe or under the pad of the toe itself and on the heel.

The filiform wart is found on the neck and chin, on the scalp, where it is often digitate, and on the genitals, where it takes the form known as *condyloma acuminatum*, and is often misnamed venereal or gonorrhœal wart. It is derived from the type of the plane wart by an enormous stretching of the papillæ, due to the very active growth of the cells of the prickle-cell layer, the horny layer being very thin. Apparently the warmth and moisture of regions upon which condylomata acuminata flourish have something to do with their characteristic profuse vegetative growth. It is a complete misnomer to call them venereal or gonorrhœal warts, for, as Charles W. Cathcart of Edinburgh was one of the first to show, they have no necessary relation whatever with gonorrhœa or other venereal disease. When I was in part charge of the V. D. clinic at St. Bartholomew's Hospital in the year 1920 we had nineteen cases with warts on the genitals (twelve male and seven female). Gonococci were found only in seven out of the nineteen, which equals 36.8 per cent. K. Brandes reported thirty-eight patients with *condyloma acuminatum*, of whom twenty-six had *verruca vulgaris* as well. More than half had no gonorrhœa. In the patients who had gonorrhœa the warts followed two to five months later. This interval is similar to the incubation period of experimental inoculation with *verruca vulgaris*. The question therefore arises, Did they get inoculated with warts at the same time as with gonorrhœa? In the non-gonorrhœal cases *verruca vulgaris* sometimes preceded the condylomata.

There is some doubt whether the senile or so-called seborrhœic wart has or has not the same etiology as the types of wart I have already described. Kyrle classes it with the others, and I shall so regard it. This wart is a rather flat, brown elevation on the skin of the back, trunk or face of middle-aged or elderly individuals.

Hoffman has described two cases of what he considers to be *generalized verrucosis* of the scalp, and what are probably other cases of the same nature have been described by others.

With the possible exception of the senile or seborrhœic wart, all the above types of wart—plane common, filiform and *condyloma acuminatum*—are due to one and the same filter-passing virus. It is well known that warts are infectious and inoculable; and there is the popular belief that, if you make a wart bleed, wherever the blood goes the patient will get a fresh crop of warts. One often sees a line of warts on the face or hand of a child obviously following a scratch. Numerous investigators have worked at the etiology of warts.

TREATMENT.

Common Warts. Chemical Caustics: Nitric Acid.—This should be applied by the medical man and not left to the patient. It is a good plan to protect the surrounding skin with vaseline and then to apply a drop of the caustic to the whole surface of the wart. This is allowed to soak in and then another drop may be applied, according to the size of the wart. Be careful not to use too

much. In four to seven days cut away with a sharp scalpel all the yellow dead tissue, but stop short of causing bleeding; re-apply the acid as before. Proceed in this way until the wart has entirely gone. Trichloroacetic acid and acid nitrate of mercury may be used in the same sort of way. The advantage of nitric acid over CO_2 snow for warts on the hands is that no blister is formed, and no raw area is left, but, on the other hand, it may produce more scar.

CO_2 Snow.—The advantages of this are that one application may cure a wart and little scar is left, but the drawbacks are that the patient may have a blister for a few days and may knock it off and be left with a small raw area which, in the case, for example, of doctors and nurses, is a disadvantage. If the degree of freezing has been exactly right the wart will drop off in about two weeks without any visible blister being formed. On the other hand, if the freezing has been insufficient nothing will happen at all. If the wart has a hard horny surface soften it first with liquor potassæ, applied with a match, for ten minutes, and then take a stick of CO_2 snow, compressed as hard as possible, and shaped so as exactly to fit the wart and not overlap it at any point. Then apply the pencil of snow with firm pressure until a ring of frozen tissue appears all round the wart. If this ring has not been in contact with the snow its appearance indicates that the wart has been frozen right through, and is a better guide than timing the application. Usually this takes one to two minutes.

Burning off the warts with the galvano-cautery under novocaine is the quickest way to remove a crop of warts, and obviates the bleeding which is associated with curetting. I think this point is of some importance as reducing the risk of fresh inoculation. As much of the burnt tissue as possible should be scraped away, short of causing bleeding.

Another rapid method is by electrolysis or zinc ionization. The needle (if of steel, negative, and if of zinc, positive) is used to transfix the base of the wart in several directions so as thoroughly to thrombose the vessels. The wart is then cut off cleanly with a sharp scalpel. A current of two milliamperes is used, and novocaine is not essential, although its use allows one to use rather more current.

In cases with a large number of common warts—on the back of the hand, for example—a pastille dose of X-rays unfiltered, to the whole area, often causes the warts to disappear. If one dose is insufficient it may be repeated once in four or five weeks. Common warts at the edge of the finger-nails are sometimes very troublesome to get rid of. The best treatment is probably by radium or X-rays; of the latter I usually give two pastille doses, unfiltered, in one sitting, through a hole in a piece of lead foil, which is cut exactly to fit the wart. The lead foil should have some adhesive strapping on its deep surface to cut off the secondary rays given off by the lead under the influence of the X-rays.

Plane Warts.—If few in number these may be touched by the patient daily with glacial acetic acid. They are usually too small and too numerous to make CO_2 snow practicable. They may be painted every day or two with salicylic acid 12 per cent. in collodion, the collodion film being washed and rubbed off before each new application. A patient with plane warts on the shaved area of the face should apply a hydrarg. perchlor. lotion, 1 in 2,000, after every shave for some months to prevent recurrence. The galvano-cautery at a very dull red heat may be used lightly without novocaine in some patients with plane warts, with good results. But there is little doubt that by far the most satisfactory treatment for a crop of plane warts is by X-rays; three-quarters to one pastille dose, unfiltered, is given to the most thickly infested areas, and very likely the less affected areas will then clear up without treatment, owing presumably to some antibody being formed as a result of the absorption of those warts actually exposed to the X-rays. This dose may be repeated, if necessary, in a month or five weeks.

Filiform Warts.—These are best treated by transfixion of the base by an electrolysis needle to thrombose the vessels, the wart being then simply cut off, as in the

case of common warts already described. Novocaine and cautery or zinc ionization can also be used.

Digitate Warts.—These are common on the scalp and can be treated in the same way as filiform warts or very successfully dealt with by applying about one drop of strong nitric acid to each. Do not use too much or at the patient's next visit you will be surprised to find a hole of unpleasant depth in the scalp. These warts have a great capacity for absorbing nitric acid. Glacial acetic acid is safer, but not so rapid.

Condylomata Acuminata.—These are best dealt with by cutting them off with a galvano-cautery under an anæsthetic, which may be local or general, according to the size and situation of the warts. The sites should be kept clean and dusted with, say, acid salicylic 1 part, talc powder 3 parts, until healed. Small condylomata acuminata can be quite successfully dealt with by rubbing with the solid silver nitrate stick, and they are in my opinion about the only kind of wart which can be treated successfully with silver nitrate.

Plantar Warts.—As I have already said, these are only common warts which, owing to the pressure against which they grow, have become invaginated into the sole of the foot. There are two successful methods of treatment, and in my experience only two. The quickest is to scrape out the wart ruthlessly with a Volkmann's spoon under a general or local anæsthetic. After some pretty vigorous work with the spoon you will find that the wart shells out nicely, leaving a smooth walled cavity whose size and depth will probably surprise you. The mouth of the cavity may be a good deal narrower than the deeper part, and the thick epidermis forming its walls must now be clipped off with curved scissors until it slopes gently away from the deepest part of the cavity. The wound is then mopped with silver nitrate solution 15 grs. to the ounce, or with tincture of iodine, and dressed with gauze soaked in tincture of iodine. After a couple of days the original dressing is removed and the wound dry dressed till healed. There is little or no pain after this operation, and although some patients prefer to rest the foot for a few days all do not do so. Occasionally as the hole heals up a small horny plug is found in the centre. This is quite superficial, and should be removed by paring once or twice just as though it were a corn. I have never seen a painful cicatrix follow this method of treatment.

The only other successful method of dealing with plantar warts that I know is by means of X-rays. These should be applied as follows. The wart is pared with a sharp scalpel as far as possible, short of pain and bleeding. This is mainly to get an idea of the real area of the wart which is usually much larger than appears from the surface. A hole is now cut in a piece of stout lead foil corresponding in size and shape with the estimated real size of the wart. The foil is backed with strapping and then secured firmly to the skin with more strapping so that the wart appears exactly in the hole cut for it. Two or three pastille doses of unfiltered X-rays are then given, at one sitting, to the wart, using a lead glass applicator whose opening must be smaller than the area of the lead foil, so that there is no chance of the healthy skin getting the heavy dose intended for the wart only. After the X-rays the patient should wear a thick piece of felt, adhesive on one side, with a hole cut in it, to relieve pressure on the wart, on the lines of the common corn plaster. Usually within three to four days all pain ceases and the patient forgets about the wart. In a month or six weeks it may be pared or scraped and will often be found to be entirely removable without any pain or bleeding. It often happens, however, that one dose of X-rays, even of three pastilles, is not enough and further doses must be given. This is no doubt due to the filtering off of the rays through the horny superficial layers of the wart.

The X-ray treatment of plantar warts is, certainly the method which gives least trouble to the patient, but its results are not so rapid or so certain as removal by scraping in the manner I have described. Radium, if available, can be used instead of X-rays.

"Seborrhæic" or "Senile" Warts.—These rough brown or black elevations are easily removed by freezing with CO₂ snow, or by painting with pure carbolic acid, once or twice, as may be required.

I shall now refer briefly to some other warty conditions which are not related to the true warts so far as we know.

The so-called *post-mortem wart* (*verruca necrogenica*) is due to direct implantation of the tubercle bacillus in the skin by accidental prick or injury. It consists of tubercles, with giant cells and tubercle bacilli, in the deeper layers of the skin with, sometimes, miliary abscesses. There is an infiltration of small round cells beneath the epidermis and some dilatation of blood vessels. There is also a secondary hypertrophy of the prickle-cell and horny layers leading to a warty appearance. The best treatment is excision or destruction by cautery, if small and acute. If chronic or large, X-rays, radium, Finzen light or selective caustics such as pyrogallol acid, locally, together with general carbon arc light baths.

The *keratoses* on the face and hands seen in elderly people, especially in those who have been exposed for many years to strong sunshine, and which form part of the picture known as "sailor's skin" or "senile skin," can be removed by the galvano-cautery, curetting or by CO₂ snow. If any of them show a tendency to rapid growth it is probably better to excise such completely, in case they should be developing into epitheliomata. The same applies to the warty growths which occur in chronic X-ray dermatitis and to the keratoses seen in men who have worked for many years with tar, or crude mineral oils, or who have taken arsenic over long periods, for example for psoriasis. Radium also may be used for the treatment of the above types of keratoses, even for those in chronic X-ray dermatitis.

Radium Implantation in Œsophageal Cancer.

By JOSEPH MUIR.

(*Laryngoscope*, 37: September, 1927, p. 660.)

CANCER of the œsophagus is generally regarded as the most hopelessly incurable of malignant lesions. None of the forms of treatment which have proved successful in combating cancer elsewhere in the body have heretofore been possible of application to the œsophagus. Radium has been less beneficial than surgery. Three prime drawbacks to this use of radium have always existed: first, the difficulty of placing it accurately; second, the practical impossibility of maintaining it in position long enough to be effectual, and third, the great danger of burning the tissues, which will induce sloughing and fistula into the mediastinum—invariably a fatal accident.

To obviate these difficulties the author has elaborated a technique of radium implantation through a specially designed œsophagoscope which can be readily carried out by anyone experienced in the use of this type of instrument. The field of operation is illuminated and an implantar passed through the tube, so that each radon seed may be placed in full view, and the entire lesion accurately mapped out and evenly implanted. The radioactive centre employed is a removable platinum radon seed, which offers the double advantage of being so screened that it will not induce necrosis, and the possibility of removal by means of an attached thread so that no foreign bodies are left in the tissue after the contained radium emanation has entirely decayed. The entire procedure is facilitated if done under the fluoroscope, though this is not absolutely essential.

The results in the small series of cases so far treated by this method have been highly gratifying, and although no permanent results can be reported before the lapse of five years, the author feels that the method merits a wide trial, even if it proves to do no more than prolong lives which otherwise will be very shortly terminated.

Reviews.

SELECTED PAPERS ON INJURIES AND DISEASES OF BONE.—By Sir William Ireland de C. Wheeler, M.D., F.R.C.S.I., F.A.C.S. (Hon.). London: Baillière, Tindall & Cox, 1928. Pp. xx plus 148, with 100 figures in the text. Price, 10s. 6d. net.

THIS book is a reprint of papers which have appeared in various journals. The first four sections are a synopsis of a series of lectures on fractures of the bones of the lower extremity which were given for the University of London at St. Bartholomew's Hospital and are an excellent epitome of the most modern methods. The results which can be obtained in cases of mal-union without open operation by refracture and powerful extension are well illustrated by the cases described, in two of which secondary displacement occurred owing to the limb having been actually over-elongated, leaving a gap between the two ends of the fractured bone though the alignment was perfect. To convert a shortening of $3\frac{1}{2}$ " of three months standing into a lengthening of $\frac{1}{2}$ " is testimony to the efficiency of the extension methods employed. The remaining papers deal with a variety of subjects, a modification of Albee's operation for fixation of the spine, with which the author has had considerable success, though he is in agreement with the general view that these operations are not indicated in children; a method of approaching the sacro-iliac joint without disturbing the posterior sacro-iliac ligament and two papers on bone grafting which contain many valuable observations and hints, to mention only the most important. All the papers in this little volume are of interest especially to post-graduate students and candidates for higher examinations.

W. L. H.

TREATMENT BY MANIPULATION.—By A. G. Timbrell Fisher, M.C., F.R.C.S. (Eng.). Second Edition. London: H. K. Lewis & Co., Ltd., 1928. Pp. xii plus 200, with 62 illustrations. Price, 9s. net.

THE first edition of this book under the title "Manipulative Surgery" was a welcome contribution to surgical literature and the appearance of a second edition so soon is evidence that at last the medical profession has begun to take an interest in this neglected branch of surgery. Bone setters thrive on cases which have been improperly treated in the first instance and if all students were instructed in the principles laid down in this book, the stream of cases which drift into the hands of quacks would soon diminish and dry up. A vast literature exists dealing with the pathology and treatment of joints stiffened or ankylosed as the result of disease or major injury, but very little attention has been paid to minor injuries and their results. Dismissed in the text-books with a brief paragraph, usually enjoining rest and fixation followed by passive movement, it is no wonder that the practitioner is at a loss what to do when this line of treatment leaves a stiff and painful joint liable to give way suddenly from muscular weakness. If he follows the traditional teaching he will probably immobilise the joint again, thus aggravating the symptoms and losing his patient who will eventually be cured by someone else breaking down the adhesions which were the cause of the trouble. The pathology of these cases is well set out in the opening chapters of the book and the detailed directions for manipulating each joint are preceded by an account of its anatomy, range of movements and the usual indications for this form of treatment. The value of the book to practitioners would be much enhanced by a short chapter on the treatment of sprains and contusions of joints when seen soon after the injury, the period when prevention of adhesions depends on the line adopted.

In the present edition the sections on osteopathy, tennis elbow, chronic arthritis and the lesions of the sacro-iliac joint have been enlarged and many case-

histories added, too many perhaps, for some of them contain too little detail to be of much instructional value. The book can be heartily recommended both to practitioners and students, but to those who have not had much experience in orthopaedic work in this country it is as well to add a word of warning, lest they be led into disaster. The stiff joints most often met with are due to septic processes in or around the joint or to chronic arthritis of gonorrhoeal or infective origin of long standing, which have led to profound intra- and extra-articular changes. The greatest caution is necessary in manipulating such joints, as acute inflammation is very likely to be lighted up by forced movement and the restoration of mobility must often be sacrificed in order to ensure a stable limb capable of weight-bearing. The section on "pros and cons of treatment of chronic arthritis by manipulation" on p. 35 should be read and pondered before tackling such cases. Considerable experience is necessary to decide in which cases the attempt to restore movement is likely to succeed.

W. L. H.

THE EYE.—By C. W. Rutherford, M.D., F.A.C.S. First Edition. New York and London: D. Appleton & Company, 1928. Pp. 404, with 12 original coloured plates and 305 black and white figures.

THE author states in his preface that the work is primarily intended for the general practitioner and student of medicine and that he has endeavoured to combine the advantages of a work of reference and of a teaching text. The arrangement of the book is such as to facilitate ready reference. The table of contents is full as also the index, and the subject matter covers practically the whole field of ophthalmology as dealt with in the larger text-books. In the reviewer's opinion the actual amount of information given under any one head is hardly what one would expect in a book of reference, but as a teaching text it undoubtedly fills a position in ophthalmic literature which is somewhat exceptional. The book should be of special value to the teacher who wishes to present his subject completely without unduly labouring certain sections to the neglect of others and who desires to give a survey of his subject in perspective, without taking his hearers into channels too remote from practical clinical considerations. In some respects it resembles a compilation of grind notes in ophthalmology for students and junior post-graduates rather than a text-book in the ordinary sense of the word. In style it is terse, controversial points are not laboured, and references to literature are few. The arrangement is convenient. Each sub-division of the eye is dealt with separately as regards its essential anatomy and its diseases, with the investigation and treatment of the latter including operative procedures. Chapters VII and VIII deal briefly with special methods of investigation, namely, ophthalmoscopy and perimetry and fall into their proper places in the text so that the reader is familiarised with these methods before their application is discussed. The teaching ought to prove acceptable to centres of ophthalmic education in India as the views expressed are in the main very similar to those taught in this country. Of the operative procedures described perhaps more than a fair share of space is devoted to those for ectropion and entropion. This being so, eye surgeons in the East will be disappointed to find no mention of Webster's operation. The plates are excellent, but as in most books on the eye some of the figures are indifferent, e.g., figure 188. The repeated mention of White's ointment may perhaps puzzle readers who are not acquainted with its composition. It is a much weaker preparation of Hydrarg. perchloride than the ointment popular in India. The author's approval of the discharge of cataract patients after 10 days would not meet the approval of many operators in India, but presumably it is safe practice in America. Transillumination of the globe in negro eyes is said to be difficult. One does not often see a reference to this fact in ordinary works on ophthalmology, but the same difficulty holds in our Indian clinics. Retained foreign bodies and their treatment, a subject which forms the major portion of the chapter on the vitreous, contains a vast amount

of valuable information in a small space. Embryological details are sparse and corneal microscopy is not dealt with. Indian readers might reasonably expect a more prominent mention of epitheliomata of the lids and limbus which are amongst the commonest new growths associated with the eye in this country. Prolapse of the iris is mentioned as an "occasional complication." This perhaps hardly does justice to one of the most serious bugbears of cataract work which occurs in most big operating centres in from 2 to 4% of the cases of cataract extraction. It is perhaps surprising to see mention of such a moot subject, and one so liable to be misunderstood without full explanations, as the non-surgical treatment of cataract. It is not clear why the author advises that yellow oxide should not be used at the same time as dionine. Muscles and refraction are dealt with simply and well. Chapter XIX, the last in the book, is exceptionally interesting and valuable in India just now as, under new legislation in connection with Workmen's Compensation, questions are continually cropping up with regard to degrees of eye injury for which there is no precedent to help the medical witness. It deals with "Industrial injuries, their compensation and simulation." The statements made therein carry the high authority of the recommendations of the Committee appointed by the Ophthalmological Section of the American Medical Association, the report of which was approved by the House of Delegates. The Committee's supplementary report published as recently as 1927, has been followed by the author. Those interested should read this chapter for themselves. It will be sufficient here to quote the following:—"Visual efficiency, industrially considered, is based on three co-ordinating functions or factors which are measurable, and on which percentages may be calculated. These are the acuity of central or macular vision, the field of vision, and the muscle or motor function for maintaining binocular single vision in the field of binocular fixation. Other defects may be present, but they are not measurable." The author proceeds to show how such defects may be expressed in percentages. The advantages of such a system are obvious. A description is given of various tests for malingering and simulation. The book is of convenient size, the print is good and it is well got up and produced. The author is to be congratulated on having brought out on new lines a work which will fill a place of its own in ophthalmic literature and for which many clinical teachers will be indebted to him.

NASAL NEUROLOGY, HEADACHES AND EYE DISORDERS.—By Greenfield Sluder, M.D., F.A.C.S. St. Louis, U. S. A.: The C. V. Mosby Company, 1927. Pp. 428, with 167 illustrations, including 2 coloured plates. Price, \$11.50.

DR. GREENFIELD SLUDER in his book "Nasal Neurology, Headaches and Eye Disorders" has set out to explain certain varieties of nasal disease which have as symptoms:—

- I. Headache,
- II. More or less eye disorders,
- III. Neurological phenomena that are evidently of nasal origin or are controllable by nasal treatment, to wit:—
 - (1) Closure of the frontal sinus without suppuration.
 - (2) Anterior ethmoidal neuralgia of the naso-ciliary nerve.
 - (3) The syndrome of nasal ganglion neurosis.
 - (4) The picture of hyperplastic post-ethmoidal-sphenoidal inflammation.
 - (5) Some neurological phenomena that are apparently not of nasal origin and are controllable by nasal treatment.
 - (6) Orbital phlegmon.

Pain in the head is gone into thoroughly and all the five points for distinguishing a pain due to the closure of the frontal or closure of the anterior ethmoidal cells or affection of the nasal nerve or affections of the nasal ganglion, are given with great care. Apparently some inflammatory condition of the sinuses, either known or unknown to the patient and often difficult of detection by the surgeon is or has been present. The syndrome

of nasal ganglion neuroses is gone into at great length, and Sluder would have us believe that such diverse conditions as writer's cramp, diarrhoea, glossodynia, photophobia, earache due to cancer of the larynx, corneal ulceration, abdominal pain and a host of other conditions may appear as symptoms due in some way to an affection of the nasal ganglion. No satisfactory explanation is, however, given for these various manifestations of disease in this neighbourhood. The ganglion is treated either by painting with 2% silver nitrate or by injections of phenol-alcohol. The injection method, however, has its dangers. The internal maxillary artery is in close relationship with the ganglion and a case is recorded where the carotid had to be ligated for bleeding from this source. Apparently trouble from hæmorrhage is negligible for Sluder says, "The number of bleedings in my experience has been few." Other dangers appear to arise from the alcohol reaching and paralysing the oculomotor, abducens and even the optic nerves, but as Sluder also tells us that "As is well known the anatomy varies in practically every nose" the method strikes one as being fraught with danger.

In dealing with hyperplastic sphenoiditis all the conditions which may result from the implication of the nerves of this neighbourhood are gone into, and the diagnosis, prognosis and the author's operative technique are fully given.

The book is to be regarded as one full of interest and full of ambitious speculation into much that is abstruse in the pathology of the many obscure phenomena described. It is worthy of serious attention and ought to be a stimulus to further research on the subject.

DISEASES OF THE NOSE, THROAT AND EAR, FOR PRACTITIONERS AND STUDENTS.—Edited by A. Logan Turner, M.D., LL.D., F.R.C.S.E. Second Edition. Bristol: John Wright & Sons, Ltd., 1927. Pp. 440, with 234 illustrations and 12 plates. Price, 20s. net.

THIS compact text-book deserves the greatest praise. It is well arranged, well balanced, and for a plain statement of the case without embellishment with fads and fancies, is unbeaten. There is not one chapter in this book which is not crammed full of useful information, no undue stress is laid upon any section, and each chapter takes its own place in the picture. The book undoubtedly is the expression of the Edinburgh school of oto-rhino-laryngology, and contains evidence of its latest work. The chapter upon the ear is particularly good and for its size is beyond reproach. One would heartily recommend this book as being something more than an ordinary text-book on the subject.

Annual Report.

ANNUAL REPORT AND STATISTICS OF THE GOVERNMENT GENERAL HOSPITAL, MADRAS, FOR THE YEAR 1927, BY LT.-COL. E. W. C. BRADFIELD, I.M.S., SUPERINTENDENT, GOVERNMENT GENERAL HOSPITAL, MADRAS. MADRAS: GOVERNMENT PRESS, 1928. PRICE, Rs. 9.

THE practice of incorporating short case histories in the annual reports of the Government General Hospital, Madras, makes these publications extremely interesting and the 1927 number is no exception.

Admission and Accommodation.—During the year 66,505 out-patients and 13,158 in-patients were treated at the Government General Hospital, or a daily average of 459.94 out-patients and 531.15 in-patients.

The results of treatment of in-patients are:—

	Non-Europeans.	Europeans.	Total.
Cured ..	5,614	1,136	6,750
Relieved ..	2,857	333	3,190
Otherwise discharged	1,732	163	1,895
Died ..	769	92	861 (6.54 per cent.).

The number of Indian in-patients treated during the past ten years shows a steady increase and the slight decrease of Europeans is accounted for by the accommodation now available in other city hospitals.

Professional Work.—The following shows the total operative work done between 1st January and 31st December 1927:—

Number of patients remaining on 1st January 1927.	Number of operations during the year.			Result of operations.				Number of patients remaining.
	Primary.	Secondary.	Total.	Cured.	Relieved.	Otherwise.	Died.	
139	7,169	151	7,320	6,455	444	58	286, i.e., 3.91 per cent.	65

It is interesting that there has been a gain of nearly 6 days in the treatment of surgical cases, although the number of operations performed in recent years has been more numerous and cases especially in abdominal and gastric surgery, have often required prolonged post-operative treatment; while the time required for the complete treatment of a medical patient has remained much the same as in 1918. Septic complications are the most frequent cause of prolonged stay in hospital and their elimination from the operative results is due partly to better team work but largely to a cleaner, more airy hospital and improved nursing.

A fractured limb often demands prolonged in-patient treatment and is a heavy charge on a hospital administration. A very moderate estimate suggests that motor accidents are costing the hospital from Rs. 15,000 to Rs. 20,000 a year.

Epidemics.—Fourteen cases of cholera among non-Europeans and five cases among Europeans were treated during the year, nine of whom died in the hospital.

Training of Medical Students.—Two hundred and fifty-three students were given clinical instruction in 1927 as compared with 232 in 1926.

During the year the clinical teaching of students has been entirely reorganized and remodelled on the lines obtaining in British medical schools. During their three years' clinical training students now hold definite appointments as Clerks or Dressers, at first, in the wards, where for twelve months they learn the rudiments of Medicine and Surgery and later in the Out-patient and Special departments. Final year students may follow any of the Medical staff on their daily ward visits and must attend the daily clinical lecture which is given by one of the Physicians or Surgeons.

To meet these requirements, the Out-patient Department has been re-organized. All patients are sorted by a junior member of the staff and are seen by the Assistants of the Hospital Physicians and Surgeons in the Medical and Surgical Clinic. Each Assistant attends from 7-30 to 9-30 on the admission day of his Chief for the purpose and is assisted by the students attached for duty. This institution of out-patient clinics has worked extremely well and has enabled the regular out-patient staff to pay more concentrated attention to all emergent cases attending the hospital.

The newly constituted Ear, Nose and Throat Department under Dr. Cherian, and the Special (Venereal) Department under Dr. Ramakrishnan are both well

organized and doing very valuable work. Orthopaedics are now treated by the Surgical Registrar on two days a week and though the scope of this department is limited in India, it has worked very successfully. All fractures attending the Out-patient Department are referred to the Surgeon-in-charge for continuous treatment.

These new departments have entailed redistribution of the very limited accommodation available, and so far as was possible, the building has been well adapted to the change under the direction of the Resident Medical Officer, Major D'Souza.

Buildings.—The acceptance of the scheme for rebuilding and remodelling the General Hospital on its existing site has necessitated the erection of five temporary sheds to replace those which occupied the space required for the proposed new buildings.

The Hospital buildings dating from 1772 have suffered severely from the financial stringency of recent years and annual repairs have always been cut down to a minimum. Original estimates for these repairs from 1924 to 1928 amounted to Rs. 49,400 but only Rs. 33,600 were actually spent. Several items have been postponed because of the rebuilding scheme. Among them the re-flooring of the wards desired to replace the present asphalt complained of as unsuitable so long ago as 1869.

During the year under review a great many improvements have been effected notably in the first-class paying wards, and in the latrine system, especially the provision of modern bed-pan flushes only three of which formerly existed for the whole hospital. The Indian Nurses' quarters had to be demolished and new quarters were built for them on the second floor. An expenditure has been sanctioned for improvements to the nurses' bath-rooms and kitchens which were in a disgraceful condition and this work will be completed during the financial year.

Diets.—The average cost of diets has not exceeded the permissible limit laid down in the Government Order except in the months of October and November 1927 under "ordinary European." These are under the daily check of the Assistant Accountant of the hospital and under the concurrent monthly audit of the Accountant-General, Madras.

Professional and Scientific Reports of Physicians and Surgeons.

FIRST PHYSICIAN'S WARD.

Plasmochin in the Treatment of Malaria.—During the course of the year twelve cases of malaria were treated with plasmochin, careful observation being made with regard to (1) disappearance of the fever, (2) disappearance of the parasite, (3) changes in the motility of the parasite in case of B.T., (4) toxicity of the drug and (5) relative value when compared with quinine.

Mode of administration:—

- (1) $1\frac{1}{3}$ grain three times a day for five days.
- (2) Three days' rest without any plasmochin.
- (3) Another three days' course with $1\frac{1}{3}$ grain three times a day.

The following conclusions were drawn:—

- (1) In cases of B.T. and quartan, the parasite disappears by the end of the fourth or fifth day after the administration of plasmochin.

(2) Diminished motility of growing trophozoites of *Plasmodium vivax* could be seen by the second day.

(3) No gametocytes could be seen after the third day.

(4) In malignant tertian infection plasmochin had no effect at all, the temperature remained and the parasite persisted.

(5) When a dosage of quinine sulphate fifteen grains was added on with the plasmochin, temperature came down and parasites disappeared.

(6) With control cases treated by quinine, in the same number of days the parasites disappeared at least forty-eight hours before the disappearance of parasites in the case of plasmochin.

(7) Toxicity. Only mild toxic symptoms were present. Headache, giddiness and abdominal pain were present in three of the patients. Only one patient showed slight cyanosis but no change could be detected in the urine. Deafness and ringing of the ears were present in one case, but this was temporary and lasted for only two days.

THIRD PHYSICIAN'S WARD.

Report of post-mortem work done in the General Hospital, by Capt. P. N. Basu, I.M.S., Professor of Pathology, Medical College, Madras, and Third Physician, General Hospital, Madras, during the year 1927.

Two hundred and five post-mortem examinations were held in the year ending December 1927. This is the largest number on record in this hospital. Of these nearly 40 were medico-legal autopsies for cases of accidents, mostly street accidents.

There were 7 cases of well-defined post-operative broncho-pneumonia with no case of collapse and only one case of infarction.

A case of Hodgkin's disease is worthy of note as it terminated by milary tuberculosis.

There was one case of post-operative acute dilatation of the stomach with a large mesentery causing a kink in the duodenum.

Another case of interest was that of an old man with multiple soft vascular tumours scattered all over the trunk and limbs in which the microscopical appearances suggested mycosis fungoides. Autopsy showed secondary deposits in the internal organs particularly in the liver and spleen.

Among medico-legal cases of interest may be mentioned one case in which a small coil of the ileum was found in a hernial sac entirely cut off from the rest of the bowel. The edges of the loop were entirely clean cut as if made with the knife. It would appear that the individual had an inguinal hernia and that the loop of bowel was cut off at the iliac crest by the mudguard of a car striking against him in the region of the inguinal canal.

FOURTH PHYSICIAN'S WARD.

Myelitis due to Gonococci.—Admitted with a history of paresis. A young man, about 24 years old, belonging to a survey party was admitted into hospital on 28th September 1927 with paresis of both legs and aphonia. The paresis is said to have set in suddenly, the patient woke up one morning to find that he could not use his legs. Five days later his voice began to get hoarse and his right upper extremity to weaken. On examination, he was found to have flaccid paralysis of the muscles affected and to be suffering from gonorrhoea, and he was put on a course of polyvalent gonococcal vaccine followed by intravenous injections of sodium iodide. The patient's aphasia cleared up very rapidly and he was discharged cured of his paralysis on 31st December 1927.

FIRST SURGEON'S WARD.

Gastric and duodenal Ulcers.—As recorded in recent annual reports, ulcers of the stomach and duodenum have become of special interest to surgeons of the General Hospital, although before 1921 they were rarely diagnosed in Madras. Pugh first drew attention to their prevalence in Travancore and South India and to the good results obtained from operative treatment and at the recent Calcutta Congress of the Far Eastern Association of Tropical Medicine

the results in 1396 patients who had been treated by the Surgical staff during the past 6 years were reviewed. Such a marked increase (from 9 gastric operations in 1920 to 246 in 1927) is difficult to explain except by a previous failure to recognize the rapidity with which these patients will recover from symptoms when given complete rest and a low diet. Dyspepsia has always been a common complaint amongst out-patients, although present experience does not agree with Furnell (Annual Report 1877) who suggested that "the principal causes were the use of indigestible food, excessive eating and drunkenness." It is possible that a careful study of dyspeptic cases especially their chronic and relapsing characteristics would reveal a greater prevalence than is now acknowledged in other parts of India.

When dealing with so many patients, methods of examination naturally follow a definite routine and although not equal to the scientific efforts of other and better equipped clinics, it may be of interest to record them here. The chronic and relapsing nature of these ulcers is their most constant characteristic and a history of recurring attacks of pain, which come on at definite regular intervals after every meal is very suggestive. The history is carefully taken by a student who makes enquiry about the earlier symptoms and especially for evidence of relapses. Careful record is kept by the nurse of the diet taken, of the time after food when the patient complains of distress and whether the pain is relieved by taking a drink or more food. So-called hunger pain is not common in the later stages of a duodenal ulcer but when present is very suggestive. Examination always reveals marked tenderness or rigidity in the right hypochondriac region and visible peristalsis of the stomach can often be seen after the patient has drunk a glass of cold water. Superficial hyperaesthesia may be elicited in a definite area internal to the tip of the 9th costal cartilage and is possibly related to the activity of the ulceration. The stools and the urine are carefully examined and the finding of ova in the faeces or bacilli in the urine may reveal the cause of a chronic dyspepsia. In doubtful cases, X-ray photographs of the stomach and intestines are taken after a bismuth meal and of the gall-bladder after the administration of Kerosol. Attempts to take fractional test meals with Indian patients have generally emptied wards. At one time the conventional Ewald test meal was given to all gastric patients but the help obtained in diagnosis was not very striking and results suggested that in Indian patients free hydrochloric acid, estimated half an hour after food, was not markedly increased either in duodenal ulcer or gastric ulcers. Most Indian patients have infected teeth, and all are referred soon after admission to the Dental Surgeon for treatment. The majority refuse dental extraction but scaling and thorough cleansing in every case are insisted on. The vague indigestion which is so frequently an early symptom of a tuberculous infection, is probably responsible for many mistakes in a province like Madras where tuberculosis is so common. It is dangerous to make a diagnosis of appendicular dyspepsia unless a very careful examination of the patient's lungs has been made.

The decision as to treatment is governed by the economical position of the patient. Few Indians either have the patience or can afford the time to carry out the prolonged medical treatment, which is necessary to ensure a cure in any but early cases.

Compression Fractures of the Spine.—Seven cases of "Traumatic Spondylitis" which were admitted during the past year and whose notes have been collected by Mr. R. Mahadevan suggest that compression fractures of the vertebrae are not so rare as is commonly supposed. Obscure back injuries to coolies engaged in lifting heavy bales or to toddy-drawers who fall from a tree directly on the buttocks are often of this nature.

SECOND SURGEON'S WARDS.

[A case of pancreatic lithiasis was admitted during 1927 and on account of the rarity and interest of such a condition we quote verbatim from the report of the

Second Surgeon Major K. G. Pandalai, I.M.S.—EDITOR,
I.M.G.]

(a) A Hindu, male, aged 26, was admitted on 5th August 1927 for pain in the epigastrium of six years' duration. He was of spare build and stated that his father had suffered from a similar complaint but lived to late middle age. In the beginning the pain in the epigastrium used to appear during the rainy season, i.e., June and July; but latterly it has appeared soon after meals throughout the year. He has also a sense of distension of the upper abdomen after meals with acid eructations. There has been no vomiting. The attacks come once or twice a month and last about a week at a time. They subside under careful dieting. In the beginning liquid diet used to relieve him but latterly this does not relieve. Lately he has suffered from occasional attacks of diarrhoea, the motions containing undigested rice. There is slight anaemia. The tongue is coated, teeth dirty, pyorrhoea alveolaris present. He has steadily lost flesh and at present weighs only 100 lb. The urine is normal. The motions under the microscope contain undigested vegetable matter, no ova are present. There is generalised tenderness all over the abdomen, but it is not severe.

On account of the prevalence of duodenal ulcer in the district from which he hailed, a clinical diagnosis of duodenal ulcer was confidently made. A pre-operative skiagram was not taken. In Madras it is customary to operate for gastric and duodenal ulcer on a clinical diagnosis alone and a laparotomy was decided upon, although the absence of vomiting and the occasional incidence of diarrhoea did not fit in with the clinical picture of the disease usually seen in these parts. On 10th August 1927 the abdomen was opened, but no ulcer was demonstrable in the stomach or duodenum. In the course of a routine examination of the viscera, the pancreas was noticed to be abnormal and head, body and tail of the organ were indurated and gave a crepitant feel to the examining fingers as if it contained a number of stones. In the centre of the body of the organ was a rounded cystic swelling and this was opened into through an incision in the gastro-hepatic omentum. The knife could be felt to pass through a shell which appeared to be the calcified wall of a cyst. It then entered a cavity, 3 inch in diameter, with a smooth lining and clear liquid contents—obviously, a cyst in the pancreas. A finger introduced into the cavity could be passed into a number of communicating channels leading away from the central cyst, proving that it was a retention cyst communicating with other dilated pancreatic ducts. Numerous calcified masses of various sizes could be felt everywhere but particularly in the head. As the whole organ appeared to be affected and the patient's condition would not permit a lengthy operative procedure, it was decided to drain the cyst and a drainage tube was fixed to the edges of the opening and brought out through the lesser omentum, the remainder of the incision being closed. For three days, drainage of clear fluid continued; analysis of this fluid did not show any pancreatic ferments. He gradually sank and died on the fourth day, on 14th August 1927. Just before death a skiagram was taken and disclosed the fact that stones were scattered throughout the organ.

A post-mortem examination was carried out and the following were the relevant findings:—

The abdominal wound is infected, and contains a few drachms of pus. Areas of fat necrosis are present in the great and lesser omenta. There are no signs of peritonitis. The pancreas is nodular, firmer than normal and, scattered in the gland substance, are a number of irregular, hard, grating lumps. On section calculi of various sizes are found everywhere. The termination of the common bile duct is partially blocked by a mass of stones in the head of the pancreas. The opening of the pancreatic duct is obstructed by a calculus 3 inch in diameter. The gall-bladder is normal. The right pleural cavity is obliterated by adhesions. The right lung weighs 15 oz., shows marked thickening of pleura, lobes adherent to one another, is not crepitant except at the apex, and is congested.

bronchi are markedly congested, the left lung weighs 10 oz., normal. Liver and spleen smaller than normal, flabby. Cause of death right-sided pneumonia in a subject of chronic pancreatitis with calculi and cyst formation. A section of the pancreas examined microscopically shows atrophy of glandular elements; but islets of Langerhans are present. There is marked increase of the interstitial tissue. The appearances are those of chronic interstitial pancreatitis.

(b) The following meagre notes of a case admitted on 21st March 1913 are of interest in this connection. An ill-nourished male, Hindu, age 36, weight 68 lb., was admitted for diabetic gangrene of the right foot. The urine contained sugar but a quantitative estimation was not done. Under general chloroform anaesthesia amputation was performed a hand's breadth below the right knee-joint. Death took place on 27th March 1913 and a post-mortem examination disclosed an atrophied pancreas which had been converted from head to tail into a long conical bag containing numerous stones. Death was due to pneumonia. A section of the pancreas examined microscopically shows complete atrophy of glandular tissue, only a few degenerate acini being visible; there is great increase of fibrous tissue; the arteries show atheromatous changes. Islets of Langerhans are absent.

(c) Another specimen preserved in the museum is the pancreas of a male, aged 29, admitted on 27th August 1912 for cerebral malaria who died the next day. A detailed clinical history is not available but a post-mortem examination revealed the usual appearances of cerebral malaria; also a stone half the size of an almond in the pancreatic duct. A section examined microscopically shows atrophy of glandular elements and marked increase of interstitial tissue. The ducts are dilated and a few islets of Langerhans are seen. The appearances are those of chronic interstitial pancreatitis. A skiagram of the specimen shows a solitary stone in the centre of the pancreas.

(d) A fourth specimen of a pancreas showing numerous stones in dilated ducts is in the museum but no clinical notes are available. Microscopically this specimen also shows the appearances of chronic interstitial pancreatitis but islets of Langerhans are visible. A radiogram of the specimen shows multiple calculi.

Comments.—A noteworthy feature of the above cases is the preponderance of males (3 out of 4) and the age incidence which is between 25 and 35. An analysis of the stones shows that they consist of organic and carbonates of calcium with a trace of organic matter. The history is of many years' duration, emaciation is marked, dyspepsia and diarrhoea are present and occasionally generalized abdominal discomfort and even tenderness; vomiting is absent. In one case diabetes was present and in this a section of the pancreas showed almost complete disappearance of the glandular acini and islets of Langerhans and replacement by fibrous tissue. Diagnosis by ordinary clinical examination alone is not easy. X-rays will clinch the diagnosis. Treatment by diet and medicines has been generally employed for long periods before the patient comes to the surgeon and on the analogy of salivary calculi which they resemble closely in composition, drugs could not be expected to dissolve stones once formed. Operation may have to be performed for the pain and should consist of the removal of as many stones as can safely be removed especially from the termination of the pancreatic duct, as here a large stone may obstruct the common bile duct. A general anæsthetic has necessarily to be administered but seems dangerous as in two of the above cases death was directly or indirectly due to pneumonia, chloroform being the drug used in both cases.

Major Pandalai also records an interesting case of thoracic aneurysm in which an attempt at radical treatment by Colt's wire wisp method was made.

"A Hindu, male, aged 40, was admitted into the Madras General Hospital on 11th February 1927. Brown complexion, medium height, spare build, no anaemia, skin rough and scaly, eyebrows and lobes of the ear thickened, finger tips and toes clubbed, presents

a pulsating swelling 2 inches in diameter in the region of the right sternoclavicular articulation. The pulsation is expansile. The skin over the swelling is glossy, a thrill is present and a loud bruit is audible; the right radial and temporal pulses are delayed and smaller than the left. The patient states that the swelling appeared 3 months ago with pain in the right side of neck, right shoulder and upper arm. Increase in size has been steady. Lately pain has been noticed in the right eyebrow. He has been unable to stand bright lights which produce lachrymation. He also feels a throbbing pain in the swelling. He and others have noticed a change in the tone of his voice lately. He is unable to abduct his right arm to more than half a right angle, and on account of the pain in the right shoulder, he has lately been sleeping on the left side. A history of syphilis was available and a strongly positive Wassermann reaction is present. X-rays showed absorption of the inner end of the right clavicle and right border of the manubrium sterni. Heart, first sound prolonged at the apex. Arteries are normal. There is slight drooping of the right cheek. Right pupil contracted and does not react to light: pulse 112, resp. 26, urine contains phosphates, otherwise normal. Wt. 80½ lb. Blood pressure, systolic 120 diastolic 80.

A diagnosis of aneurysm of the innominate artery involving its bifurcation was made and anti-syphilitic treatment with rest in bed was ordered. A dose of 0.2 grm. of Neosalvarsan intravenously produced such a severe reaction with cardiac distress that further intravenous medication was abandoned. He was thenceforward placed on Hg. and iodides t.d.s. by mouth. This he tolerated and continued until death. A fortnight's stay in bed with the above treatment did not produce any apparent improvement in the symptoms or reduction in the size of the swelling, and it was decided to try ligation of the third part of the axillary artery. This was carried out on 24th February 1927 and was followed by marked relief of the pain in the shoulder and upper arm. The right radial pulse disappeared entirely after operation. The aneurysm appeared to become firmer to the feel and its pulsations were appreciably reduced. However this improvement was maintained only for about ten days when the aneurysm began to enlarge and pulsate as vigorously as before. It was therefore decided to introduce into it Colt's wire wisp which was done under light chloroform anæsthesia on 16th March 1927. At the most prominent part of the anterior surface of the aneurysm a tiny nick in the skin about 1½ inch in length was made and in penetrating the wall of the aneurysm with the instrument one encountered more resistance than one had anticipated as there was a thick stratum of tough fibrous covering to go through before the point was felt to be in a free cavity. Colt's No. 2 wire wisp was introduced. One expected on entering the aneurysmal sac to see a forceful jet of blood escape; but this did not happen, probably owing to the blocking of the lumen of the instrument by shreds of clot. Only a few drops of blood escaped; the introduction of the wire was an easy process and on removing the trocar the edges of the small puncture fell together and there was hardly any hæmorrhage. The small incision in the skin was closed by a stitch and sealed with collodion. Following the little operation marked relief of symptoms was noted by the patient who was now able to abduct his arm up to the horizontal. The pulsations of the aneurysm became weaker and it felt firmer than before. Improvement was maintained for a period of about 3 months when the aneurysm began steadily to enlarge again. About a month previous to death a small prominence of the diameter of an inch and rising above the level of the surrounding wall of the aneurysm was noticeable at the site of the puncture. As it grew steadily it became clear that the aneurysm was going to give way in this situation. About 4 days before death the shiny and atrophic skin at the summit of this projection gave way with the escape of a small quantity of blood. This was protected by a thick gauze pad bandaged on, but some oozing of blood occurred constantly from this spot until a couple of

minutes before his death when the base of the ulcer in the skin gave way *en bloc* allowing the escape of a large firm clot about 3 inches in diameter followed by a profuse gush of blood which ended in death within a few minutes on 31st October 1927.

Post-mortem.—There was a large saccular aneurysm 5 inches in diameter springing from the antero-lateral wall of the innominate artery 1½ inch from its origin and compressing the right common carotid and right subclavian arteries. It was lined by a thick and shaggy layer of laminated reddish-brown clot in the centre of which lay the wire wisp which had been introduced about 8 months previously. The free ends which in previous skiagrams had been noticed to be spread out umbrella fashion were now glued together by clot and had become comparatively straightened out and could not in their present condition have presented any great extent of surface for producing coagulation. It was also noticed that a number of the ends of the expanded wire wisp had been broken off and were lying free in the cavity of the aneurysm intermingled with the layers of the clot. These broken ends were not visible to the naked eye and became apparent only in a skiagram of the specimen removed after death. The wisp used was not a new one and had been stored on the instrument shelf for several months in a hot climate and had therefore become brittle and readily broken off when played upon by the currents of blood entering the sac. It is remarkable that none of these had been washed into the aorta, an accident which might possibly happen in other cases, unless very fresh and elastic material is always used. The arch of the aorta was thin and presented generalised syphilitic aortitis.

Comment.—There is no doubt that the wire wisp produced marked relief of pain temporarily but the point of entry of the instrument remained a weak spot in the wall of the aneurysm. Perhaps a second operation for introducing another wisp might have afforded further relief from pain but in the light of what happened after the first operation it is doubtful whether life could have been prolonged. The severe reaction following intravenous arsenical medication and the futility of mercury and iodides given orally for 8 months in the cure of syphilitic aortitis are points worthy of note. Post-mortem examination showed that the wire was lying in a free cavity, and it is interesting therefore to know that the aneurysmal cavity may be entered by the trocar and yet no gush of blood may occur to indicate the fact. Also blood clot may become so sticky as to glue together the wires of a No. 2 wisp and make it resemble a straight rod rather than an umbrella. Fresh material should always be used, otherwise the tips of the individual wires may break off and possibly become lodged in the aorta, heart or elsewhere."

THIRD SURGEON'S WARD.

(*Vesical Calculus eleven ounces.*) A Hindu, male, aged 40, admitted on 5th February 1927 for difficulty in passing urine, dribbling in drops, and frequency of micturition. He had also difficulty in passing motions, and complained of pain at the root of the penis; rectal examination revealed a hard mass in the region of the prostate, whose upper border could not be reached by the finger in the rectum. Lumen of the rectum much obliterated. Blood urea 90 mgms. per 100 c.c. Urea concentration, first hour 0.89, second hour 1.1.

Suprapubic cystotomy was done on 8th February 1927 and a large stone weighing 11 ounces was removed from the bladder. The bladder was practically filled up with this calculus which gave considerable difficulty in its removal as the bladder wall, which was much hypertrophied, was tightly gripping the stone. The bladder was washed out and a rubber drain put in and continuous suction drainage established. Patient progressed well for first few days but subsequently on account of severe pyococcal infection of the bladder and septic moribund on 4th March 1927 at the insistence of the relatives.

Essential Hæmaturia.—A young man, aged 20, was admitted on 7th August 1927 passing large quantities of blood in the urine and wide difficulty of micturition and severe pain referred to the tip of the penis. He gave a history of passing small quantities of blood occasionally for the previous two years. At the time of admission he had not passed urine for 24 hours and was complaining of severe hypo-gastric pains.

A rubber catheter was passed in easily but only a small quantity of blood-stained urine could be drawn due to blocking of the eye of the catheter by clots. The bladder was repeatedly washed out but the fluid never returned clear. As the patient continued to pass larger and larger quantities of blood, cystoscopy was done but no clear vision of the interior of the bladder could be obtained, as the clots therein could not be fully dislodged for a clear view. Suprapubic cystotomy done. Clots removed. No growth or calculus seen but rather a prominent inter-trochanteric bar. The bleeding appeared to be from the mucous membrane in general, which was purplish in colour; wound closed, with provision for bladder draining. Patient was subsequently put on hexamine grs. 10 thrice a day. Patient had no further hæmaturia, but intensive putrefactive cystitis with sloughing of parts of the mucous membrane resulted (ex-foliative). Repeated washings with H2O2 and with silver nitrate solution half a grain to one ounce gradually restored the bladder to a healthy condition. Suprapubic opening closed and the patient discharged cured on 13th September 1927.

Foreign Body in Stomach. (*Coin with a Coin catcher.*)—A child, aged 2 years, swallowed a one anna coin in a mofussil station and an attempt was made there by a local doctor to take it out with a coin catcher. The coin catcher broke inside and both the coin and the broken piece of the instrument had slipped into the stomach.

Patient was admitted on 1st June 1928 and the skiagram revealed the coin and the piece of the instrument. An open operation was done and the foreign bodies were removed. Patient was discharged cured on 12th June 1927.

Ovarian Cyst. 44 pints.—A Hindu, female, aged 50, was admitted on 9th March 1927 for an enormously distended abdomen, duration five years. Fluid thrill elicited. Dilated veins all over, swelling more marked on the right side, abdomen opened and a large multilocular ovarian cyst with a thin practically colourless fluid (44 pints) was removed. A small incision was made below the navel which had to be extended upwards later on. The extensive cyst wall was adherent to the parietal peritoneum, omentum and to several parts of the large bowel. Freeing of the collapsed cyst wall after tapping gave considerable difficulty. Adhesions had to be clamped and ligatured in several places. The cyst grew evidently from the ovary. The left ovary was functioning as it presented a recent ruptured Graffian follicle on it. The uterus was long, elongated, flabby, six times its normal size and had to be amputated supravaginally, before liberating the tumour. The right ureter was considerably elongated and adherent and had to be carefully safeguarded. The left ureter was not identified. The pelvic peritoneum was peeled off over a large area and eventually a raw cavity was left behind which could not be covered over. Intravenous saline two pints had to be given on the table and about 3 pints of saline were put into the general peritoneal cavity and the abdomen closed.

Patient made an uninterrupted recovery and was discharged cured on 4th April 1927.

OUT-PATIENT DEPARTMENT.

Anti-rabic treatment done in the General Hospital, during 1927:—

1. Total number of cases who attended for anti-rabic treatment ..	518
2. Number who completed 14 days' course ..	445
3. Number who did not complete the course ..	73
4. Number that developed hydrophobia ..	2
i.e., (i) after full course ..	1
(ii) incomplete course ..	1
(iii) who were not treated ..	Not known.

5. Number that died and cause of death:—Two of them died from hydrophobia.
6. Condition of patients on admission who died of hydrophobia and any other information regarding the Anti-rabic section. } Both patients died in this Hospital.

X-RAY DEPARTMENT.

Barium Meals.—During the year 421 patients were examined with the Umbrose shadow meal and the results obtained were very satisfactory, the conditions seen being verified at operation, in a large number of cases.

It was found necessary to increase the number of examinations in many of the patients especially the "gastrics," in order to keep in close touch with the emptying stomach, radiographs being taken every 20 minutes or half an hour in some cases. It is hoped to have the screen room in use at an early date when it will not be necessary to take so many radiographs.

Dental Radiography.—1,133 radiographs were taken against 981 in the previous year. The value of this class of radiograph is being increasingly recognized, not only to assist the dentist in extractions where the tooth fangs may be malformed but cases of neuritis and other ailments have been traced to root abscesses and have been relieved after dental treatment.

Thoracic Examination.—1,694 radiographs were carried out during the year against 1,333 the previous year, most of the patients being from Dr. Kesava Pai, M.D., Superintendent, Government Tuberculosis Hospital and Institute, Madras. The erect posture is being demanded in all cases to show readily any fluid in the pleural cavity.

An interesting case of subclavian aneurysm which Major K. G. Pandalai, I.M.S., treated with insertion of wire was demonstrated. The patient died some time later and the post-mortem specimen was subsequently radiographed, these, with those taken during the patient's life, being published in Europe and America.

Examination of Skull.—Patients continued to be sent through Lt.-Col. R. E. Wright, I.M.S., Superintendent, Government Ophthalmic Hospital, Madras. 605 cases were radiographed in all against 462 the previous year. These included fractures, pituitary tumours and hydrocephalus, etc.

Examination in Pregnancy.—40 patients were examined during the year sent mainly from the Government Hospital for Women and Children, Madras. At the request of Dr. A. Lakshmanasawmy Mudaliar, B.A., M.D., a number of foetal monstrosities have been radiographed for publication in a monograph by that Medical Officer.

Sodium Iodide to outline the ureter and pelvis of the kidneys has been used by Major K. G. Pandalai, I.M.S., and several good radiographs have been obtained.

Kerasol has been used by many of the Physicians and Surgeons of General Hospital, the shadow of the gall-bladder being visible in a number of cases 12 to 17 hours after ingestion.

Diathermy and High Frequency.—9,340 sittings were given during 1927, this being an increase of 4,188 over the figures of 1926. Several cases of prostatitis and enlarged prostate were given diathermy and the patients obtained much relief with this treatment.

A number of patients suffering from bronchopneumonia and asthma were sent by the Superintendent, Government Victoria Goshia Hospital, for diathermy and all these showed decided improvement. These patients were also given Quartz Light (ultra-violet rays) exposure. Their temperature came down and the lungs cleared soon and in cases of asthma the acuteness of the attacks abated.

A case of high blood pressure with nervous disorder such as staggering gait, etc., improved marvellously

after a fortnight's treatment with high frequency current. He had suffered much for several months. A large number of cases of acne, blackheads of the face and eczema did very well under high frequency. Several cases of alopecia and dandruff were also treated in this department, most of whom did remarkably well, though in a few the treatment effected no change. A patient who had a circular bald patch about 3 inches in diameter came for this treatment. After two series of treatments the whole patch was covered with a thick growth of hair.

Several warts were removed successfully with high frequency current, leaving no scar or mark of any kind behind. This was particularly useful when the warts were on the face and more so when the patients concerned were ladies.

The cases for which diathermy and high frequency were mainly used are sycosis, pyorrhœa alveolaris, arthritis and synovitis of joints, lumbago, fractures of various kinds of different parts of the body, injuries of joints with or without ankylosis, neuralgia, and neuritis of the different parts of the body, myalgia, tennis elbow, writer's cramp, sinusitis (maxillary, ethmoidal, frontal), etc., and excellent results were obtained in a large number of them.

There were 21 diathermic operations performed during this year, for carcinoma of tongue, jaw and breast and for one case of chronic ulcer of penis.

Bergonie Chair.—This was successfully used for obesity in a young woman aged 17, weighing 14 stones 7 lb. After 4 months' treatment, off and on, her weight came down to 11 stones 2 lb.

Orthopaedic exercises were systematically given in cases of fibrous ankylosis injury to joints, particularly the ones with ankylosis and hemiplegia, with good results.

Ultra-violet Rays.—The Quartz Light and Tungsten Arc Lamps, which produce ultra-violet rays, were used for patients suffering from the following diseases:—

1. Eczema	128 cases.
2. Lupus	24 "
3. T. B. Lungs (early)	51 "
4. Chronic tubercular peritonitis	58 "
5. Tubercular glands neck	31 "
6. Sycosis	37 "
7. Others	181 "

The results were satisfactory in most though a few showed improvement up to a certain stage only.

1. A patient of M4, a lady aged 31 with low fever, early signs in lungs, noticed clinically and in the radiograph, had exposure to ultra-violet rays for two months. Her weight at the start was 95 lb. During the first few treatments her fever stopped and at the end of the course she was apparently well and her weight went up to 110½ lb. In addition to the above she had open air treatment and calcium internally.

2. A Mahommadan gentleman, aged 37, with slight fever, cough, etc., had treatment for nearly 3 months at the end of which time he had no fever, almost free from cough and his weight went up from 107 lb. to 126. He had no other treatment excepting 6 injections of colossal calcium.

The Sollux Lamp with blue and red filters, was used with good results in a large number of cases of inflammatory lesions, painful joints, eczema with severe itching.

The blue light, especially, was very useful in allaying the pain in the joints, in cases of neuralgia and sciatica and also relieved the itching in several cases of skin diseases and gave sleep to many such patients.

The Radiant Heat apparatus is fitted with special red, carbon bulbs to assist in the absorption of pathological fluids and to increase the heating and curative effect of the red rays of the spectrum through a red liquid medium, viz., the red blood corpuscles. This was used in many cases of ascites due to nephritis, cirrhosis of liver, cardiac disease and tubercular peritonium.

Superficial X-ray Therapy.—During the year under

report 3,923 treatments were administered, the aggregate dosage being 3,272 Sabouraud "B" doses.

Deep X-ray Therapy.—1,052 exposures were administered, this figure giving an average of 9.31 treatments for each patient, the average dose being 20.97 Sabouraud "B".

Diseases.—The principal diseases for which X-Ray treatment was given were:—

1. Skin affections including eczema, ring-worm, sycosis, etc.
2. Enlargement of lymphatic glands, chiefly due to tubercle.
3. Infective granuloma.
4. Tumours, malignant and non-malignant.
5. Diseases of uterus both functional and organic.
6. Goitre.
7. Tuberculosis of lungs.
8. Tuberculosis of abdominal organs.
9. Constitutional diseases, such as rickets.
10. Diseases of blood, such as leukaemia, pernicious anemia, etc.

Below is given the reports received from Medical Officers with regard to some of their patients:—

1. **Skin.**—(1) **Eczema.**—A patch of 1½ inches diameter on the inner side of right ankle. After four exposures of ½ "B", and 7 exposures of "B" doses, the patch completely disappeared.

(2) **Eczema.**—Patches of eczema on the dorsum of both feet and lateral aspect of both ankles, in duration 6 months, very thick and black. After the first course of exposures the thickness of the patches was reduced and the black colour changed to a lighter tone. A second course was given when the thickness completely disappeared and the skin regained almost the natural colour.

(3) **Chronic Eczema**, duration 3 years, dry black patch on the inner aspect of left leg. Thin scaly eczema on the back of neck. The first course of treatment did not give much improvement. At the end of a second course after three weeks' rest, all the thickness disappeared and the colour of skin was almost normal.

Skin.—(1) **Barbers' itch.**—A course of 6 fractional exposures was given and the condition was cured.

(2) **Sycosis-neck.**—A course of 7 fractional exposures was given, with complete disappearance of the disease.

Skin.—(1) **Lupus Erythematosus**, duration 8 months, on either side of the nose, patch about the size of a rupee. At the end of a five weeks' course of treatment, the left side of the nose completely cleared, right side much improved.

(2) **Patches of ulcer** on the right side of face, upper lip and over both eyelids, duration 1 year. A course of 4 weeks' exposures was given and the ulcers, except the one in the lip, are almost healed.

2. **Enlargement of Lymphatic glands.**—There were enlarged glands on both sides of neck. Duration 1 year. Two courses of exposures were given with an interval of a month between. At the end of the second course, the glands on the left side completely disappeared, and those on the right were very much improved.

3. **Hodgkin's disease.**—Duration 4 years. Glands in the axilla, neck, and supraclavicular region were enlarged. Patient had one course of treatment in 1924. A second course of treatment in 1925. There was a slight improvement. A third course was given in 1927. At the end of this the glands completely disappeared. At the commencement of the treatment glands were about the size of a big lime.

4. **Functional disease of the uterus.**—(1) **Menorrhagia.** Patient aged 45 with a history of profuse bleeding at irregular intervals. A course of "deep therapy" exposures was given. After a rest two more courses were given with the usual interval of 3 weeks. At the end of the sittings the patient was completely relieved.

(2) Patient, aged 24, unmarried, had severe bleeding at each period. A course of six exposures was given and at the end of the treatment the hæmorrhage completely stopped.

5. *Organic disease of uterus—Fibroid.*—Patient aged 30 was suffering (1) from anæmia, loss of sleep and debility. P.V. uterus as large as a mango, soft, painless, slight bleeding on examination. Vagina and cervix all right; soft fibroid tumour of the uterus. A course of "deep" X-Ray exposures was given. After the sixth exposure, the hæmorrhage completely stopped. After the twelfth tumour was found to be smaller on abdominal palpation. Six weeks' rest was given. In the meanwhile patient was examined by a lady doctor whose findings are:—"No appreciable diminution of the tumour but it is much softer. Patient's general condition much improved."

A second course of exposures was given and at the end an examination showed the tumour to be much smaller.

A number of other cases showed improvement, such as cessation of hæmorrhage, improvement in general health, etc.

A number of cases of cancer of cervix showed improvement in the way of diminution of offensive discharge, and improvement of general condition.

6. *Leukæmia.*—Patient, European, aged 50, female, was admitted to the hospital on 22nd August 1927 for splenomedullary leukemia. Condition of the blood on admission was as follows:—

R.B.C.	3,000,000
W.B.C.	91,500
Hæmoglobin	56 per cent.
Colour index	0.9

Treatment commenced on 24th August 1927. After the first treatment, the result of blood examination was as follows:—

R.B.C.	3,500,000
W.B.C.	25,625
Hæmoglobin	60 per cent.
Colour index	0.85

At the end of the course the blood was almost normal except for the presence of mast cells and a few myelocytes. There was enlargement of spleen at the commencement of the treatment which completely disappeared by the end of the course.

Disease of Thyroid—(a) (Functional).—Patient, Hindu, male, age 28, admitted into the hospital with tremors of the hand with a pulse rate of 14 a minute, the result of post-encephalitis. A course of exposures was given and after the fourth treatment the pulse rate came down to about 78, the tremors improving. At the end of the course the patient was normal.

(b) *(Organic).*—(1) Patient, Anglo-Indian, aged 38, was admitted to hospital with enlargement of the thyroid and a pulse rate of 112 per minute. A course of exposures was given. Size of the tumour was much reduced and hardly noticeable, except by palpation. Pulse rate 92 per minute. After an interval of 6 weeks, patient returned to the institute with a pulse rate of 100 per minute. Size of the swelling not increased.

At the end of a second course of exposures, the pulse rate fell to 84 per minute, the size of the thyroid remaining the same.

(2) Patient, Hindu, female, aged 45, was admitted to hospital with a swelling on the right side of neck corresponding to right lobe of thyroid. Pulse rate on admission 96 per minute.

At the end of a course of X-Ray treatment the size was much reduced and the pulse rate fell to 84.

Radium.—The Superintendent of the Tuberculosis Hospital and Institute has a small plaque containing a few milligrammes of radium element and this has been in use for several years by that Medical Officer.

The X-Ray Institute received its first supply of radium early in the year. It consisted of 115 milligrammes of radium sulphate (Ra SO_4) equal to 214.5 milligrammes of radium bromide ($\text{Ra Br}_2 \cdot 2\text{H}_2\text{O}$). This was distributed in 32 platinum-iridium needles or tubes and one Monel metal plaque.

A patient of Lt.-Col. R. E. Wright, I.M.S., suffering from angioma of the left upper eyelid, was the first to be treated. This was on 2nd March and on 17th March Major K. G. Pandalai, I.M.S., did the first

implantation of radium needles, in a case of growth of the tonsils.

During the year 329 exposures were given, these including four cases of cancer of the buccal region in which Lieut.-Col. E. W. C. Bradfield, I.M.S., implanted needles, the exposures being about 1,440 milligramme hours (Ra SO_4). The remainder of the patients were sent by medical officers in Madras to the X-Ray Institute for external applications of radium, when a varied number of milligrammes of radium were applied for three hours or more at a sitting, some of the patients receiving more than one exposure.

It is too early for any definite opinion to be formed as to the permanent value of the treatment, but we understand that the medical officers concerned are well satisfied with the results up to now.

With the price of radium at about £12,000 per gramme it was only possible to begin the "Madras Radium Service" with a small quantity and the demand has exceeded the supply, however, with co-operation between the medical officers concerned, who use the radium by turn when requiring big doses, there has been no hitch.

During 1927 a further supply of 115 milligrammes Ra SO_4 was ordered from Belgium and this should be received in Madras at the end of March 1928.

Radium Emanation.—The life of radium is about 2,500 years and during its disintegration gives an emanation called Radon, a gas which during its active period—lasting a week or so—has the same radio active intensity as the mother element. Although the radium remains practically the same weight, this gas is being constantly formed. It is prepared from a solution of radium bromide by means of an intricate apparatus. Radon is extensively used in Europe and America, the emanation being despatched by post to medical practitioners and hospitals having no radium. The Radium Institute in London and the Middlesex Hospital in London each have an apparatus, which is a source of income to those institutions. The Radiologist proposes to obtain the Surgeon-General's approval and Government sanction to install such an apparatus in the X-Ray Institute, Madras, so that he may provide the District Medical and Sanitary Officer up-country, and medical practitioners, with Radon with which they can carry out radium treatment.

Correspondence.

SULFARSENOL IN THE TREATMENT OF SYPHILIS.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—The following case presents a point of interest such as to warrant its publication:

Mr. Y. R., aged 30 years, came to this dispensary for treatment of syphilis (secondary stage). He was in a weak state. I gave an intramuscular injection of 18 cgm. of Sulfarsenol immediately. He was rather nervous and felt giddy. This, however, soon passed away. Half an hour later, profuse bleeding commenced from the gums, particularly from the portion adjoining the upper incisors.

I immediately applied tinct. benzoin co. on cotton-wool as a plug. This had no effect. I applied tinct. ferri perchloride, tannic acid, and adrenalin swabs in succession but in vain. Then as a last resort, I gave 5 min. of adrenalin chloride sol. (1 in 1000). Even this had no effect. The patient was getting exhausted. I had no other drugs on hand and to get such drugs as calcium chloride or lactate was impossible, as this place is in the interior of the Kurnool district devoid of any communication.

By this time, 4 hours had elapsed since the commencement of the bleeding. In the meanwhile the medical officer in charge of the cholera party came here. I consulted him and he kindly gave me 2 ampoules (2 c.c.) of calcium chloride. I immediately gave an

intramuscular injection. After half an hour the bleeding stopped completely.

In this particular case the patient gave a history of bleeding from the gums of a mild nature a month back.

In the literature supplied with the tube of Sulfarsenol, it is stated under the heading "Blood Transfusion" that 6 cgm. of Sulfarsenol dissolved in 12 c.c. of water renders 100 grms. of blood incoagulable.

Now I wish to know if the anti-coagulating property of Sulfarsenol was responsible for the bleeding which resisted treatment for some hours till calcium chloride came to the rescue.—Yours, etc.,

B. SUKHAVANAM, L.M.P.,
Sub-Assistant Surgeon.

GADIVEMULA,

22nd September, 1928.

RAT-BITE FEVER.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—On perusing the most illuminating article on "Rat-bite fever as an Indian disease" by Lieutenant-Colonel R. Knowles, I.M.S., and Assistant Surgeon B. M. Das Gupta in the current number of the *Indian Medical Gazette*, I am tempted to request you kindly to allow me a little space in the *Gazette* for the publication of the following few observations of mine regarding "Rat-bite fever" in the Madras Presidency.

Rat-bite fever is fairly common in the Madras Presidency also. The fever is of the usual type so excellently described in the article with the aid of temperature charts. It is a common belief in some parts, at least, of the Madras Presidency that the bite of a rat, which is thoroughly upset and in the full frenzy after or during a fierce quarrel with a fellow rat, is the one that is really infectious and produces symptoms of rat-bite fever, and not the bites on other occasions. Probably the acute *Spirillum minus* infection produces in the rat, a state of violent delirium which may account for its quarrel with a fellow and his unprovoked bite on the human-being. The infectious rat-bite has almost always occurred in the night.

Asthma is believed to be a very common sequel to "rat-bite fever" and I have seen and heard of cases of asthma dating their origin from a rat-bite. The village folk are used to undergoing elaborate native treatment for any kind of rat-bite lest they should suffer from the terrible "rat-bite asthma" as they call it.

Like untreated "relapsing fever" that cures itself in some cases after a few relapses, rat-bite fever also cures itself in some after a few bouts and in rare instances even after asthma has set in.

I remember a case which occurred some years ago in my own village in this Presidency. The person, a female, aged about 30 years was bitten by a rat on the dorsum of her left hand. About ten days after she developed high fever with brawny induration of the bitten part and with swelling and acute lymphangitis of the whole extremity. No septic complications, such as abscess formation, ulcerations, etc., occurred at the site of the bite. After the usual course the fever passed away only to recur regularly once a fortnight or a month peculiarly coincident with the new moon or full moon. She gradually became much debilitated and in the course of a year developed acute asthma. She dragged on a miserable existence and finally pulmonary tubercle ended the scene after about 5 years or so.

Many cases of rat-bite fever do not come to light as the public are still ignorant of the discovery of the specific cure for rat-bite fever, viz., salvarsan and its allies.

Thanking you in anticipation.—Yours, etc.,

T. S. DAKSHINAMURTHI,
Sub-Assistant Surgeon, Alipuram Jail.

BELLARY CANTONMENT,
25th September, 1928.

Service Notes.

APPOINTMENTS AND TRANSFERS.

Colonel J. W. D. Megaw, C.I.E., M.B., V.H.S., I.M.S., Inspector-General of Civil Hospitals, Punjab, is appointed to officiate as Surgeon-General with the Government of Madras, with effect from the forenoon of 26th September 1928.

Lieutenant-Colonel H. M. Mackenzie, M.B., I.M.S., Professor of Pathology, King Edward Medical College, Lahore and Bacteriologist to the Government of the Punjab, is appointed to officiate as Inspector-General of Civil Hospitals, Punjab, with effect from the forenoon of the 19th September 1928.

Lieutenant-Colonel S. J. Bhathena, L.R.C.P. & S. (Edin.), L.F.P.S. (Glas.), I.M.S., is appointed Civil Surgeon, Surat.

Lieutenant-Colonel A. Cameron, O.B.E., I.M.S., Civil Surgeon, on return from leave, to Aligarh.

Lieutenant-Colonel E. C. Hepper, I.M.S., Civil Surgeon, on return from leave, to Bareilly.

Lieutenant-Colonel H. Ross, C.I.E., O.B.E., I.M.S., Civil Surgeon, on return from leave to Cawnpore.

Major C. J. Stocker, M.C., M.D., I.M.S., Civil Surgeon, Hoshangabad, is appointed to be Civil Surgeon, Pachmarhi, from the 15th September 1928 to the 31st October 1928.

Major G. T. Burke, I.M.S., Civil Surgeon, from Cawnpore to Saharanpur.

Captain S. D. S. Greval, I.M.S., and Lieutenant-Colonel T. C. McCombie Young, I.M.S., are appointed substantively to the Medical Research Department, with effect from the 16th August 1928.

The following officers of the Indian Medical Service are appointed substantively to be Agency Surgeons under the Government of India in the Foreign and Political Department, with effect from the dates shown against their names:—

Major R. Hay. Dated 3rd July 1928.

Captain R. S. Aspinall. Dated 7th August 1928.

Captain L. K. Ledger. Dated 4th July 1928.

LEAVE.

Lieutenant-Colonel A. G. Tresidder, C.I.E., M.D., I.M.S., is granted leave for four months and fourteen days, with effect from the 8th December 1928.

Lieutenant-Colonel J. F. Boyd, I.M.S., Civil Surgeon, leave for three months in extension of the leave already sanctioned.

Lieutenant-Colonel W. A. Mearns, I.M.S., Assistant Director of Public Health, United Provinces, leave for two months and thirteen days in extension of the three months' combined leave already sanctioned.

Leave for two months is granted to Lieutenant-Colonel P. M. Rennie, I.M.S., in extension of the leave already granted to him.

Major A. C. Craighead, I.M.S., an officer of the Medical Research Department on foreign service under the Indian Research Fund Association, is granted combined leave for one year, i.e., eight months on average pay and four months on half average pay, with effect from the 1st January 1929, or the date on which he avails himself of it. His services are replaced at the disposal of the Director-General, Indian Medical Service, with effect from the date on which he proceeds on leave.

Major W. C. Spackman, I.M.S., is granted leave on average pay for eight months combined with leave on half average pay for one month and study leave for three months, with effect from the 3rd November 1928 or date of relief.

Leave for eight months is granted to Major G. H. Mahony, I.M.S., with effect from the 21st May 1928.

RETIREMENTS.

Lieutenant-Colonel S. H. Middleton-West, M.C., M.B., I.M.S., with effect from the 15th August 1928.

Lieutenant-Colonel H. Watts, M.B., on account of ill-health from 10th May 1928.

PROMOTION.

Major A. A. McNeill, I.M.S., to be Temporary Lieutenant-Colonel, 28th January to 22nd October 1927.

whilst Commanding No. 33 Field Ambulance, Shanghai Defence Force.

Captain (Temporary Major) A. N. Sharma, I.M.S., to be Temporary Lieutenant-Colonel, 5th August 1927 to 7th February 1928, whilst Commanding No. 1 Indian General Hospital, Shanghai Defence Force.

Captains to be Majors.

Jagat Ram Kochhar, M.B. Dated 16th September 1928.

J. G. Bird. Dated 23rd July 1928.

J. E. Dhunjibhoy. Dated 20th August 1928.

Lieutenants to be Captains.

A. Rosenbloom. Dated 3rd March 1928.

M. P. Conroy. Dated 3rd March 1928.

W. J. Shipsey. Dated 31st March 1928.

C. L. Pasricha. Dated 20th May 1928.

NOTES.

DIMOL AS AN INTESTINAL ANTISEPTIC.

THERE has been considerable discussion in medical journals during recent years as to the value of "Dimol"—an intestinal antiseptic to which we have previously drawn attention. That the drug "suits" some "intestinal" patients cannot be denied; we know indeed of one patient who is in a "pre-sprue" condition who is never comfortable unless he is taking a steady course of it from time to time. The value of intestinal antiseptics—so-called—of any class is very much open to question, but Dimol is at least a remedy which has been "under consideration" of the medical profession for some years.

In *The Medical Officer* for the 3rd March, 1928, there appears an article by J. O. Oliver, M.B., B.S. (Lond.). M.R.C.S., L.R.C.P., on "Intestinal disinfection in the treatment of rheumatic arthritis," which describes the treatment of 10 cases by "pulverettes" of Dimol, from which we take the following abstract.

"*Nature of the tests.*—The cases treated in this series were in no way selected for treatment. The test consisted of an estimation of the numbers of each of the more important aerobic micro-organisms present in the faeces before treatment was commenced, and again at the

conclusion of a course of treatment consisting of the daily exhibition of pulverettes of Dimol by the month over a period of two months, a comparatively short time considering the chronicity of the disease.

A routine method of dealing with the specimens bacteriologically was adopted in order that the results obtained might be comparable with one another.

A case history was asked for and supplied by the usual medical attendant of each of the cases and a further report supplied at the conclusion of the treatment.

Report of cases.—Ten cases of rheumatoid arthritis were treated and tested in the manner described.

Six cases, or 60 per cent., showed definite improvement under treatment.

Four cases, or 40 per cent., did not show definite improvement as a result of the treatment.

As the cases were unselected from the point of view of their especial suitability for treatment with Dimol, it is instructive to inquire more particularly concerning those cases regarded as failures or partial failures of treatment. In doing this I find that whereas the average duration of the illness in those cases showing improvement was 1½ years (with periods ranging from 1 to 3 years), in those cases which did not show this improvement the average duration of the illness was four years (with periods ranging from 2 to 8 years). Such a fact clearly indicates the advantages of early treatment, and at the same time shows that in this series the early case had an excellent chance, amounting to some 80 per cent, of deriving benefit from the course of treatment with Dimol.

Such findings as these are distinctly encouraging, and the fact that the cases were unselected and, therefore, may include some having a focus of toxin production other than an intestinal one (which alone could be benefited by such a drug as Dimol), as well as the known unsuitable conditions under which at least two of the cases were living, must add to the credit given to the treatment.

A study of the bacteriological findings, both before and after the treatment, shows that as far as streptococci are concerned there was an average reduction of 42 per cent. in the specimen taken after treatment as compared with that examined before treatment was commenced. The actual reductions recorded in the present series of cases were: 23, 38, 97, 70, 53, 51, 20 and 13 per cent.

This work is being very considerably extended, and for that reason the full records of each individual case have not been given; at a later date it is hoped to publish these with a further and larger series of cases."

Publishers' Notice.

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles will receive 25 reprints gratis, if asked for at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions, Advertisements, and Reprints should be addressed to THE PUBLISHERS, Messrs. Thacker, Spink & Co., P. O. Box No. 54, Calcutta.

Annual Subscription to "The Indian Medical Gazette," Rs. 16 including postage, in India. Rs. 18 including postage, abroad.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.
